Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The aim of this book is to provide a basis for the understanding of how medical and surgical conditions influence oral health and oral health care, and to help dental health workers (DHWs) keep their patients informed of health risks and respect their choices.

Learning outcomes are for DHWs to be aware of systemic disorders and treatments that may cause complications in dental and oral health care. The reader should thus be able to understand relevant illness identified from the history, physical examination and investigations; be able to present a succinct and, where appropriate, unified list of all problems that could influence oral health care; and formulate a diagnosis/treatment plan for each problem (appropriate to the level of training). The reader should understand that the management of patients with diseases should take into consideration the severity of the condition; the type of operative procedure envisioned and, in particular, the amount of trauma, likely distress and time taken; other risk factors; and the health-care setting (skills/facilities) available. They should appreciate issues of access and informed consent, and the desirability of preventive oral health care and avoidance of harm. The reader should also be able to communicate appropriately and work with other health-care providers; to retrieve medical information using the recommended further reading sections and the Internet, in a manner that reflects an understanding of medical language, terminology, and the relationship between medical terms and concepts; to refine search strategies to improve the relevance and completeness of retrieved items; and to identify and acquire full-text electronic documents available from the Internet sites quoted.

Though dentistry remains largely a technical subject, there are a number of reasons why the education and training of dental professionals should have this basis. Dentistry is a profession and not a trade; medical problems can influence oral health and health care, whilst oral health and health care can influence general health and health care. DHWs need to understand patients and their attitudes to health care; they need to communicate at a reasonable level with other health professionals, with patients and sometimes with the media; they may need to act as advocates for patients; and, finally, they can find themselves in need of health care. It is incumbent upon DHWs to treat their patients in an appropriate way, taking into account both their dental needs and any special considerations related to their medical and drug history. To prevent any implication of negligence, a professional must administer appropriate care, and the patient should agree to it and receive adequate information about it. In general terms, DHWs need to develop strategies to identify patients at risk of medical problems, to assess the severity of those risks and, where necessary, to recognize the need for help and be able to seek advice from a colleague with special competence in the relevant fields.

Since the first edition of this book to this 7th edition, the importance of medicine in dentistry, interactions between medicine and dentistry, and the need for medical knowledge on the part of all members of the dental team have all increased radically – as has the whole of medicine. Increasing evidence supports, but does not prove, an association between oral infection and various systemic diseases. Thus there is interest in the possible associations of oral infection (periodontitis) with conditions such as atherosclerosis, Alzheimer disease, cancers (mouth, pancreas, renal), diabetes, erectile dysfunction,

low-birth-weight babies, lung disease and rheumatoid arthritis, although space precludes all but a passing mention. Health-care needs are changing globally as people live longer and medical interventions advance. The populations in many countries are often surviving and ageing with the help of complex treatments. For example, in the UK the proportion of people aged over 65 is predicted to increase from 16% in 2006 to 22% in 2031. Advances in surgical and medical interventions and therapeutics are astounding, raising issues in relation to the understanding of these interventions and therapies, advantages and disadvantages, and the importance of informed consent. The US Federal Drug Administration recognizes this and may now approve new drugs with a Risk Evaluation and Mitigation Strategy (REMS), which consists of a Medication Guide advising patients of important safety information and a communication plan to inform health-care providers about the serious risks associated with their use. Advances in genetics have been equally impressive. During the life of this book, the human genome has been completely catalogued – revealing some 23 000 protein-coding genes. However, these genes were seen to occupy only 1.5% of the genome and, by 2012, the regulatory importance of the remaining DNA became evident. The genetic basis for many disorders has been or is being elucidated, and gene therapy is becoming a reality.

The knowledge base of medicine has thus been extended and effective new technologies, techniques and drugs have been developed, many of which have resulted in complications relevant to oral health care. Many patients who would, in earlier times, have succumbed are alive and live to much greater ages, thanks to advances in drugs, pacemakers and other cardiac devices, radiotherapy, public health and transplants – and they need good oral health and may well need oral health care. A wider range of medical problems has thus become relevant to oral health-care sciences. The world has changed further and the relevance of the book has grown even more, with a greater number of persons who require special care, and with increasing travel, not least by DHWs and trainees to developing countries. This text has become one of the most widely used sources of information for all DHWs who need to contend with the increasing variety of medical problems, particularly as they are aware that they face a growing risk of litigation if they do not keep themselves familiar with current knowledge, in line with the increasing acceptance of the need for continuing professional education and development. Sadly the evidence base in this area is not always strong and clinicians may need to resort to an heuristic approach. Nevertheless they should halt before making decisions when Hungry, Angry, Late or Tired!

In addition to the comments in previous prefaces, I thank Dr Andrew Narendran Robinson sincerely for his help with suggestions and literature searching, and Drs Paes de Almeida, Bagan, Carrozzo, Diz Dios, Malamos and Mosqueda for help with some new illustrations.

This edition has attempted to provide information about the most common diseases, though these, of course, vary depending on the area of the world concerned. The main killing conditions worldwide – trauma, cardiovascular disease, infectious and parasitic diseases, malignant disease, cerebrovascular disease, respiratory infections, AIDS and chronic obstructive pulmonary disease – receive considerable attention. There is detail on the other most common afflictions

in resource-rich countries, such as: anaemia, the common cold, diabetes, diarrhoea, hepatitis, lung cancer, sexually shared infections and streptococcal sore throat (<http://www.livestrong.com/article/161780-10-most-common-health-diseases/#ixzz25tfVtfQu>; accessed 12 June 2013). Less common or rare disorders do not receive so much attention.

Although previous editions have been extremely well received, the new edition has nevertheless been updated throughout and includes several added areas – such as a number of new medications, and comment about anticonvulsant hypersensitivity syndrome, anti-synthetase syndrome, antithrombotic therapy, biological therapies, Brugada syndrome, cosmetic and other implants, darkroom syndrome, dental materials hypersensitivity (chlorhexidine, nickel, titanium), drugs and dietary interactions, E numbers, elder maltreatment, food poisoning, hypnotherapy, implanted cardiac devices, imported infections, long QT syndrome (LQTS), mass gathering medicine, medication-overuse headache, *Mycobacterium abscessus* infections, neuropathic pain, new antiretrovirals, new aspects of alternative medicine, new autoinflammatory disorders (deficiency of the interleukin-1 receptor antagonist [DIRA]; and interleukin-36–receptor antagonist deficiency), new hospital-associated infections, new oral anticoagulants, new substance abuse, *N*-methyl-D-aspartate (NMDA) antagonists such as ketamine, parenteral nutrition, propofol infusion syndrome (PRIS), radiocontrast media, recreational water illnesses, relapsing polychondritis, self-harm, sexual minorities, titanium allergy, transfusion-related immunomodulation (TRIM), vagal nerve stimulation therapy, variably protease-sensitive prionopathy (VPSPr), various newly recognised immunodeficiencies, ventilator-associated pneumonia and vulnerable people. Space precludes more than brief discussion of the association between periodontal infection and various systemic diseases, and there is no examination of forensic issues.

Many data are available nowadays on the Internet, and the explosion in numbers of guidelines means that it is nigh on impossible to summarize all of these in a book, especially avoiding ambiguities and plagiarism at the same time. Increasingly, evidence-based medicine challenges current practice – including that in vital areas such as cardiopulmonary resuscitation. Practitioners should be aware of, and use, the best evidence-based medicine, current teaching and guidance from a responsible body of opinion, which also necessitates access to updated material such as that on the Internet: for example, <http://pathways.nice.org.uk/> or <http://www.sign.ac.uk/guidelines/published/index.html> (accessed 12 June 2013). There is a growing desire in the health-care community for specific practice guidelines but, with advances in the field, guidelines can sometimes restrict diagnostic or therapeutic options; clinician and patient education and discussions are the key, with decisions individualized. Good communication between all health-care professionals (HCPs), and between HCPs and patients, is essential and this is true for DHWs. If contrary advice is received from another HCP, a discussion around the differing opinions is advised with this practitioner.

It is important for the patient not to be compromised in any way. The discussion should be supported by evidence-based written information tailored to the person's needs. Treatment and care, and the information people are given about them, should be culturally appropriate and should take into account people's needs and preferences. It should also be accessible to those with additional needs such as physical, sensory or learning disabilities, and to people who do not speak or read English. Patients should have the opportunity to make informed decisions about their care and treatment, in partnership with their HCPs. If the person agrees, families and carers should be given the option of being involved in decisions about treatment and care. If people do not have the capacity to make decisions, HCPs should follow the UK Department of Health's advice on consent and the code of practice that accompanies the Mental Capacity Act in the UK.

The content of the book is for information and educational purposes only; in no way should it be considered as a substitute for medical consultation with a qualified professional. A physician should always be consulted for any health problem or medical condition. Clinicians are advised always to check the latest guidelines from bodies such as the National Institute for Health and Care Excellence (NICE), the Royal Colleges of Surgeons, the Royal Colleges of Physicians, the British Dental Association (BDA), the General Dental Council (GDC), the Resuscitation Council and the various specialist medical and dental societies or associations (e.g. <http://www.sdcep.org.uk/>). The spectre of litigation increasingly influences decisions and, although in some instances guidelines may not have led to clarity, clinicians may find their decisions difficult to defend if they fail to record a very good reason for not adhering to the guidelines. Readers should always check the most recent guidelines, drug doses, and potential reactions and interactions before use, discuss management issues with the patient, and never proceed with any intervention without the clear formal informed consent of the patient and consultation with their health-care advisers.

The comments and recommendations herein should be used as guidelines to care, not commandments. Unfortunately, there are very few randomized controlled trials available to provide evidence for the various practices, and so many of the recommendations have to be based on consensus. Any comments or criticisms from readers will, of course, be gratefully received, though I hope that the further significant improvements in this edition, together with the dearth of criticism of previous editions, means that I have fulfilled the aims as best I can. As my now-deceased co-author Professor Rod Cawson said in the preface to one of his other books: 'Some people will criticize this for being too brief, some for being too long but, sad as it may be, this is the best I can do.'

Crispian Scully

KEY POINTS

- Be prepared
- Ensure access to appropriate drugs and equipment
- Ensure training
- Know who to call
- Take a medical history

This chapter is focused on the main diagnostic and management issues in emergency management; fuller discussion of these conditions may be found in the relevant chapters and the controversies in this area are discussed in the references. The expanded knowledge base of medicine, and effective new technologies, techniques and drugs have allowed patients, who in earlier times would have succumbed, to remain alive and live to much greater ages; such patients in particular may be prone to medical emergencies. Collapse and other emergencies are a cause of concern for all involved ([Box 1.1](#)).

In general terms, health-care professionals (HCPs) should develop strategies to identify patients at risk of emergencies, assess the severity of those risks and, where necessary, recognize the need for help and be able to seek advice from a colleague with special competence in the relevant fields. All need to contend with the increasing variety of medical problems, particularly as they are aware that they face a growing risk of litigation if they do not keep themselves familiar with current knowledge, in line with the increasing acceptance of the need for continuing professional development (CPD).

There are few randomized controlled trials (RCTs) available to provide evidence for the various practices, and so many of the recommendations have to be based on consensus. The comments and recommendations herein should be used as guidelines to care, not commandments.

Annual theoretical and practical training of all clinical staff is required. Clinical staff have an obligation to be conversant with the current Resuscitation Council (UK) guidelines (2012) (see Further reading). The UK General Dental Council (GDC), in *Standards for the dental team* (2013), states that all dental professionals are responsible for putting patients' interests first and for acting to protect them. Central to this responsibility is the need to ensure that HCPs are able to deal with medical emergencies that may arise. All members of the dental team need to know their roles in the event of an emergency.

Box 1.1 Common emergencies

- Collapse
- Fitting
- Chest pain
- Shortness of breath
- Mental disturbances
- Reactions to drugs or sedation
- Bleeding

The GDC guidance, *Principles of dental team working* (2005), states that dental staff who employ, manage or lead a team should make sure that:

- there are arrangements for at least two people to be available to deal with medical emergencies when treatment is planned to take place
- all members of staff, not just the registered team members, know their role if a patient collapses or there is another kind of medical emergency
- all members of staff who might be involved in dealing with a medical emergency are trained and prepared to deal with such an emergency at any time, and regularly practise simulated emergencies together.

The GDC has stipulated that 10 hours of training and retraining in emergency management is a mandatory requirement of CPD in every 5-year period.

Emergencies are rare. A medical emergency occurring in dental practice is most likely to be the result of an acute deterioration of a known medical condition. It may pose an immediate threat to an individual's life and needs rapid intervention. It is best prevented! The most common medical emergency is the simple faint. Other common emergencies include fitting in an epileptic patient, angina pectoris (ischaemic chest pain), hypoglycaemia in a diabetic patient and haemorrhage. Myocardial infarction and cardiopulmonary arrest are more immediately dangerous ([Box 1.2](#)).

PREVENTING EMERGENCIES

Emergency management algorithms are of paramount importance and dental employers are ultimately responsible for the performance of their staff as regards delivery.

Confidence and satisfactory management of emergencies can be improved by the following measures:

- Repeatedly assessing the patient whilst undertaking treatment, noting any changes in appearance or behaviour.
- Never practising dentistry without another competent adult in the room.
- Always having accessible the telephone numbers of the emergency services and nearest hospital accident and emergency

Box 1.2 Likely causes of sudden loss of consciousness and collapse

- Simple faint
- Diabetic collapse secondary to hypoglycaemia
- Epileptic seizure
- Anaphylaxis
- Cardiac arrest
- Stroke
- Adrenal crisis

Table 1.1 Suggested minimal equipment for emergency use in dentistry^a

Equipment	General comments	Detail
Oxygen (O ₂) delivery	Portable apparatus for administering oxygen Oxygen face mask (non-rebreathe type) with tube Basic set of oropharyngeal airways (sizes 1, 2, 3 and 4) Pocket mask with oxygen port Self-inflating bag valve mask (BVM; 1-L size bag), where staff have been appropriately trained Variety of well-fitting adult and child face masks for attaching to self-inflating bag	Two portable oxygen cylinders ('D' size) with pressure reduction valves and flow meters. Cylinders should be of sufficient size to be easily portable but also to allow for adequate flow rates (e.g. 10L/min), until the arrival of an ambulance or full recovery of the patient. A full 'D' size cylinder contains 340L of oxygen and should allow a flow rate of 10L/min for up to 30min. Two such cylinders may be necessary to ensure the oxygen supply does not fail
Portable suction	Portable suction with appropriate suction catheters and tubing (e.g. Yankauer sucker)	
Spacer device for inhalation of bronchodilators		
Automated external defibrillator (AED)	All clinical areas should have immediate access to an AED (collapse-to-shock time <3min)	
Automated blood glucose measuring device		
Equipment for administering drugs intramuscularly	Single-use sterile syringes (2-mL and 10-mL sizes) and needles (19 and 21 sizes)	Drugs as in Table 1.2

^aAfter Resuscitation Council (2012).

department. Details of the patient's general medical practitioner should be recorded in the notes.

- Training staff in emergency service contact protocols and emergency procedures. This should be repeated annually. All clinics should have a defined protocol for how the emergency services are to be alerted. The protocol should include clear directions to enable the emergency services to locate and access the clinic. In a large building, a member of the team should meet the emergency services at the main entrance.
- Having a readily accessible emergency drugs box and equipment that is checked on a weekly basis ([Tables 1.1 and 1.2](#); [Figs 1.1–1.3](#)).
- Taking a careful medical history, assessing disease severity, scheduling and planning treatment carefully, and, in some cases, administering medication prior to treatment.
- Using the simple intervention of laying the patient supine prior to giving local analgesia/anaesthesia (LA). This will prevent virtually all simple faints.
- Ensuring that diabetic patients have had their normal meals, medication has been appropriately administered, and treatment is given early in the morning session or immediately after lunch. These measures are likely to prevent most hypoglycaemic collapses.

All this is even more important when conscious sedation (CS) is used, when invasive or painful procedures are planned, or when medically complex individuals are being treated. 'Forewarned is forearmed,' and dental professionals must ensure that medical and drug histories are updated at each visit prior to initiating treatment. It is suggested that disease severity should be assessed using a risk stratification system – for example, the American Society of Anesthesiologists (ASA) classification (Chs 2 and 3) – as this may help identify high-risk individuals.

Few emergencies can be treated definitively in the dental clinic. The role of the dental team is one of support and considered intervention using algorithms that can 'do no harm'. Previously, it has been suggested that 20 or more drugs should be available to the dental professional for the management of emergencies but this is impractical, may

Table 1.2 Suggested minimal drugs for emergency use in dentistry^a

Emergency	Drugs required	Dosages for adults
Anaphylaxis	Adrenaline (epinephrine) injection 1:1000, 1 mg/mL	Intramuscular adrenaline (0.5 mL of 1 in 1000 solution) Repeat at 5 min if needed
Hypoglycaemia	Oral glucose solution/tablets/gel/powder (e.g. GlucoGel®, formerly known as Hypostop® gel [40% dextrose]) Glucagon injection 1 mg (e.g. GlucaGen HypoKit)	Proprietary non-diet drink or 5g glucose powder in water Intramuscular glucagon 1 mg
Acute exacerbation of asthma	(β ₂ agonist) Salbutamol aerosol inhaler 100 mcg/activation	Salbutamol aerosol Activations directly or up to six into a spacer
Status epilepticus	Buccal or intranasal midazolam 10 mg/mL	Midazolam 10 mg
Angina	Glyceryl trinitrate ^b spray 400 mcg/metered activation	Glyceryl trinitrate, two sprays
Myocardial infarct	Dispersible aspirin 300 mg	Dispersible aspirin 300 mg (chewed)

^aAfter Resuscitation Council (2012). No corticosteroid is included.^bDo not use nitrates to relieve an angina attack if the patient has recently taken sildenafil, as there may be a precipitous fall in blood pressure; analgesics should be used. Where possible, all emergency equipment should be single-use and latex-free. The kit does not include any intravenous injections.

be a source of confusion and, if a drug is incorrectly administered, may be life-threatening.

The Resuscitation Council recommendations for equipment and drugs are detailed in [Tables 1.1 and 1.2](#). Other agents (e.g. the midazolam antagonist flumazenil) and equipment (e.g. a pulse oximeter) are needed if CS is administered.

General anaesthesia (GA) must be undertaken only by anaesthetists and where advanced life support (ALS) is available.

Fig. 1.1 Emergency kit.

Fig. 1.2 Automatic defibrillator.

Fig. 1.3 Automatic external defibrillator (AED).

RESUSCITATION AND EMERGENCIES

The GDC does not have any guidelines on resuscitation but would refer registrants to the Resuscitation Council, which does have relevant guidance. Full details are available at <http://www.gdc-uk.org/Dentalprofessionals/Standards/Pages/home.aspx> (accessed 30 September 2013).

The GDC's *Principles of dental team working* (2005) covers medical emergencies.

MANAGING EMERGENCIES

For all medical emergencies, a structured approach to assessment and reassessment prevents any symptoms and signs being missed and any

Box 1.3 Assessment in emergencies

Airway	Identify foreign body obstruction and stridor
Breathing	Document respiratory rate, use of accessory muscles, presence of wheeze or cyanosis
Circulation	Assess skin colour and temperature, estimate capillary refill time (normally, 2s with hand above heart), assess rate of pulse (normal is 70 beats/min)
Disability	Assess conscious level using acronym AVPU: - Alert - responds to Voice - responds to Painful stimulus - Unresponsive - Blood glucose
Exposure	Respecting the patient's dignity, try to elicit the cause of acute deterioration (e.g. rash, signs of recreational drug use)

incorrect diagnoses being made. The sequence is best remembered as 'ABCDE' (Box 1.3). 'Drs ABC' highlights the sequence:

- *danger* (recognizing an emergency)
- *respiration* (establishing an airway)
- shout for help.
- *A*; airway
- *B*; breathing
- *C*; circulation

People who collapse should be put in the 'recovery position' to maintain a clear airway UNLESS there could be a neck injury, such as after a fall or road traffic accident.

CARDIOPULMONARY RESUSCITATION

Dental staff should be trained in basic cardiopulmonary resuscitation (CPR) so that, in the event of cardiac arrest, they should be able to:

- recognize cardiac arrest (the heart stops beating)
- summon immediate help (dial for the emergency services)
- initiate CPR according to current resuscitation guidelines (evidence suggests that chest compressions can be effectively performed in a dental chair)
- ventilate with high-concentration oxygen via a bag and mask
- apply an automated external defibrillator (AED) as soon as possible after collapse. Follow the machine prompts and administer a shock if indicated, with a maximum collapse-to-shock time of 3 minutes.

Hands-only CPR

- Call the emergency services
- Push hard and fast in the centre of the chest to double a person's chances of survival (the song 'Stayin' Alive' has the right beat for hands-only CPR)
- The method of delivering chest compressions remains the same, as does the rate (at least 100 per minute).

EMERGENCY PROCEDURE

- Call for local assistance
- Assess the patient – ABCDE (as Box 1.3) – and give oxygen if appropriate
- Use the acronym MOVE:
 - Monitor* – reassess ABCDE regularly, attach an AED if appropriate
 - Oxygen* – 15 L/min through a non-rebreathe mask
 - Verify* – check that emergency services are coming
 - Emergency action* – correct positioning and drug administration.

Intramuscular (i.m.) injection is used nowadays for giving most emergency drugs. The most accessible site in a clothed patient sitting in a dental chair is the lateral aspect of the thigh. There the vastus lateralis is a large muscle with no large nerves or arteries running through it. In an emergency, the injection can be administered through clothing. The mid-point between the pelvis and the knee is the preferred site.

The Advanced Medical Priority Dispatch System (AMPDS) is a unified system that sends appropriate aid to medical emergencies, including systematized caller interrogation and pre-arrival instructions. AMPDS works on the following response categories:

- A (immediately life-threatening)
- B (urgent call)
- C (routine call).

This may well be linked to a performance targeting system where calls must be responded to within a given time period. For example, in the UK, calls rated as 'A' on AMPDS aim to have a responder on scene within 8 minutes.

The 'ABCDE' approach to the sick patient

The 'ABCDE' approach to the sick patient is outlined at <http://www.resus.org.uk/pages/MEdental.pdf> by the UK Resuscitation Council (2006, updated 2012; accessed 30 September 2013). Appendix (i), which cannot be bettered, and states:

Dental Practitioners, Dental Care Professionals and their staff should be familiar with standard resuscitation procedures as recommended by the Resuscitation Council (UK). In all circumstances it is advisable to call for medical assistance as soon as possible by dialling 999 and summoning an ambulance.

Early recognition of the 'sick' patient is to be encouraged. Pre-empting any medical emergency by recognising an abnormal breathing pattern, an abnormal patient colour or abnormal pulse rate, allows appropriate help to be summoned, e.g. ambulance, prior to any patient collapse occurring. A systematic approach to recognising the acutely ill patient based on the 'ABCDE' principles is recommended. Accurate documentation of the patient's medical history should further allow those 'at risk' of certain medical emergencies to be identified in advance of any proposed treatment. The elective nature of most dental practice allows time for discussion of medical problems with the patient's general medical practitioner where necessary. In certain circumstances this may lead to a postponement of the treatment indicated or a recommendation that such treatment be undertaken in hospital.

General principles

1. Follow the Airway, Breathing, Circulation, Disability, and Exposure approach (ABCDE) to assess and treat the patient.
2. Treat life-threatening problems as they are identified before moving to the next part of the assessment.
3. Continually reassess, starting with Airway, if there is further deterioration.
4. Assess the effects of any treatment given.
5. Recognise when you need extra help and call for help early. This may mean dialling 999 for an ambulance.
6. Use all members of your dental team. This will allow you to do several things at once, e.g. collect emergency drugs and equipment, dial 999.
7. Organise your team and communicate effectively.

8. The aims of initial treatment are to keep the patient alive, achieve some clinical improvement and buy time for further treatment whilst waiting for help.
9. Remember – it can take a few minutes for treatment to work.
10. The ABCDE approach can be used irrespective of your training and experience in clinical assessment or treatment. Individual experience and training will determine which treatments you can give. Often only simple measures such as laying the patient down or giving oxygen are needed.

First steps

- In an emergency, stay calm. Ensure that you and your staff are safe.
- Look at the patient generally to see if they 'look unwell'.
- In an awake patient ask, 'How are you?' If the patient is unresponsive, shake him and ask, 'Are you all right?' If they respond normally, they have a clear airway, are breathing and have brain perfusion. If they speak only in short sentences, they may have breathing problems. Failure of the patient to respond suggests that they are unwell. If they are not breathing and have no pulse or signs of life, start CPR according to current resuscitation guidelines.

Airway (A)

Airway obstruction is an emergency.

1. Look for the signs of airway obstruction:
 - ◆ Airway obstruction causes 'paradoxical' chest and abdominal movements ('see-saw' respirations) and the use of the accessory muscles of respiration, e.g. neck muscles. Central cyanosis (blue lips and tongue) is a late sign of airway obstruction. In complete airway obstruction, there are no breath sounds at the mouth or nose.
 - ◆ In partial airway obstruction, air entry is diminished and usually noisy:
 - Inspiratory 'stridor' is caused by obstruction at the laryngeal level or above.*
 - Expiratory 'wheeze' suggests obstruction of the lower airways, which tend to collapse and obstruct during expiration. This is most commonly seen in patients with asthma or chronic obstructive pulmonary disease.*
 - Gurgling suggests there is liquid or semi-solid foreign material in the upper airway.*
 - Snoring arises when the pharynx is partially occluded by the tongue or palate.*
2. Airway obstruction is an emergency:
 - ◆ In most cases, only simple methods of airway clearance are needed:
 - Airway opening manœuvres – head tilt/chin lift or jaw thrust. Remove visible foreign bodies, debris or blood from the airway (use suction or forceps as necessary).*
 - Consider simple airway adjuncts, e.g. oropharyngeal airway.*
3. Give oxygen initially at a high inspired concentration:
 - ◆ Use a mask with an oxygen reservoir. Ensure that the oxygen flow is sufficient (15 litres per minute) to prevent collapse of the reservoir during inspiration.
 - ◆ If you have a pulse oximeter, titrate the oxygen delivery aiming for normal oxygen saturation levels (94–98%).

In very sick patients this may not be possible and a lower oxygen saturation (more than 90%) is acceptable for a short period of time.

Breathing (B)

During the immediate assessment of breathing, it is vital to diagnose and treat immediately life-threatening breathing problems, e.g. acute severe asthma.

1. *Look, listen and feel for the general signs of respiratory distress: sweating, central cyanosis (blue lips and tongue), use of the accessory muscles of respiration (muscles of the neck) and abdominal breathing.*
2. *Count the respiratory rate. The normal adult rate is 12 to 20 breaths per minute and a child's rate is between 20 and 30 breaths per minute. A high, or increasing, respiratory rate is a marker of illness and a warning that the patient may deteriorate and further medical help is needed.*
3. *Assess the depth of each breath, the pattern (rhythm) of respiration and whether chest expansion is equal and normal on both sides.*
4. *Listen to the patient's breath sounds a short distance from their face. Gurgling airway noises indicate airway secretions, usually because the patient cannot cough or take a deep breath. Stridor or wheeze suggests partial, but important, airway obstruction.*
5. *If the patient's depth or rate of breathing is inadequate, or you cannot detect any breathing, use bag and mask (if trained) or pocket mask ventilation with supplemental oxygen while calling urgently for an ambulance.*
6. *Hyperventilation and panic attacks are relatively common in general dental practice. In most patients these will resolve with simple reassurance.*

Circulation (C)

Simple faints or vasovagal episodes are the most likely cause of circulation problems in general dental practice. These will usually respond to laying the patient flat and, if necessary, raising the legs (see Appendix (ii) Syncope). The systematic ABCDE approach to all patients will ensure that other causes are not missed.

1. *Look at the colour of the hands and fingers: are they blue, pink, pale or mottled?*
2. *Assess the limb temperature by feeling the patient's hands: are they cool or warm?*
3. *Measure the capillary refill time. Apply cutaneous pressure for five seconds on a fingertip held at heart level (or just above) with enough pressure to cause blanching. Time how long it takes for the skin to return to the colour of the surrounding skin after releasing the pressure. The normal refill time is less than two seconds. A prolonged time suggests poor peripheral perfusion. Other factors (e.g. cold surroundings, old age) can also prolong the capillary refill time.*
4. *Count the patient's pulse rate. It may be easier to feel a central pulse (i.e. carotid pulse) than the radial pulse.*
5. *Weak pulses in a patient with a decreased conscious level and slow capillary refill time suggest a low blood pressure. Laying the patient down and raising the legs may be helpful. In patients who do not respond to simple measures urgent help is needed and an ambulance should be summoned.*

6. *Cardiac chest pain typically presents as a heaviness, tightness or indigestion-like discomfort in the chest. The pain or discomfort often radiates into the neck or throat, into one or both arms (more commonly the left) and into the back or stomach area. Some patients experience the discomfort in one of these areas more than in the chest. Sometimes pain may be accompanied by belching, which can be misinterpreted as evidence of indigestion as the cause. The patient may have known stable angina and carry their own glyceryl trinitrate (GTN) spray or tablets. If they take these, the episode may resolve. If the patient has sustained chest pain, give GTN spray if the patient has not already taken some. The patient may feel better and should be encouraged to sit upright if possible. Give a single dose of aspirin and consider the use of oxygen.*

(See Appendix (ii) Cardiac Emergencies.)

Disability (D)

Common causes of unconsciousness include profound hypoxia, hypercapnia (raised carbon dioxide levels), cerebral hypoperfusion (low blood pressure), or the recent administration of sedatives or analgesic drugs.

1. *Review and treat the ABCs: exclude hypoxia and low blood pressure.*
2. *Check the patient's drug record for reversible drug-induced causes of depressed consciousness.*
3. *Examine the pupils (size, equality and reaction to light).*
4. *Make a rapid initial assessment of the patient's conscious level using the AVPU method: Alert, responds to Vocal stimuli, responds to Painful stimuli or Unresponsive to all stimuli.*
5. *Measure the blood glucose to exclude hypoglycaemia, using a glucose meter. If below 3.0 mmol per litre give the patient a glucose containing drink to raise the blood sugar (e.g. Glucogel; DextroGel; GSF-syrup or RapiLOSE gel: see Appendix (ii) Hypoglycaemia) or glucose by other means.*
6. *Nurse unconscious patients in the recovery position if their airway is not protected.*

Exposure (E)

To assess and treat the patient properly loosening or removal of some of the patient's clothes may be necessary. Respect the patient's dignity and minimize heat loss. This will allow you to see any rashes (e.g. anaphylaxis) or perform procedures (e.g. defibrillation).

COMMON EMERGENCIES

See also Appendix 1.1 for the Resuscitation Council guidelines (2012) on dealing with common emergencies.

COLLAPSE (TABLE 1.3)

The cause of sudden loss of consciousness may be suggested by the medical history:

- Collapse at the sight of a needle or during an injection is likely to be a simple faint.
- Following some minutes after an injection of penicillin, collapse is more likely to be due to anaphylaxis.

Table 1.3 Common emergencies

Emergency	Recognition	Actions; reassure patient and accompanying people, and			
		1. Call for assistance	2. Give oxygen 15 L/min	3. Other main actions	4. Alert emergency services
Anaphylaxis	Acute Collapse Rash Angioedema Wheezing	Yes	Yes	Adrenaline (epinephrine) 500 mcg for adult i.m. (0.5 mL of 1 in 1000 adrenaline) Legs-up position	Yes
Angina	Severe chest pain, responding to glyceryl trinitrate	Yes	Yes	Glyceryl trinitrate 2 puffs sublingually	Only if no spontaneous recovery after action (3)
Asthma exacerbation	Breathless Wheeze Speechlessness Possible cyanosis	Yes	Yes	Sit patient up and forwards, salbutamol 2 × 100 mcg puffs for adult inhaled via spacer	If no spontaneous recovery after action (3)
Cardiac arrest	Severe chest pain, not responding to glyceryl trinitrate Collapse Pallor Breathlessness Sweating	Yes	Yes	Glyceryl trinitrate 2 puffs and aspirin 300 mg sublingually CPR	Yes
Choking	Inhaled foreign material Coughing Choking	Yes	Yes	Back slap five times, then abdominal thrust five times	Only if no spontaneous recovery after action (3)
Epileptic fit	Collapse Seizures Maybe incontinence	Yes	Yes	Protect patient from harm Consider midazolam 10 mg for adult in buccal mucosa (or i.m. or sublingually)	Only if no spontaneous or other recovery after 5 min, persistent altered conscious state or the fit characteristics are different to those previously described
Faint	Collapse, responding to laying flat Pallor Slow pulse Sweating No chest pain	Yes	No*	Lay patient flat Give glucose orally	Only if no spontaneous recovery after action (3)
Hypoglycaemia	Confusion or aggression, often known diabetes Shake or tremor Collapse	Yes	Yes	Blood glucose assay Give glucose drink, gel or tablets If unconscious, glucagon 1 mg for adult i.m.	Only if no spontaneous recovery after action (3)
Stroke	Face weakness Arm weakness Speech difficulties (Test all above)	Yes	Yes	–	Yes

*Not essential but oxygen may do no harm.

- Collapse of a diabetic at lunchtime, for example, is likely to be caused by hypoglycaemia.
- Collapse of a patient with angina or previous myocardial infarction may be caused by a new or further myocardial infarction.

The clinical features of the episode may also aid diagnosis; for example, severe chest pain suggests a cardiac cause. A structured and systematic assessment, regardless of perceived causative factors, is required to mitigate management errors.

For collapse of uncertain cause, see Table 1.3 and Figure 1.4.

The principles of the *chain of survival*, which applies to emergencies where the patient is not breathing and has no pulse, involve four stages:

- Early recognition and call for help
- Early CPR

- Early defibrillation
- Early ALS.

SIMPLE FAINT

Fainting (syncope) is the most common cause of sudden loss of consciousness. It is associated with a loss of postural tone, and there is spontaneous recovery. Up to 2% of patients may faint before or during dental treatment. Young, fit, adult males in particular are prone to faint, especially before, during and after injections.

Vasovagal (vasodepressor) attack (or pressure on the vagus) is the usual cause of a simple faint. The diagnosis rests on the history, upright posture, an emotional or painful stimulus, gradual not sudden

Fig. 1.4 Reduced consciousness algorithm.

fading of consciousness, sweating, nausea, pallor, other manifestations of autonomic activity, and rapid recovery on lying down. Simple faints tend to occur, and recur, in young people.

Other causes of sudden loss of consciousness include:

- situational syncope provoked by coughing, micturition (urination) or postural change
- sudden cardiac syncope due to arrhythmia or circulatory obstruction – typically in older people
- orthostatic hypotension
- neurological disorders.

These should be considered in the differential diagnosis.

Predisposing factors for vasovagal attack include:

- anxiety
- pain
- fatigue

- fasting (rarely)
- high temperature and relative humidity.

Signs and symptoms of a simple faint include:

- premonitory dizziness, weakness or nausea
- pallor
- cold, clammy skin
- dilated pupils
- pulse that is initially slow and weak, then rapid and full
- loss of consciousness.

The simple precaution of laying patients flat *before* giving injections will prevent fainting. Very rarely, patients can suffer *malignant vasovagal syncope* with recurrent, severe and otherwise unexplained syncope; their clinical history is intermediate between that of vasovagal and cardiac syncope, and diagnosis is confirmed by a tilt test.

Fig. 1.5 Anaphylaxis algorithm.

ANAPHYLAXIS

- Always detail known allergies and the severity of any previous type 1 hypersensitivity reactions.
 - Avoid possible allergens and, when this is not possible, refer the patient for specialist assessment.
 - Life-threatening anaphylaxis may occur, despite no previous history of allergen exposure.
 - Anaphylaxis is the most severe allergic response and manifests with acute hypotension, bronchospasm, urticaria rash and angioedema (Fig. 1.5).
- The causal agents include:
 - penicillins – the most common cause, but also other antimicrobials (cephalosporins, sulphonamides, tetracyclines, vancomycin)
 - latex
 - muscle relaxants
 - non-steroidal anti-inflammatory drugs (NSAIDs)
 - opiates
 - radiographic contrast media
 - others – vaccines, immunoglobulins, various foods and insect bites.

- Strict avoidance of the causal agent is essential.
- Where there is a previous history of anaphylaxis, the patient should carry a self-administered i.m. injection device, e.g. EpiPen® (ALK-Abelló, Hungerford, Berkshire, UK) or Twinject® (Verus Pharmaceuticals, San Diego, California, USA) (or less commonly, an adrenaline (epinephrine) aerosol, such as MedihalerEpi). Patients should carry 2 EpiPens® with them because >35% of patients may require more than one adrenaline dose and up to 20% of patients will go on to develop a biphasic anaphylactic response sometimes hours later. The standard dosage of adrenaline supplied by an EpiPen for adults is 0.3 mL of 1 in 1000 (0.3 mg). Child-sized dosages (0.15 mg) are available as the EpiPen JR.
- Diagnosis is as follows:
 - facial flushing, itching, paraesthesiae, oedema or sometimes urticaria, or peripheral cold clammy skin
 - stridor or wheeze
 - abdominal pain, nausea
 - loss of consciousness
 - pallor progressing to cyanosis
 - rapid, weak or impalpable pulse.

Management

Treatment of an anaphylactic reaction should be based on general life-support principles:

- Use the ABCDE approach to recognize and treat problems.
- Call for help early.
- Treat the greatest threat to life first.
- Do not delay initial treatments because of the lack of a complete history or definite diagnosis.

Patients having an anaphylactic reaction in any setting should expect the following as a minimum:

- Recognition that they are seriously unwell
- An early call for help
- Initial assessment and treatments based on an ABCDE approach
- Adrenaline (epinephrine) therapy if indicated
- Investigation and follow-up by an allergy specialist.

CARDIAC ARREST

- Cardiac arrest can occur in a patient with no previous history of cardiac problems, but is more likely in those with a history of ischaemic heart disease, in diabetics and older people.
- Previous angina or myocardial infarction predispose to cardiac arrest.
- Ventricular fibrillation accounts for most sudden cardiac arrests. Causes include myocardial infarction, hypoxia, drug overdose, anaphylaxis, severe infection or severe hypotension.
- After airway and breathing assessment, basic life support (BLS) needs to be initiated immediately to maintain adequate cerebral perfusion until the underlying cause is reversed (Fig. 1.6).
- Basic life support comprises:
 - initial assessment
 - airway maintenance
 - chest compression
 - ventilation.

Management

See Figures 1.5 and 1.7.

Fig. 1.6 Cardiac arrest – basic life support algorithm (*see Fig. 1.7).

DIABETIC COLLAPSE: HYPOGLYCAEMIA

- Hypoglycaemia is dangerous because the brain becomes starved of glucose.
- Diabetics treated with insulin, those with poor blood glucose control and those with poor awareness of their hypoglycaemic episodes have a greater chance of losing consciousness.
- Remember that a collapse in a diabetic may be caused by other emergencies, e.g. a faint or myocardial infarction. Ischaemic heart disease is common in long-standing diabetes.
- Hypoglycaemia may present as a deepening drowsiness, disorientation, excitability or aggressiveness, especially if it is known that a meal has been missed.
- A management algorithm is provided in Figure 1.8.

Fig. 1.7 Cardiac arrest – automated external defibrillator (AED) algorithm.

FITTING

- Fits are usually seen in known epileptics.
- Various factors may precipitate a fit, including not eating, cessation of anticonvulsant therapy, menstruation and some drugs, such as alcohol, flumazenil or tricyclic antidepressants.
- Fits may also affect people with no history of epilepsy, especially following hypoxia from loss of consciousness for other reasons or in hypoglycaemia.
- Diagnosis of a tonic-clonic (grand mal) seizure is as follows: loss of consciousness with rigid, extended body, which is sometimes preceded by a brief cry widespread jerking movements possible incontinence of urine and/or faeces slow recovery with the patient sometimes remaining dazed (post-ictal).
- A management algorithm for the fitting patient is shown in Figure 1.9.

Guidance from the Resuscitation Council is as follows:

If a patient continues to fit after an ambulance has been called then the emergency administration of buccal midazolam to assist in terminating the seizure is warranted. The dose is 10mg for adults and an appropriately reduced dose for children. The evidence for using midazolam in this manner and for this indication is strong. It is recommended in the British National Formulary, by the Advanced Paediatric Life Support course, the National Epilepsy organisations and the Royal College of Paediatrics and Child Health. After many years of using midazolam for seizure control as an 'unlicensed' product, the drug has recently acquired a paediatric use marketing authorisation (PUMA) from the European Commission and as such is now classed as a 'licensed' product. 'Buccolam' is available as a 5mg/ml solution for use in children up to 17 years old. Its use in adults will therefore remain 'off license' but the recommended dose is the same as that for the older child, i.e. 10mg (2ml). This 'off license' use is justified in the emergency situation described above. In both the 'licensed' and 'off licensed' setting, the drug does not need to have been prescribed to the patient when used in an emergency. It should, however, be administered by (or under the supervision of) a dental practitioner. There have been concerns regarding the reclassification of midazolam as a 'Schedule 3' Controlled Drug. Such reclassification requires certain legal processes. However, the law for this Schedule 3 drug does NOT require safe custody, i.e. locked cupboard, nor the need to keep a midazolam controlled drug register. Some institutions are encouraging such practices as part of their own Health and Safety protocols but there is no legal obligation to do so. Similarly, concerns have been raised about acquiring stocks of midazolam for use in the emergency setting of seizure control. A dentist can issue a requisition for any licensed product for use within their practice, as appropriate. The dentist will need to use the standardized requisition form, FP10CDF. Dental practitioners who do not use midazolam regularly are permitted to requisition this Schedule 3 Drug under the conditions laid out by the Royal Pharmaceutical Society of Great Britain in their guidance 'Medicines, Ethics and Practice: the professional guide for pharmacists'.

CHEST PAIN

- Acute severe chest pain is usually caused by angina or, less commonly, myocardial infarction.
- Patients with 'unstable' angina and those with a recent history of hospital admission for ischaemic chest pain have the highest risk, and should not be considered for routine dental treatment in primary care.
- Diagnostic features include: severe crushing retrosternal pain radiating down the left arm breathlessness that may be described as 'heartburn' vomiting and loss of consciousness if there is an infarct weak or irregular pulse if there is an infarct.
- Management is detailed in Figure 1.10.

SHORTNESS OF BREATH

ACUTE SEVERE ASTHMA

- Anxiety, infection, or exposure to an allergen or drugs may precipitate asthma.
- High-risk asthmatics include those individuals who: take oral medication in addition to inhaled β_2 agonists and corticosteroids

Fig. 1.8 Hypoglycaemia algorithm.

use a nebulizer regularly at home
have required oral steroids for their asthma within the last year
have been admitted to hospital with asthma within the last year.

- Diagnostic features are:
breathlessness
expiratory wheeze
use of accessory muscles – shrugging the shoulders with each respiratory cycle with increased severity
rapid pulse (usually over 110 beats/min) with increasing severity but this may slow in life-threatening exacerbation.
- Management is detailed in [Figure 1.11](#).

FOREIGN BODY RESPIRATORY OBSTRUCTION

- Causes of respiratory obstruction include laryngeal spasm and foreign body. Although these may occur in any individual, the sedated patient poses a significant risk.
- Prevention of inhalation of foreign bodies, including teeth, crowns, filling materials or endodontic instruments, is far better than the event occurring. At the least, such an event causes great embarrassment, at worst respiratory obstruction, lung abscess or death.
- Use a rubber dam.

Fig. 1.9 Fitting/convulsions algorithm.

- Diagnosis is as follows:
irregular breathing with crowing or croaking on inspiration
violent respiratory efforts using accessory muscles
deepening cyanosis.
- Management is shown in [Figures 1.12 and 1.13](#).

- Diagnosis varies with the size and site of brain damage but typically includes:
loss of consciousness
unilateral weakness of the arm and leg
facial palsy.
- Management details are shown in [Box 1.4](#).

LESS COMMON EMERGENCIES

STROKE

- Stroke may rarely occur in apparently healthy patients, but is more common in older and hypertensive individuals. A history of stroke predisposes to a further event.

ADRENAL CRISIS: COLLAPSE OF A PATIENT WITH A HISTORY OF CORTICOSTEROID THERAPY

- Collapse in a patient with Addison disease or a history of systemic corticosteroid therapy may be caused by adrenal insufficiency, triggered by general anaesthesia, trauma, infections or other stress, but has never been recorded in primary dental care.

Fig. 1.10 Chest pain algorithm.

- Prevention of this emergency is contentious and will be dealt with in Chapter 6.
- Diagnosis is as follows:
pallor
pulse – rapid, weak or impalpable
loss of consciousness
rapidly falling blood pressure.
- Management is detailed in [Figure 1.14](#).

REACTIONS TO DRUGS OR SEDATION

Intravascular injection of local anaesthetic agent

- Diagnostic features may include:
agitation
confusion
drowsiness
fitting
eventually, loss of consciousness.
- Management is detailed in [Box 1.5](#).

Fig. 1.11 Asthma algorithm.

Temporary facial palsy, diplopia or localized facial pallor

- These occur rarely as a result of action of the anaesthetic agent on the facial nerve or orbital contents; the transient effects resolve.
- If the individual is unable to blink, the eyelids should be taped closed until the anaesthetic abates.

Local anaesthetic allergy

- Allergy to LA is managed as for anaphylaxis, but is very rare.

Cardiovascular reactions to local anaesthetic

- Usually, only palpitations are experienced.
- Identify the likely cause and reassure the patient.

- Await natural subsidence of symptoms.
- If chest pain occurs, treat as above.
- Where possible, defer further immediate dental treatment.

Hypotension resulting from interaction with antihypertensive drugs

- Assess and clear the airway.
- Assess breathing and administer oxygen.
- Assess circulation.
- Lay the patient flat.
- Reassure.
- Summon assistance.
- Where possible, defer further immediate dental treatment.

Fig. 1.12 Choking algorithm.

Fig. 1.13 Abdominal thrust (formerly the Heimlich manoeuvre).

Box 1.4 Management of stroke

- Assess (FAST: face, arm, speech, time), clear the airway and check breathing
- Check pulse and capillary refill
- Reassure the patient
- Give high-flow oxygen
- Call an ambulance
- Defer dental treatment

SEDATION EMERGENCIES

Respiratory failure

- Causes include drug overdose or hypoxia.
- Diagnosis is as follows:
Respiratory rate slows and then stops.
There is ashen cyanosis.
Pulse is initially rapid and weak, later irregular or impalpable.
Cardiac arrest may follow.
- Management is as follows:
Assess the patient using ABCDE.
Call an ambulance.
Administer no further sedation.
Lay patient flat.
Commence ventilation with bag and mask containing high oxygen concentration.
Consider flumazenil administration.
Defer dental treatment.

Sedative drug overdose or drug interaction

- Accidental overdose or the combination of the sedative agent with another drug used by the patient may be responsible.
- Diagnosis is as follows:
pallor
decreased pulse rate
hypotension
respiratory depression.
- Management is as follows:
Stop the drug.
Give oxygen and ventilate artificially if required.
For midazolam overdose, give flumazenil.
If the patient progresses to cardiac arrest, commence CPR.
Call the emergency services.
Defer dental treatment.

MENTAL DISTURBANCES

HYPERVENTILATION SYNDROME

- Causes of hyperventilation include:
anxiety or neurosis
pain
cardiovascular disease
nervous system disease
acidosis (either metabolic or drug-associated)
poor respiratory exchange (but in this case it is a compensatory physiological response).
- The clinical features vary widely, but neurological and psychological features may include:
anxiety
weakness
light-headedness
dizziness
disturbed consciousness
perioral and peripheral paraesthesiae
tetany
muscle pain or stiffness.
- The most common underlying diagnosis is psychological and is typically seen in a young woman overbreathing secondary to anxiety until carbon dioxide washout results in paraesthesia.

Fig. 1.14 Adrenal insufficiency algorithm.

Box 1.5 Management of intravascular injection of local anaesthetic

- Stop the local anaesthetic administration
- Lay the patient flat
- Reassure the patient
- Assess and maintain the airway
- Check breathing and circulation
- Remember that most patients recover spontaneously within half an hour
- Stabilize and defer further dental treatment until another day

Box 1.6 Management of hyperventilating patients

- Assess airway, breathing and circulation; identify any disability
- Reassure the patient
- Encourage the patient to decrease the respiratory rate slowly
- If there is obvious sympathetic overactivity, as shown particularly by tachycardia or arrhythmias, a cardiologist's opinion should be obtained, as treatment with a beta-blocker may be necessary
- Defer dental treatment until medical assessment has taken place

- Cardiovascular and respiratory features may include:
palpitations
chest pain
breathlessness.
- Management is detailed in [Box 1.6](#).

DISTURBED OR AGGRESSIVE BEHAVIOUR

- Disturbed or aggressive behaviour may be the result of:
an annoyed patient or underlying psychiatric disorder
drugs, especially barbiturates, alcohol or other drugs of addiction
or drug withdrawal, or corticosteroids
pain or discomfort
infections, particularly in the elderly

hypoglycaemia or other endocrine disorders
temporal lobe epilepsy
cerebral tumours.

- Management is detailed in [Box 1.7](#).

BLEEDING

- Post-extraction bleeding causes are usually secondary to local trauma.
 - Haemorrhagic disease, though uncommon, must always be considered (see [Box 1.8](#) and Ch. 8).
- Management is detailed in [Box 1.8](#).

Box 1.7 Management of disturbed or aggressive behaviour

- Reassure and try to calm the patient, and not to restrain
- Do not sedate, as this may confuse the diagnosis and may occasionally be fatal
- Remember that midazolam or diazepam is likely to worsen the excitement of a psychotic patient
- Call an ambulance
- If the patient is violent and uncontrollable, call the police
- Defer dental treatment

Box 1.8 Management of the bleeding patient

- Assess airway, breathing, circulation, disability and exposure
- Reassure the patient. Post-extraction bleeding often worries the patient excessively because a little blood dissolved in saliva gives the impression of a major bleed
- Ask partners or relatives to remain in the waiting room, as their anxiety can prevent early resolution
- Gently clean the mouth
- Locate the source of the bleeding
- Suture the socket under local analgesia
- Enquire into the patient's history, especially family history of abnormal bleeding
- If the bleeding is persistent or severe and there has been an estimated loss of more than about 500 mL, or if the patient is already compromised secondary to severe anaemia, arrange for the patient to be admitted to hospital
- Use tranexamic acid mouthwash 5%, which may help to stabilize the clot in the interim
- If the bleeding is uncontrollable, call an ambulance

APPENDIX 1.1 MANAGEMENT OF COMMON EMERGENCIES

The Resuscitation Council guidelines (2012), Appendix ii, deal with common emergencies.

ASTHMA

Patients with asthma (both adults and children) may have an attack while at the dental surgery. Most attacks will respond to a few 'activations' of the patient's own short-acting beta2-adrenoceptor stimulant inhaler such as salbutamol (100 micrograms/actuation). Repeat doses may be necessary. If the patient does not respond rapidly, or any features of severe asthma are present, an ambulance should be summoned. Patients requiring additional doses of bronchodilator should be referred for medical assessment after emergency treatment. If the patient is unable to use the inhaler effectively, additional doses should be given through a large-volume spacer device. If the response remains unsatisfactory or if the patient develops tachycardia, becomes distressed or cyanosed (blueness around the lips or extremities), arrangements must be made to transfer them urgently to hospital.

Symptoms and signs

Clinical features of **acute severe asthma** in adults include:

- Inability to complete sentences in one breath
- Respiratory rate > 25 per minute
- Tachycardia (heart rate > 110 per minute).

Clinical features of **life-threatening asthma** in adults include:

- Cyanosis or respiratory rate < 8 per minute
- Bradycardia (heart rate < 50 per minute)
- Exhaustion, confusion, decreased conscious level.

Treatment

- Whilst awaiting ambulance transfer, oxygen (15 litres per minute) should be given.
- Assuming the patient's nebuliser is unavailable, up to 10 activations from the salbutamol inhaler should be given using a large-volume spacer device and repeated every 10 minutes if necessary until an ambulance arrives. All emergency ambulances in the UK carry nebulisers, oxygen and appropriate drugs.
- If bronchospasm is part of a more generalized anaphylactic reaction and there are 'life-threatening' signs, an intramuscular injection of adrenaline should be given (see Anaphylaxis).
- The perceived risk of giving patients with chronic obstructive pulmonary disease too much oxygen is often quoted but this should not distract from the reality that ALL sick, cyanosed patients with respiratory difficulty should be given high-flow oxygen until the arrival of the ambulance. This short-term measure is far more likely to be of benefit to the patient than any risks of causing respiratory depression.
- If any patient becomes unresponsive always check for 'signs of life' (breathing and circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps'). For further information about the management of the patient with asthma see <http://www.brit-thoracic.org.uk/guidelines/asthma-guidelines.aspx> (accessed 30 September 2013).

ANAPHYLAXIS

Anaphylaxis is a severe, life-threatening, generalized or systemic hypersensitivity reaction. It is characterised by rapidly developing life-threatening airway and/or breathing and/or circulation problems usually associated with skin and mucosal changes.

Anaphylactic reactions in general dental practice may follow the administration of a drug or contact with substances such as latex in surgical gloves. In general, the more rapid the onset of the reaction, the more serious it will be. Symptoms can develop within minutes and early, effective treatment may be life-saving. Anaphylactic reactions may also be associated with additives and excipients in medicines. It is wise therefore to check the full formulation of preparations which may contain allergenic fats or oils (including those for topical application, particularly if they are intended for use in the mouth).

Symptoms and signs

The lack of any consistent clinical manifestation and a wide range of possible presentations can cause diagnostic difficulty. Clinical assessment helps make the diagnosis.

Signs and symptoms may include:

- urticaria, erythema, rhinitis, conjunctivitis
- abdominal pain, vomiting, diarrhoea and a sense of impending doom
- flushing is common, but pallor may also occur
- marked upper airway (laryngeal) oedema and bronchospasm may develop, causing stridor, wheezing and/or a hoarse voice
- vasodilation causes relative hypovolaemia leading to low blood pressure and collapse. This can cause cardiac arrest
- respiratory arrest leading to cardiac arrest.

Treatment

- Use an ABCDE approach to recognize and treat any suspected anaphylactic reaction. First-line treatment includes managing the airway and breathing and restoration of blood pressure (laying the patient flat, raising the feet) and the administration of oxygen (15 litres per minute).
- For severe reactions where there are life-threatening airway and/or breathing and/or circulation problems, i.e. hoarseness, stridor, severe wheeze, cyanosis, pale, clammy, drowsy, confusion or coma ... adrenaline should be given intramuscularly (anterolateral aspect of the middle third of the thigh) in a dose of 500 micrograms (0.5 mL adrenaline injection of 1:1000); an autoinjector preparation delivering a dose of 300 micrograms (0.3 mL adrenaline injection 1:1000) is available for immediate self-administration by those patients known to have severe reactions. This is an acceptable alternative if immediately available. The dose is repeated if necessary at 5-minute intervals according to blood pressure, pulse and respiratory function. The paediatric dose for adrenaline is based on the child's approximate age or weight. ...
- In any unconscious patient always check for 'signs of life' (breathing and circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps').
- In less severe cases any wheeze or difficulty breathing can be treated with a salbutamol inhaler as detailed above in the section on Asthma.
- All patients treated for an anaphylactic reaction should be sent to hospital by ambulance for further assessment, irrespective of any initial recovery.

Antihistamine drugs and steroids, whilst useful in the treatment of anaphylaxis, are not first-line drugs and they will be administered by the ambulance personnel if necessary.

For further information about the management of the patient with an emergency anaphylactic reaction see <http://www.resus.org.uk/pages/reaction.pdf> (accessed 30 September 2013).

CARDIAC EMERGENCIES

The signs and symptoms of cardiac emergencies include chest pain, shortness of breath, fast and slow heart rates, increased respiratory rate, low blood pressure, poor peripheral perfusion (indicated by prolonged capillary refill time) and altered mental state.

If there is a history of angina the patient will probably carry glyceryl trinitrate spray or tablets (or isosorbide dinitrate tablets) and they should be allowed to use them. Where symptoms are mild and

resolve rapidly with the patient's own medication, hospital admission is not normally necessary. Dental treatment may or may not be continued at the discretion of the Dental Practitioner. More severe attacks of chest pain always warrant postponement of treatment and an ambulance should be summoned.

Sudden alterations in the patient's heart rate (very fast or very slow) may lead to a sudden reduction in cardiac output with loss of consciousness. Medical assistance should be summoned by dialling 999.

Myocardial infarction

The pain of myocardial infarction is similar to that of angina but generally more severe and prolonged. There may only be a partial response to GTN.

Symptoms and signs of myocardial infarction

- Progressive onset of severe, crushing pain in the centre and across the front of chest. The pain may radiate to the shoulders and down the arms (more commonly the left), into the neck and jaw or through to the back.
- Skin becomes pale and clammy.
- Nausea and vomiting are common.
- Pulse may be weak and blood pressure may fall.
- Shortness of breath.

Initial management of myocardial infarction

- Call 999 immediately for an ambulance.
- Allow the patient to rest in the position that feels most comfortable; in the presence of breathlessness this is likely to be the sitting position. Patients who faint or feel faint should be laid flat; often an intermediate position (dictated by the patient) will be most appropriate.
- Give sublingual GTN spray if this has not already been given.
- Reassure the patient as far as possible to relieve further anxiety.
- Give aspirin in a single dose of 300mg orally, crushed or chewed. Ambulance staff should be made aware that aspirin has already been given, as should the hospital. Many ambulance services in the UK will administer thrombolytic therapy before hospital admission. Any dental treatment carried out that might contraindicate this must be brought to the attention of the ambulance crew.
- High-flow oxygen may be administered (15 litres per minute) if the patient is cyanosed (blue lips) or conscious level deteriorates.
- If the patient becomes unresponsive always check for 'signs of life' (breathing and circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps').

EPILEPTIC SEIZURES

Patients with epilepsy must continue their normal dosage of anti-convulsant drugs before attending for dental treatment. Epileptic patients may not volunteer the information that they are epileptic, but there should be little difficulty in recognising a tonic-clonic (grand mal) seizure.

Symptoms and signs

- There may be a brief warning or 'aura'.
- There will be a sudden loss of consciousness, the patient becomes rigid, falls, may give a cry, and becomes cyanosed (tonic phase).
- After a few seconds, there are jerking movements of the limbs; the tongue may be bitten (clonic phase).
- There may be frothing from the mouth and urinary incontinence.
- The seizure typically lasts a few minutes; the patient may then become floppy but remain unconscious.
- After a variable time the patient regains consciousness but may remain confused.
- Fitting may be a presenting sign of hypoglycaemia and should be considered in all patients, especially known diabetics and children. An early blood glucose measurement is essential in all actively fitting patients (including known epileptics).
- Check for the presence of a very slow heart rate (<40 per minute) which may drop the blood pressure. This is usually caused by a vasovagal episode (see Syncope section below). The drop in blood pressure may cause transient cerebral hypoxia and give rise to a brief seizure.

Treatment

- During a seizure try to ensure that the patient is not at risk of injury but make no attempt to put anything in the mouth or between the teeth (in the mistaken belief that this will protect the tongue).
- Do not attempt to insert an oropharyngeal airway or other airway adjunct while the patient is actively fitting.
- Give high-flow oxygen (15 litres per minute).
- Do not attempt to restrain convulsive movements.
- After convulsive movements have subsided place the patient in the recovery position and reassess.
- If the patient remains unresponsive always check for 'signs of life' (breathing and circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps').
- Check blood glucose level to exclude hypoglycaemia. If blood glucose <3.0mmol per litre or hypoglycaemia is clinically suspected, give orallbuccal glucose (e.g. Glucogel; DextroGel; GSF-syrup or RapiLOSE gel), or glucagon (see above and Hypoglycaemia section below).

After the seizure the patient may be confused ('post-ictal confusion') and may need reassurance and sympathy. The patient should not be sent home until fully recovered and they should be accompanied. It may not always be necessary to seek medical attention or transfer to hospital unless the convulsion was atypical, prolonged (or repeated), or if injury occurred. The National Institute for Care and Health Excellence (NICE; formerly the National Institute for Clinical Excellence) guidelines suggest the indications for sending to hospital are:

- status epilepticus
- high risk of recurrence
- first episode
- difficulty monitoring the individual's condition.

Medication should only be given if seizures are prolonged (convulsive movements lasting 5 minutes or longer) or recur in quick

succession. In this situation an ambulance should be summoned urgently.

With prolonged or recurrent seizures, ambulance personnel will often administer IV diazepam, which is usually rapidly effective in stopping any seizure. An alternative, although less effective treatment, is midazolam given via the buccal route in a single dose of 10 mg for adults. For children the dose can be simplified as follows: child 1–5 years 5 mg, child 5–10 years 7.5 mg, above 10 years 10 mg. This might usefully be administered while waiting for ambulance treatment, but the decision to do this will depend on individual circumstances.

(See Appendix (viii) Emergency use of buccal midazolam).

HYPOGLYCAEMIA

Patients with diabetes should eat normally and take their usual dose of insulin or oral hypoglycaemic agent before any planned dental treatment. If food is omitted after having insulin, the blood glucose will fall to a low level (hypoglycaemia). This is usually defined as a blood glucose <3.0 mmol per litre, but some patients may show symptoms at higher blood sugar levels. Patients may recognize the symptoms themselves and will usually respond quickly to glucose. Children may not have such obvious features but may appear lethargic.

Symptoms and signs

- Shaking and trembling
- Sweating
- Headache
- Difficulty in concentration/vagueness
- Slurring of speech
- Aggression and confusion
- Fitting/seizures
- Unconsciousness.

Treatment

The following staged treatment protocol is suggested depending on the status of the patient. If any difficulty is experienced or the patient does not respond, the ambulance service should be summoned immediately; ambulance personnel will also follow this protocol. Confirm the diagnosis by measuring the blood glucose.

Early stages – where the patient is co-operative and conscious with an intact gag reflex, give oral glucose (sugar [sucrose], milk with added sugar, glucose tablets or gel [e.g. Glucogel; Dextrogel; GSF-syrup or RapiLOSE gel]). If necessary this may be repeated in 10–15 minutes.

In more severe cases – where the patient has impaired consciousness, is uncooperative or is unable to swallow safely, buccal glucose gel and/or glucagon should be given.

- Glucagon should be given via the IM route (1 mg in adults and children > 8 years old or >25 kg, 0.5 mg if <8 years old or <25 kg). Remember it may take 5–10 minutes for glucagon to work and it requires the patient to have adequate glucose stores. Thus, it may be ineffective in anorexic patients, alcoholics or some non-diabetic patients.
- Recheck blood glucose after 10 minutes to ensure that it has risen to a level of 5.0 mmol per litre or more, in conjunction with an improvement in the patient's mental status.

- If any patient becomes unconscious, always check for 'signs of life' (breathing and circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps').
- It is important, especially in patients who have been given glucagon, that once they are alert and able to swallow, they are given a drink containing glucose and if possible some food high in carbohydrate. The patient may go home if fully recovered and they are accompanied. Their General Practitioner should be informed and they should not drive.

SYNCOPE

Inadequate cerebral perfusion (and oxygenation) results in loss of consciousness. This most commonly occurs with low blood pressure caused by vagal overactivity (a vasovagal attack, simple faint, or syncope). This in turn may follow emotional stress or pain. Some patients are more prone to this and have a history of repeated faints.

Symptoms and signs

- Patient feels faint/dizzy/light-headed
- Slow pulse rate
- Low blood pressure
- Pallor and sweating
- Nausea and vomiting
- Loss of consciousness.

Treatment

- Lay the patient flat **as soon as possible** and raise the legs to improve venous return.
- Loosen any tight clothing, especially around the neck and give oxygen (15 litres per minute).
- If any patient becomes unresponsive, always check for 'signs of life' (breathing, circulation) and start CPR in the absence of signs of life or normal breathing (ignore occasional 'gasps').

Other possible causes

- **Postural hypotension** can be a consequence of rising abruptly or of standing upright for too long. Several medical conditions predispose patients to hypotension with the risk of syncope. The most common culprits are drugs used in the treatment of high blood pressure, especially the ACE inhibitors and angiotensin antagonists. When rising, patients should take their time. Treatment is the same as for a vasovagal attack.
- Under stressful circumstances, many anxious patients **hyperventilate**. This may give rise to feelings of light-headedness or faintness but does not usually result in syncope. It may result in spasm of muscles around the face and of the hands. In most cases reassurance is all that is necessary.

CHOKING AND ASPIRATION

Dental patients are susceptible to choking with the potential risk of aspiration. They may have blood and secretions in their mouths

for prolonged periods. Local anaesthesia may diminish the normal protective pharyngeal reflexes and 'impression material' or dental equipment is often within their oral cavity and poses additional risks. Good teamwork and careful attention to detail should prevent aspiration episodes and any risk of choking.

Symptoms and signs

- The patient may cough and splutter.
- They may complain of difficulty breathing.
- Breathing may become noisy with wheeze (usually aspiration) or stridor (usually upper airway obstruction).
- They may develop 'paradoxical' chest or abdominal movements.
- They may become cyanosed and lose consciousness.

Treatment

- In cases of aspiration, allow the patient to cough vigorously.
- Symptomatic treatment of wheeze with a salbutamol inhaler may help (as for asthma).
- If any large pieces of foreign material have been aspirated, e.g. teeth or dental amalgam, the patient should be referred to hospital for a chest X-ray and possible removal.
- Where the patient is symptomatic following aspiration they should be referred to hospital as an emergency.
- The treatment of the choking patient involves removing any visible foreign bodies from the mouth and pharynx.
- Encourage the patient to cough if conscious. If they are unable to cough but remain conscious then sharp back blows should be delivered. These can be followed by abdominal thrusts (Heimlich manoeuvre) if the foreign body has not been dislodged. If the patient becomes unconscious, CPR should be started. This will not only provide circulatory support but the pressure generated within the chest by performing chest compressions may help to dislodge the foreign body.

See Appendix (iv) for the Resuscitation Council (UK) Adult and Child Choking Algorithm.

ADRENAL INSUFFICIENCY

Adrenal insufficiency may follow long-term administration of oral corticosteroids and can persist for years after stopping therapy. A patient with adrenal insufficiency may become hypotensive when under physiological stress. The nature of dental treatment makes this a rare possibility, however, and if a patient collapses during dental treatment other causes should be considered first and managed before diagnosing adrenal insufficiency. Routine enquiry about the current or recent use of corticosteroids as part of the medical history prior to dental treatment should alert the Dental Practitioner to the patient at risk of this condition. Some patients carry a steroid warning card. Acute adrenal insufficiency can often be prevented by administration of an increased dose of corticosteroid prior to treatment.

Dental treatment that requires an increased steroid dose is that which may cause significant physiological stress. Usually, simple dental extractions and restorative procedures, including endodontics, are not a cause for concern, but surgical extractions or implant placement should be considered as a risk. Patients who are systemically unwell from a dentally related infection are also recommended to have a prophylactic increase in steroid dose in addition to any surgical and antimicrobial treatment indicated.

Guidance on the management of those patients with known Addison's disease is available from the Addison's Clinical Advisory Panel (<http://www.addisons.org.uk/>; accessed 30 September 2013), who recommend doubling the patient's steroid dose before significant dental treatment under local anaesthesia and continuing this for 24 hours.

2

Medical history, examination, investigations and risk assessment

KEY POINTS

- Crucial history-taking includes (A–E):
 1. allergies
 2. bleeding tendency
 3. cardiac history
 4. drug history
 5. endocrine disease (e.g. diabetes)
- Patients may be unclear about, or unaware of or not disclose their medical history or drug history
- Confidentiality is essential

PROTECTING PATIENTS

Health care aims to improve the health of patients but can itself carry risks. The first principle should be to do no harm (*primum non nocere*). Nevertheless, a UK report estimated that up to 18% of the population believe that they have suffered from a ‘medical error’, 10% of hospital admissions may result in something going wrong and 5% have had adverse effects from medical care. In a survey of Dutch oral surgeons who had had, on average, 21 years of work experience, 40% of respondents confirmed that they had experienced the death of a patient after oral surgery. Most of these patients had died after a dental extraction, the most important causes of death being postoperative spread of an infection, failure to survive cancer treatment, or heart and/or lung failure.

Operations are now associated with far less morbidity and mortality than formerly but there remains room for improvement. Morbidity and mortality in the dental surgery providing local anaesthesia (LA) and conscious sedation (CS) are rare but greater in patients with medical and/or dental problems; for example, extractions attributed to dental infections were significant predictors for risk factors for myocardial infarction compared with tooth extraction for trauma and other reasons in an Oslo study. Deaths as a result of the use of general anaesthesia (GA) in the dental surgery in the past were few but nevertheless provoked widespread public concern, and it is no longer permissible for a dentist in the UK to act as anaesthetist (this had been the case for some time in some other countries). *GA must only be given in a hospital with critical care facilities – because of the need to have resuscitation equipment available – and must be carried out by a qualified anaesthetist.*

If working in hospital, however, dentists may be required to assess patients for GA and to ensure that essential prerequisites are met before GA, and may need to manage GA patients postoperatively. They must therefore have an understanding of risk assessment and perioperative care.

RISK ASSESSMENT

At the start of a patient’s visit, it is essential to:

1. obtain a careful medical, dental, family, social (and sometimes developmental) history, and make a risk assessment

2. assess the patient’s needs and agree them with the patient
3. obtain the patient’s valid consent to any investigations required
4. obtain the patient’s consent to an agreed treatment plan.

Adequate risk assessment is essential and endeavours to anticipate and prevent trouble. The criteria of ‘fitness’ for a procedure are not absolute but depend on a number of factors, as shown in [Box 2.1](#). Dentistry should be very safe, especially if the procedure is not dramatically invasive and the patient is healthy.

Surgical procedures are generally the most hazardous. The World Health Organization (WHO) recognizes this and grades risks on the basis of severity of the procedure ([Table 2.1](#)). WHO also identifies three phases of an operation at each of which, for patient safety, a checklist coordinator must confirm that the surgery team has completed the listed tasks before it proceeds:

- Before anaesthesia induction (‘sign in’)
- Before skin incision (‘time out’)
- Before the patient leaves the operating room (‘sign out’).

Drug use is also potentially dangerous; all agents should be carefully administered, particularly those acting on the neurological system and affecting consciousness and cardiac or respiratory functioning (e.g. sedatives and anaesthetic agents). Most oral care is given under LA and then morbidity is minimal. CS is not as safe as LA, though considerably safer than GA. Even so, CS must be carried out in appropriate facilities, by adequately trained personnel and with due consideration of the possible risks. By contrast, GA with intravenous or inhalational agents is only occasionally required for dental treatment and then only in a hospital setting; control of vital functions is impaired or lost to the anaesthetist. As stated above, GA is only permitted in a hospital with appropriate resuscitation facilities.

A patient attending for dental treatment who is apparently ‘fit’ may actually have serious systemic disease(s) and be taking drugs (including recreational drugs), either or both of which might influence the health care required. Many patients with life-threatening diseases now survive as a result of advances in surgical and medical care, and either or both can significantly affect the dental management or even the fate of the patient. Though this is most likely when treating hospital patients and other risk groups such as older people, one study showed that 30% of dental patients have a relevant medical condition. The risk is greatest when surgery is needed, and when GA or CS are

Box 2.1 Factors influencing outcomes of health-care procedures

- Health of the patient
- Type of procedure
- Duration of the procedure
- Degree of trauma and stress
- Degree of urgency of the procedure
- Skill and experience of the operator
- Skill and experience of the anaesthetist/sedationist
- Facilities and equipment

Table 2.1 WHO grades of surgery

Grade	Termed	Includes
1	Minor	Excision of skin lesion; drainage of breast abscess ^a
2	Intermediate	Primary repair of inguinal hernia; excision of varicose vein(s) of leg; tonsillectomy/adenotonsillectomy; knee arthroscopy
3	Major	Total abdominal hysterectomy; endoscopic resection of prostate; lumbar discectomy; thyroidectomy
4	Major+	Total joint replacement; lung operations; colonic resection; radical neck dissection; neurosurgery; cardiac surgery

^a Includes dentoalveolar surgery.

Table 2.2 Risk assessment and management

Risks increased by	Risks reduced by
Increasing age	Planned treatment
Medical treatments	Non-invasive procedures
Surgical treatments	Monitoring
Lengthy dental procedures	Reassurance
Drug use – medication or recreational	Competent operator

given – and these problems may be compounded if close medical support is lacking.

Although every care must be taken to identify the medically compromised patient, it must be appreciated that the means to do so in conventional dental settings are limited and by no means always successful. It is impossible to legislate for all possibilities and there have been many cases where apparently fit people have died suddenly within a short time of being declared healthy on medical examination.

The main aims are to ensure that procedures are carried out:

- promptly but safely
- on the correct patient and at the correct site
- with minimal complications and the best possible outcome.

However, although risks arise mainly when the procedure is invasive (tissues are disrupted) and/or the patient is not healthy, they may also be a factor if health-care professionals (HCPs) are overambitious in terms of their skill or knowledge. Clinicians should work only within their field of competence. No interventional procedure is entirely free from risk but care can be improved by making an adequate assessment based on history, clinical signs and, where appropriate, investigations, and by minimizing trauma and stress to the patient (Table 2.2).

Assessment of the risks involved must include the health of the patient, which may be evaluated using a risk-stratification scoring system such as the Physical Status Classification of the American Society of Anesthesiologists (ASA) (Table 2.3). ASA I and II patients can generally be treated in general dental practice or community services. ASA III patients are often best treated in a hospital-based clinic where expert medical support is available. ASA IV and V patients are usually hospitalized or bedridden, and generally are only seeking emergency dental treatment.

Dental treatment must be significantly modified if the patient has an ASA score of III or IV, which is true of a relatively high percentage of patients aged 65–74 years (23.9%) and 75 years or over (34.9%). Controversies can arise in relation to the management of patients with

Table 2.3 American Society of Anesthesiologists (ASA) classification

ASA class	Definition
I	Normal, healthy patient
II	A patient with mild systemic disease (e.g. well-controlled diabetes, asthma, hypertension or epilepsy), pregnancy, anxiety
III	A patient with severe systemic disease limiting activity but not incapacitating (e.g. epilepsy with frequent seizures, uncontrolled hypertension, recent myocardial infarct, uncontrolled diabetes, severe asthma, stroke)
IV	A patient with incapacitating disease that is a constant threat to life (e.g. cancer, unstable angina or recent myocardial infarct, arrhythmia or recent cerebrovascular accident)
V	Moribund patient not expected to live more than 24 h with or without treatment

Table 2.4 American Society of Anesthesiologists (ASA) grades II and III

	ASA II	ASA III
Chronic obstructive pulmonary disease (COPD)	Cough or wheeze; well controlled	Breathless on minimal exertion
Angina	Occasional use of glyceryl trinitrate (GTN)	Regular use of GTN or unstable angina
Hypertension	Well controlled on single agent	Poorly controlled; multiple drugs
Asthma	Well controlled with inhalers	Poorly controlled; limiting lifestyle
Diabetes	Well controlled; no complications	Poorly controlled or complications

ASA scores of II and III. Table 2.4 summarizes these scores for some of the more common disorders.

The Prognosis and Assessment of Risk Scale (PARS) is another assessment tool, which is virtually identical to the ASA scale but can be modified by factors such as those shown in Table 2.5; it categorizes patients into groups I–V. Other factors considered in PARS are shown in Table 2.6. The Karnofsky scale, which has been adapted for use in many areas including hospices, cancer clinics and so on, is a quick and easy way to indicate how a patient is feeling on a given day, without going through several multiple choice questions or symptom surveys (Table 2.7). The Medical Complexity classification is another available tool (Table 2.8).

Good communication is essential with both patient and other health professionals. Often, dental treatment in medically compromised patients may have to be delayed until expert advice has been sought and this is always the case for patients undergoing procedures under GA, who must be pre-assessed by the anaesthetist.

INFORMED CONSENT (OTHERWISE KNOWN AS VALID CONSENT)

The patient's autonomy must be respected at all times. Patients can determine what investigations and treatment they are or are not willing to receive. Before they are asked to make a decision, they must be given sufficient information about their condition, suggested treatment(s) (including alternative management if available), any associated risks involved in the proposed treatment, and possible outcomes if nothing is done. They have the right to refuse treatment, even if this could

Table 2.5 Dental care modifications and the American Society of Anesthesiologists (ASA) scale and Prognosis and Assessment of Risk Scale (PARS)

ASA	Definition	PARS	Dental care modifications
I	Normal, healthy patient	I	None
II	A patient with mild systemic disease (e.g. well-controlled diabetes, asthma, hypertension or epilepsy), pregnancy, anxiety	II	Dental care should focus on elimination of acute infection before medical/surgical procedure (e.g. prosthetic cardiac valve)
III	A patient with severe systemic disease limiting activity but not incapacitating (e.g. epilepsy with frequent seizures, uncontrolled hypertension, recent myocardial infarct, uncontrolled diabetes, severe asthma, stroke)	III	Dental care should focus on elimination of acute infection and chronic disease before medical/surgical procedure (e.g. organ transplant patients)
IV	A patient with incapacitating disease that is a constant threat to life (e.g. cancer, unstable angina or recent myocardial infarct, arrhythmia or recent cerebrovascular accident)	IV	All potential dental problems should be corrected before medical/surgical procedure (e.g. prior to radiotherapy to head and neck)
V	Moribund patient not expected to live more than 24h with or without treatment	V	Control of acute dental pain and infection only

Table 2.6 Prognosis and Assessment Risk Scale

Factor	Comment
Medical status	Any complicating medical factors
Physical status	
Oral hygiene	
Psychological needs	
Functional ability	
Mental status	Level of understanding
Social environment	Support or significant events planned shortly after treatment
Family environment	
Access issues	Access to dental building, etc.
Financial issues	
Communication needs	Is an interpreter required?
Behaviour	Is behaviour management needed?
Consent	Is patient competent to give consent?

adversely affect the outcome or result in their death. Depending on the situation, time should be allowed for the patient to think about and discuss the proposed treatment with people close to them. Consent is the expressed or implied agreement of the patient to undergo an examination, investigation or treatment. Consent is not an isolated event, but involves a continuing dialogue between clinician and patient (and occasionally their relatives or partner). In order to give informed (valid) consent, the individual concerned must have adequate reasoning faculties and be in possession of all relevant facts at the time consent is given. *Patients who undergo procedures performed without their valid consent may be entitled to claim damages in the civil courts by making a*

Table 2.7 Karnofsky scale

Score	Definition
100	Able to work. Normal, no complaints, no evidence of disease
90	Able to work. Able to carry out normal activity, minor symptoms
80	Able to work. Normal activity with effort, some symptoms
70	Independent, not able to work. Cares for self, unable to carry out normal activity
60	Disabled, dependent. Requires occasional assistance, cares for most needs
50	Moderately disabled, dependent. Requires considerable assistance and frequent care
40	Severely disabled, dependent. Requires special care and assistance
30	Severely disabled. Hospitalized, death not imminent
20	Very sick. Active supportive treatment needed
10	Moribund. Fatal processes are rapidly progressing

Table 2.8 Medical Complexity classification

Class	Medical condition	Status	Complications
MC-0	No significant medical problems	MC-0	No complications anticipated
MC-1	Controlled and stable condition/disease	MC-1A	No complications anticipated
		MC-1B	Minor complications anticipated
		MC-1C	Major complications anticipated
MC-2	Poorly controlled and/or unstable condition/disease	MC-2A	No complications anticipated
		MC-2B	Minor complications anticipated
		MC-2C	Major complications anticipated
MC-3	Cardiac or other conditions needing continuous monitoring		

claim of negligence. The clinician is also vulnerable in the criminal courts to a charge of assault and battery following a complaint to the police by the person who received the treatment.

Information about what the proposed investigations or treatment will involve, the benefits and risks (including adverse effects and complications), and the alternatives available is crucial for patients when they are making up their minds. The courts have stated that patients should be told about 'significant risks which would affect the judgment of a reasonable patient'.

'Significant' has not been legally defined but the General Medical Council (GMC) requires doctors to tell patients about 'serious or frequently occurring' risks. In addition, if patients make it clear that they have particular concerns about certain kinds of risk, the clinician must ensure that they are informed about these risks, even if they are very small or rare. Sometimes, patients may make it clear that they do not want any information about the options, but want the health professional to decide on their behalf. In such circumstances, ensure that the patient receives at least some very basic information about what is proposed. Where information is refused, this should be documented in the patient's notes and/or on a consent form. The important thing is for the clinician to record sufficient details of the consent process in order to be able to reconstruct the discussions and the thinking that led to a particular course of treatment in the event of a challenge at a later stage – possibly years later.

The patient's open agreement to proceed with the investigation or treatment proposed after full discussion and the patient's receipt of sufficient information is sometimes called 'informed consent'.

When obtaining consent, patients should be informed of:

- details of the diagnosis and prognosis with and without treatment
- uncertainties about the diagnosis
- options available for treatment
- the purpose of all aspects of a proposed investigation or treatment
- the likely benefits and probability of success
- any possible adverse effects and the risks of the procedure proposed
- the likelihood of one or more of the risks coming to pass
- likely outcomes if a procedure is not carried out
- the need for drains, catheters, tracheostomy, etc.
- their right to change their mind at any stage
- their right to a second opinion.

Other issues that should be discussed at this stage include:

- time of appointment or admission
- eating/starving instructions
- management of usual daily medications
- specific preoperative preparation that may be required
- transport to where the procedure will be performed
- specific anaesthetic issues
- anticipated duration of procedure
- likely recovery period
- likely discharge date
- specific postoperative care
- follow-up requirements
- anticipated date of return to full activity.

'Informed' consent means that the patient must be fully aware of the procedure, its intended benefits and its possible risks, and the level of these benefits and risks. In particular, patients must be warned about:

- preoperative preparation
- possible adverse effects
- postoperative sequelae (e.g. pain)
- where they will be during their recovery
- the possibility of intravenous infusions, catheters, nasogastric tubes, any deformity, swelling, bruising, pain, etc.

All questions should be answered honestly. Information should not be withheld that might influence the decision-making process. Patients should never be coerced. Finally, for consent to be valid, the person who obtains it must have sufficient knowledge of the proposed treatment and its risks, and should be the person who is undertaking the procedure.

At any time, the information on the form can be augmented by an additional record made in the patient's notes covering conversations, discussions or warnings.

Consent may be:

- implied (a patient lying in the dental chair with an open mouth is consenting to a dental examination).
- expressed in writing.

Although rarely a legal requirement (but frequently a contractual obligation), it is good practice to seek written consent on most occasions and this is essential where the treatment is complex or involves

significant risks or adverse effects. Written consent must always be obtained from all patients having an operation. The possible benefits of the treatment must be weighed against the risks and always discussed by the person carrying out the procedure; if, for some reason, this is not possible, it must be done by a delegated person with the appropriate expertise to do so (i.e. a person who is competent to carry out the proposed surgery themselves as an independent practitioner in their own right). Written consent is also essential when provision of clinical care is not the primary purpose, the treatment is part of a project or research, or there are significant consequences for personal or social life. Your organization may have a policy setting out when you need to obtain written consent. A signature on a consent form does not itself prove the consent is valid; the point of the form is to record the patient's decision and also, increasingly, the content of the discussions that have taken place. A signed consent form is not a legal waiver; if, for example, patients do not receive enough information on which to base their decision, then the consent may not be valid, even though the form has been signed. A signed consent form will not protect the clinician if there is doubt as to whether consent was actually 'informed'. Ideally, the form should be designed to serve as an *aide-mémoire* to health professionals and patients, by providing a checklist of the kind of information patients should be offered, and by enabling the patient to have a written record of the main points discussed. However, the written information provided for the patient in no way should be regarded as a substitute for face-to-face discussions with the individual. Patients are also entitled to change their mind after signing the consent form, if they retain capacity to do so.

Although the law in relation to consent continues to evolve (as does most legislation) and there are significant variations between countries, the principles are as follows:

- Before examining, treating or caring for competent adults, consent must be obtained.
- Adults are assumed to be competent unless demonstrated otherwise.
- Patients may be competent to make some health-care decisions, even if they are not competent to make others.
- Giving and obtaining consent is usually a process, not a one-off event. *Patients can change their minds and withdraw consent at any time.*

For consent to be valid, patients must receive sufficient information about their condition and proposed treatment. It is the HCP's responsibility to explain all the relevant facts to the patient and to ascertain that they are understood. If there are doubts about their competence, the question to ask is: 'Can this patient understand, retain and then weigh up the information needed to make this decision?' If patients are not offered as much information as they reasonably need to make their decision, and in a form they can understand, their consent may not be valid. For example, information for those with visual impairment should be provided in the form of audio tapes, Braille or large print.

Patients whose first language is not English may need the help of an interpreter. Most organizations have access to experienced interpreters. It is preferable to rely on a neutral interpreter (i.e. *not* a family member) when examining and seeking consent from a patient for surgery or treatment.

Ensure the patient, staff and, where appropriate and in accordance with the patient's wishes, the patient's relatives and/or partner are kept fully informed. Maintain good, clear, contemporaneous records of the nature of all discussions that take place, including the names of those involved. Good communication and documentation can prevent future dispute and litigation. If there is any reason to believe

that consent may be disputed later, or if there are concerns about an individual's attitude or behaviour, meticulous documentation in the case notes is essential. The UK Department of Health's *Reference guide to consent for examination or treatment* (available at www.gov.uk/government/publications; accessed 30 September 2013) offers a comprehensive summary of the law on consent.

SPECIFIC CONSENT ISSUES

- No one else can make a decision on behalf of a competent adult.
- In an emergency, a life-saving procedure can be performed without consent.
- All actions must, however, be justifiable to one's peers.
- No one can give or withhold consent on behalf of a mentally incapacitated patient; decisions lie primarily with the clinicians, who should act in the patient's best interest. Where there is doubt, ultimately a court will decide on the best course of action, having taken expert advice. The Mental Capacity Act 2005 provides guidance for HCPs in England and Wales (see also The Adults with Incapacity (Scotland) Act 2000) who treat this group of patients. Guidance has been published by the UK Department of Health (Mental Capacity Act 2005 Code of Practice) and is available at <http://www.dca.gov.uk/legal-policy/mental-capacity/mca-cp.pdf> (accessed 30 September 2013).

Essentially, everyone aged 16 or more is presumed to be competent to give consent for themselves, unless the opposite is demonstrated.

Competent adults – namely, persons aged 16 and over who have the capacity to make their own decisions about treatment – can consent to dental treatment and they are also entitled to refuse treatment, even where it would clearly benefit their health. If a patient is mentally competent to give consent but is physically unable to sign a form, you should complete this form as usual and ask an independent witness to confirm that the patient has given consent orally or non-verbally.

If the patient is 18 or over and is not legally competent to give consent, you should use a form for adults who are unable to consent to investigation or treatment. Patients will not be legally competent to give consent if:

- they are unable to comprehend and retain information material to the decision; and/or
- they are unable to weigh and use this information in coming to a decision.

You should always take all reasonable steps (e.g. involving more specialist colleagues) to support patients in making their own decision before concluding that they are unable to do so.

Relatives *cannot* be asked to sign this form on behalf of an adult who is not legally competent to consent for him or herself, unless the patient has appointed a friend or relative to act for them, creating a lasting power of attorney (LPA). This LPA must have been created when the patient was competent and the LPA must be lodged with the Court of Protection. An LPA may allow the relative or friend to take decisions about the health of the patient, should the patient be found to be lacking capacity.

Children under the age of 16 years may also have capacity to consent if they have the ability to understand the nature, purpose and possible consequences of the proposed investigation or treatment, as well as the consequences of non-treatment. Children below 16 who have *Gillick* competence (i.e. they understand fully what is involved in the

proposed procedure) may therefore consent to treatment without their parents' authority or knowledge, although their parents will ideally be involved. 'Gillick competence' is a term used in medical law to decide whether a child (16 years or younger) is able to consent to medical treatment, without the need for parental permission or knowledge:

As a matter of Law the parental right to determine whether or not their minor child below the age of sixteen will have medical treatment terminates if and when the child achieves sufficient understanding and intelligence to understand fully what is proposed.

The standard is based on a House of Lords' decision in the case *Gillick v West Norfolk and Wisbech Area Health Authority* [1985] 3 All ER 402 (HL). The case is binding in England, and has been approved in Australia, Canada and New Zealand. Similar provision is made in Scotland by the Age of Legal Capacity (Scotland) Act 1991. In Northern Ireland, although separate legislation applies, the then Department of Health and Social Services Northern Ireland stated that there was no reason to suppose that the House of Lords' decision would not be followed by the Northern Ireland Courts.

Where a child under 16 years old is not deemed competent to consent, a person with parental responsibility (e.g. their legal parent or guardian, or a person appointed by the courts) has authority to consent for investigations or treatment that are in the child's best interests.

There are several legal tests that have been described in relation to consent. The *Bolam* test states that a doctor who:

acted in accordance with a practice accepted as proper by a responsible body of medical men skilled in that particular art is not negligent if he is acting in accordance with such a practice, merely because there is a body of opinion which takes a contrary view.

However, a judge may, on certain rare occasions, choose between two bodies of expert medical opinion, if one is to be regarded as 'logically indefensible' (*Bolitho* principle). The main alternative to the *Bolam* test is the '*prudent-patient test*' widely used in North America. According to this test, doctors should provide the amount of information that a 'prudent patient' would want.

Obtaining consent from adult patients without capacity

The more elective the procedure, the more care should be taken in ensuring that the patient, parent, guardian or carer has been consulted. In true emergency situations, a dentist may rely on the best-intent principle in relation to the overall well-being of the patient, although, where there is any doubt, advice should be taken. Involve the patient as far as possible; some incapacitated patients may be quite capable of giving partial consent. Decide who else should be involved in any decision to proceed with the patient's treatment. The current position (in the UK) is that no adult can consent to the treatment of another adult (with the exception of cases that fall under the Mental Capacity Act 2005). Before anyone can give valid consent to treatment, she or he must possess the requisite capacity. The law presumes that, in the absence of evidence to the contrary, patients over the age of 16 years are capable of giving (or withholding) consent to treatment. The broad test of capacity is that the person concerned should be able

to understand the nature and purpose of the treatment and must be able to weigh the risks and benefits. They should be able to retain and weigh this information, as well as communicate their decision.

Where there is doubt, a decision has to be made as to the capacity of the patient. This presents a problem for dentists providing care for patients with learning impairment. Where the patient lacks the capacity to consent, then the dentist would normally act in the patient's best interests and treatment should not be withheld simply because consent has not been obtained, or a charge of failure in duty of care could be made. If a person is incapable of giving or refusing consent, and has not validly refused such care in advance, treatment may still be given lawfully if it is deemed to be in the patient's best interests. However, this should happen only after full consideration of its potential benefits and unwanted effects, and in consultation with the carer(s), relatives and other people close to the patient. Where treatment involves taking irreversible decisions or carrying greater risks, then the agreement of another dentist or doctor is appropriate. For those with learning difficulties, it is important to have a discussion with the parent, carer or, in their absence, two professionals who should sign their approval in the best interests of the patient. The discussions and agreement should be documented in the patient's record and, whilst this does not constitute consent, it represents good practice.

The Mental Health Act 1983 is primarily concerned with the care and treatment of people who are diagnosed as having a mental health problem which requires that they be detained or treated in the interests of their own health and safety or with a view to protecting other people.

The Mental Capacity Act 2005 applies to everyone involved in the care, treatment or support of people aged 16 years and over in England and Wales who lack capacity to make all or some decisions for themselves. This Act also applies to situations where a person may lack capacity to make a decision at a particular time due to illness, drugs or alcohol. Assessments of capacity should be time- and decision-specific. The Act clarifies the terms 'mental capacity' and 'lack of mental capacity', and says that a person is unable to make a particular decision if they cannot do one or more of the following:

- Understand information given to them
- Retain that information long enough to be able to make the decision
- Weigh up the information available to make the decision
- Communicate their decision; this could be done, for example, by talking, using sign language, or even making simple muscle movements such as blinking an eye or squeezing a hand.

A new criminal offence of ill-treatment or wilful neglect of people who lack capacity also came into force in 2007. Within the law, 'helping with personal hygiene' (that would include tooth-brushing) attracts protection from liability, as long as the individual has complied with the Act by assessing a person's capacity and acting in their best interests. 'Best-interest' decisions made on behalf of people who lack capacity should be the least restrictive of their basic rights and freedoms.

Further changes within the Act include the introduction of LPAs that extend to health and welfare decisions. When a health professional has a significant concern relating to decisions taken under the authority of an LPA that relate to serious medical treatment, the case can be referred for adjudication to the *Court of Protection*, which is ultimately responsible for the proper functioning of the legislation. The Act also created a new *Public Guardian* with responsibility for the registration and supervision of both LPAs and court-appointed deputies. Furthermore, *Independent Mental Capacity Advocates* (IMCAs) have been introduced to support particularly vulnerable incapacitated adults – most often those who lack any other forms of external support – in making certain decisions.

In Scotland, the position is complicated by the fact that the dentist has to comply with the Adults with Incapacity Act 2000. This requires the patient's doctor to issue a certificate before treatment. The document is procedure-specific and a new one is required for each treatment plan or in the event of a change to the plan. Episodes requiring GA or sedation not included in the original treatment plan will need further certification. The interesting nuance is that the dentist can assess capacity but it is the doctor who has to assess incapacity. This has created significant practical difficulties for many health-care providers.

Obtaining consent for child patients

Changing social patterns have meant that the position relating to who is able to consent to treatment for a child is no longer the same. Parental responsibility lies with the natural mother, natural father (if married to the mother at birth), adoptive parents or those who have temporary residence orders (where the child lives with them). The local authority may acquire responsibility. The natural father not married to the natural mother does *not* have parental responsibility. Parental responsibility can be granted by court order, by agreement with the mother or on her death, if stated in her will. Step-parents can be granted parental responsibility by court order.

It is important to remember that the legal situation with regard to consent varies around the world and is subject to continued debate and development.

THE USE OF RESTRAINT

Occasionally, patients may need some assistance in order to be able to undergo or cooperate with investigations or treatment. The dividing line between assistance and trespass to the person can be fine. Three forms of trespass to the person exist:

- Assault – the fear or threat of impending harm
- Battery – the unlawful application of force or unwanted touching
- False imprisonment – the infliction of restraint.

These issues must be considered carefully when the patient lacks the necessary capacity to understand the procedure being carried out. Any physical intervention is subject to the rule of 'reasonableness'. Sometimes it is necessary to control movements during operative procedures or to support an arm, for example, for the injection of intravenous drugs in order to prevent patients injuring themselves. It is wise to seek the assistance of a carer or relative at such times and to ensure that this is documented. Learning disabilities teams may be able to assist and are likely to have developed protocols and procedures to deal with such problems.

MEDICAL HISTORY

The history (or anamnesis) is the information gained by an HCP with the aim of formulating a diagnosis, providing medical care and identifying medical problems relevant to health care. The history is obtained from either the patient or people who know the patient and can provide the necessary information. History-taking also allows the HCP to develop rapport with the patient, place the diagnosis in the context of the patient's life, identify relevant physical signs, and assess mental state and attitude towards health care. Age and cultural factors may also be important (Appendices 2.1 and 2.2). Due cognisance must be taken of a person's "protected characteristics", of which there are nine (Table 2.9).

Table 2.9 Protected characteristics

Age	Where this is referred to, it refers to a person belonging to a particular age (e.g. 32 year olds) or range of ages (e.g. 18–30 year olds).
Disability	A person has a disability if s/he has a physical or mental impairment which has a substantial and long-term adverse effect on that person's ability to carry out normal day-to-day activities.
Gender reassignment	The process of transitioning from one gender to another.
Marriage and civil partnership	Marriage is defined as a 'union between a man and a woman'. Same-sex couples can have their relationships legally recognised as 'civil partnerships'. Civil partners must be treated the same as married couples on a wide range of legal matters.
Pregnancy and maternity	Pregnancy is the condition of being pregnant or expecting a baby. Maternity refers to the period after the birth, and is linked to maternity leave in the employment context. In the non-work context, protection against maternity discrimination is for 26 weeks after giving birth, and this includes treating a woman unfavourably because she is breastfeeding.
Race	Refers to the protected characteristic of Race. It refers to a group of people defined by their race, colour, and nationality (including citizenship), ethnic or national origins.
Religion and belief	Religion has the meaning usually given to it but belief includes religious and philosophical beliefs including lack of belief (e.g. Atheism). Generally, a belief should affect your life choices or the way you live for it to be included in the definition.
Sex	A man or a woman.
Sexual orientation	Whether a person's sexual attraction is towards their own sex, the opposite sex or to both sexes. http://www.equalityhumanrights.com/advice-and-guidance/new-equality-act-guidance/protected-characteristics-definitions/

It may occasionally be helpful to carry out a formal assessment of the patient's feelings about health care, and tools such as the Corah anxiety scale are available for this (Box 2.2; Ch. 10).

When taking a history, a structured guide such as that shown in Box 2.3 should be followed. Patients should also be given a form on which to supply all the information they can about their health and any medication they are receiving. Medical and drug history should be regularly updated at subsequent dental visits. *Remember that all such information is confidential.*

PERSONAL DETAILS

The patient's personal details include age, sex, educational status, religion or faith, occupation, relationship status, address and contact details. This information is necessary for administrative purposes and, since the questions are largely non-threatening, this stage provides a gentle introduction into the meeting of patient and clinician, in a format that can be individualized to suit a particular culture.

PRESENTING COMPLAINT

This should be recorded in the patient's own words (e.g. 'pain in my face').

HISTORY OF PRESENTING COMPLAINT

The timing of the complaint and its evolution should be elicited. If the patient has pain, a useful mnemonic is 'SOCRATES': S – site,

Box 2.2 Corah dental anxiety scale

If you had to go to the dentist tomorrow, how would you feel about it?

- I would look forward to it as a reasonably enjoyable experience
- I wouldn't care one way or the other
- I would be a little uneasy about it
- I would be afraid that it would be unpleasant and painful
- I would be so anxious that I might break out in a sweat or almost feel physically sick

When you are waiting in the dental surgery for your turn in the chair, how do you feel?

- Relaxed
- A little uneasy
- Tense
- Anxious
- So anxious that I sometimes break out in a sweat or almost feel physically sick

When you are in the dentist's chair waiting while the drill is prepared to begin work on your teeth, how do you feel?

- Relaxed
- A little uneasy
- Tense
- Anxious
- So anxious that I sometimes break out in a sweat or almost feel physically sick

You are in the dentist's chair to have your teeth cleaned. While you are waiting and the dentist is getting out the instruments for scraping your teeth around the gums, how do you feel?

- Relaxed
- A little uneasy
- Tense
- Anxious
- So anxious that I sometimes break out in a sweat or almost feel physically sick

Box 2.3 Essentials of history-taking

- Personal details
- Presenting complaint (PC)
- History of presenting complaint (HPC)
- Relevant medical history (RMH)
- Drug history
- Social history
- Family history

O – onset (gradual/sudden), C – character, R – radiation, A – associations (other symptoms), T – timing/duration, E – exacerbating and alleviating factors, S – severity (pain rated on a visual analogue scale of 1 [minimal] to 10 [unbearable]).

RELEVANT MEDICAL HISTORY

This includes any past medical and surgical problems. Patients should be asked if they carry a medical warning card or device and careful note should be taken of it, particularly in respect of allergies, a bleeding disorder, cardiac disease or diabetes (see, for example, Medic-Alert and Talisman; Figs 2.1–2.3). Patients increasingly wear wristbands and bracelets that show the major medical issues they face. These may be seen clearly in writing; available electronically with bar codes or QR codes; supplied on a USB stick; or provided on a chip that is available for electronic scanning with a sensor (Fig. 2.4).

Fig. 2.1 Medic-Alert bracelet. The patient's main diagnosis or drug treatment is engraved on the reverse, together with the telephone number of the company that holds details of the medical history.

Fig. 2.2 Diabetes alert necklace.

Fig. 2.3 Talisman warning emblem.

Fig. 2.4 Electronic reading of medical data. (Courtesy of Google).

Box 2.4 Review of systems (see Table 2.10)

- Allergies
- Bleeding disorders
- Cardiorespiratory disorders
- Drug treatment
- Endocrine disorders
- Fits or faints
- Gastrointestinal disorders
- Hospital admissions and attendances
- Infections
- Jaundice and liver disease
- Kidney and genitourinary disorders
- Likelihood of pregnancy
- Mental state
- Neurological problems

The completion of a medical history form provides a useful basis for the dental professional to enquire further, and the following chapters describe in more detail the nature and relevance of any diseases that are mentioned. The completion of such a form and appropriate response to its contents also constitute useful evidence when the clinician is faced with any medico-legal claims. The medical history is crucial but has limitations, not least because patients may be confused or ill informed. *The history may also change radically with time, so it is essential for it to be updated before each new course of treatment and every sedation session, and especially before surgery or GA.* For example, patients not pregnant at one course of treatment could well be by the next. One study followed a small group of middle-aged and older dental patients, and found that nearly 20% developed significant medical disorders (mostly cardiovascular) over a period of 5 years.

Functional enquiry or review of systems (ROS) helps disclose undeclared medical problems. Patients should be asked specifically about their conditions; Box 2.4 offers an alphabetical list that is easy to recall.

The relevance of the main points from the history is shown in Table 2.10. It may also be necessary to enquire about constitutional symptoms (e.g. fever, weight loss, night sweats, fatigue/malaise/lethargy, sleeping pattern, appetite, fever), musculoskeletal conditions (pain, stiffness, swelling of the joints), and rash, blistering or lumps (Figs 2.5–2.8).

DRUG (MEDICATION) HISTORY

Enquire whether the patient has any allergies, and ask for a description of any reactions that have occurred.

Often, a medical problem is revealed only after a drug history has been elicited, but some patients may be unaware of the name of, or reason for taking, their medication. Multiple drug use is common in older people with complex medical histories (Figs 2.9–2.11). Sometimes, the nature of the drug used may be suggested by the name (Table 2.11). Ask the patient if they are taking any prescription-only medication (POM; this may be tablets, injections, patches or inhalers) and also any over-the-counter (OTC) medications, including herbal preparations. Some of these can influence health care.

SOCIAL HISTORY

Enquire tactfully about occupation, marital status, partner's job and health, housing, dependants, mobility, lifestyle habits (alcohol,

Table 2.10 *Relevance of medical history to dentistry*

Condition	Main features	Other comments	Relevance in dentistry
Allergies	Range from urticaria to anaphylaxis	Rashes? Racial origins may be important, especially in the case of drug reactions. Carbamazepine-induced Stevens–Johnson syndrome is strongly associated with HLA-B1502 in Han Chinese, Hong Kong Chinese, Thais and Indians, and HLA-A3101 in Northern Europeans	Common allergies relate to latex, iodine, Elastoplast® and drugs (hence acronym ‘LIED’). Anaesthetics, analgesics (e.g. aspirin or codeine) and antibiotics (e.g. penicillin) are main offending drugs
Bleeding disorders	Bleeding and/or bruising	Haematological/lymphatic: lymph node swelling? Bleeding or bruising? History of involvement of other family members or of admission to hospital for control of bleeding is particularly important	Significant hazard to surgery
Cardiorespiratory disorders	Wheezing, cough, dyspnoea, chest pain, swelling of ankles, palpitations, hypertension	Chest pain? Shortness of breath? Exercise tolerance? Orthopnoea? Oedema? Palpitations? Cough? Sputum? Wheeze? Haemoptysis? Patient’s ability to climb 15–20 stairs without pain, dyspnoea or tiredness may indicate degree of fitness of cardiorespiratory system	Often a contraindication to GA or CS
Drug treatment	Obtaining useful answers about drug treatment, including over-the-counter medications, will necessitate asking: ‘Do you ever have any injections or take drugs, pills, tablets, medicines or herbal preparations of <i>any</i> kind?’	Drug use may be only indication of serious underlying disease. Corticosteroids, antihypertensives, anticonvulsants, anticoagulants, antibiotics, insulin and oral hypoglycaemics are all important in this respect	Most serious drug interactions are with GA agents (intravenous or inhalational), monoamine oxidase inhibitors and antihypertensive drugs. Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) may be a hazard in anticoagulated, asthmatic, diabetic or pregnant patients, those with peptic ulcer, or children under 16 y. If patient does not know name of medicines, defer treatment until drug is identified by patient’s doctor, Drugs Information Unit or pharmacy, or by checking <i>Monthly Index of Medical Specialties</i> (MIMS), <i>Physicians’ Desk Reference</i> (PDR) or <i>British National Formulary</i> (BNF)
Endocrine disorders	Diabetes mellitus may lead to collapse	Diabetes: irritability, aggression, lassitude, anorexia, weight loss Hyperthyroidism: heat intolerance, emotional lability, sweating, diarrhoea, oligomenorrhoea, weight loss despite increased appetite, tremor, palpitations, visual disturbances Hypothyroidism: dislike of cold weather, lethargy, tiredness, depression, dry skin and hair, hoarseness, menorrhagia, constipation Hyperadrenocorticism: weight gain and redistribution, moon face, hirsutism, skin striae, purpura Hypoadrenalism: weakness, weight loss, hypotension, pigmentation	Hypoglycaemia is main problem
Fits or faints	History of fits or faints	Type? Frequency? Precipitating factors? Awareness may allow preventive measures to be instituted	Fainting, epilepsy and other causes of loss of consciousness can disrupt dental treatment and may result in injury to patient
Gastrointestinal disorders	Abdominal pain, frequency and type of stool, bleeding and weight loss	Difficulty swallowing? Indigestion? Nausea/vomiting/haematemesis? Bowel habit? Faecal colour, consistency, blood (or melaena), smell, difficulty flushing away, tenesmus (feeling of incomplete evacuation) or urgency?	Crohn disease or coeliac disease may lead to oral complications, and gastric disorders may increase risk of vomiting during GA
Hospital admissions and attendances	Hospital admissions may also indicate underlying disease, and past operations may suggest possibility of future complications that can influence dental treatment		A history of operations may provide knowledge of possible reactions to GA and surgery. A patient who has had a tonsillectomy, for example, without complications is most unlikely to have a congenital bleeding disorder. Retinal operations, since they may use intraocular gases, may be a contraindication to GA or relative analgesia, which may cause rapid expansion of ocular gas and lead to blindness

(Continued)

Table 2.10 (Continued)			
Condition	Main features	Other comments	Relevance in dentistry
Infections	Various, possibly rashes and/or fever	Ever attended a clinic for sexually shared infections (SSIs), or been admitted to hospital for an infection, or been accepted or refused for blood donation? Men who have sex with men, abusers of intravenous drugs and patients who have attended SSI clinics are more likely to have a history of infection with human immunodeficiency virus (HIV), hepatitis viruses, herpes simplex, syphilis, gonorrhoea and many other infections (Ch. 21)	The possibility of transmission of infections and their sequelae must be considered. Carriers of meticillin-resistant <i>Staphylococcus aureus</i> (MRSA) may be a hazard to others; carriers of <i>Neisseria meningitidis</i> may be sources of meningitis outbreaks
Jaundice and liver disorders	A history of jaundice may imply carriage of hepatitis viruses, although jaundice is a clinical sign of other underlying liver diseases		Liver disease can lead to prolonged bleeding and impaired drug metabolism can result (Ch. 9). Jaundice after an operation may have resulted from halothane hepatitis and, if this is suspected, a different general anaesthetic, such as isoflurane, desflurane or sevoflurane, should be given
Kidney and genitourinary disorders	Manifestations of chronic kidney disease may include hypertension, pallor and bruising	Incontinence (stress or urge), dysuria (pain), haematuria, nocturia, frequency, polyuria, hesitancy, terminal dribbling? Vaginal discharge?	Can affect dental management, as excretion of some drugs is impaired. Tetracyclines should be given in lower doses. Complications of renal failure or transplants can produce oral signs
Likelihood of pregnancy		Menses (periods) – frequency, regularity, heaviness, duration, painfulness? First day of last menstrual period (LMP)? Number of pregnancies and births? Menarche? Menopause? Any chance of pregnancy now? Which trimester?	Any essential procedures involving drugs (even aspirin), radiography or GA should be arranged during middle trimester
Mental state	Behavioural changes	Appearance and behaviour; thought (speech) form, rate, quantity, pattern, flight of ideas, loosening of associations; mood (subjective); affect (observed); thought content, preoccupations, obsessions, overvalued ideas, ideas of reference, delusions; suicidality; abnormal experiences, hallucinations, passivity, thought interference; cognition; consciousness; attention/concentration; memory; orientation; intelligence; executive function; insight. It may sometimes be useful to assess degree of patients' anxiety in a relatively objective way by using Corah dental anxiety scale (see Box 2.2)	Anxiety is inexorably associated with attending for dental treatment. Anxious patients may sometimes react aggressively and anxiety may limit extent of dental treatment that can be provided under LA
Neurological problems		Special senses – any changes in sight, smell, hearing and/or taste? Seizures, faints, fits, funny turns? Headache? Pins and needles (paraesthesiae) or numbness? Limb weakness, poor balance? Speech problems? Sphincter disturbance?	Movement disorders can significantly disrupt operative procedures. Access can be a barrier to care

tobacco, betel, etc., and recreational drugs), culture and faith. Any social or religious engagements that are dependent on the patient being unimpeded following an elective treatment (wedding, examination, job interview) need discussion and possibly the treatment should be rescheduled; see also Chapters 25, 28 and 30.

FAMILY HISTORY

The medical history of blood relatives may be very informative.

Fig. 2.10 Manual organizer for multi-drug therapy.

Fig. 2.11 Digital organizer for multi-drug therapy. (Courtesy of Google).

CLINICAL EXAMINATION

It is important for dental professionals not merely to inspect and examine the mouth and neck, but also to inspect the exposed areas of the patient (the face, neck, arms and hands). The patient's appearance, behaviour, speech and body language can reveal many significant conditions (Fig. 2.12). However, it must be stressed that even very ill patients can look remarkably well. A search should be made for such readily visible signs as anxiety, movements, tremors, dyspnoea, wheezing and tiredness, and also for changes in the face (e.g. expression, pallor, cyanosis or jaundice), neck (e.g. lumps) or hands (e.g. finger clubbing, Raynaud phenomenon, rashes).

Facial movement and sensation should be assessed in the course of testing the cranial nerves (Ch. 13). Eyes and ears should be observed and examined (Fig. 2.13). Maxillary, mandibular or zygomatic deformities or swellings may be more reliably confirmed by inspection from above (maxillae, zygomas) or behind (mandible). The degree and direction of opening of the mandible should be assessed; this can be disturbed in temporomandibular joint (TMJ) disease and

Table 2.11 Drug names and possible identification

Drugs ending in ...	Possible type of drug ^a
-am	Benzodiazepines
-ase	Fibrinolytics
-apine	Antipsychotics
-asone/one	Corticosteroids
-azine	Antipsychotics
-azole	Azole antifungals
-azosin	α -adrenoreceptor blockers
-cillin	Penicillins
-cin	Some antimicrobials
-coxib	Newer non-steroidal anti-inflammatory drugs (NSAIDs)
-cycline	Tetracyclines
-dopa	Antiparkinsonian agents
-dronate/dronic	Bisphosphonates
-erol	β_2 agonists (used for asthma)
-fibrate	Fibrates
-gatran	Newer oral anticoagulants (NOACs)
-imab/umab	Monoclonal antibodies (MoAbs)
-ipine	Calcium-channel blockers
-lukast	Leukotriene-receptor antagonists
-navir	Protease inhibitors (PIs)
-nitrate	Nitrates
-olol	Beta-blockers
-ovir	Antivirals
-parin	Heparins
-prazole	Proton-pump inhibitors (PPIs)
-pril	Angiotensin-converting enzyme inhibitors (ACEIs)
-relin	Gonadorelin analogues
-salazine	Salicylate derivatives
-sartan	Angiotensin-receptor antagonist
-setron	5HT ₃ antagonists
-statin	Statins
-terol	β_2 -adrenergic agonist
-tidine	H ₂ -receptor antagonists
-triptan	5HT ₁ agonists
-tropium	Antimuscarinic bronchodilators
-vudine	Nucleoside reverse transcriptase inhibitors (NRTIs)

^aAlways check in *British National Formulary* (BNF).**Fig. 2.12** Café-au-lait patch indicative of neurofibromatosis.**Fig. 2.13** Gouty tophi.**Fig. 2.14** Salivary gland swelling.

other conditions causing restricted mouth-opening (trismus) discussed in Chapter 4.

Inspection of the major salivary glands may reveal swelling of the parotid gland, which causes outward deflection of the lower part of the ear lobe, best observed by looking at the patient from behind (Fig. 2.14).

Examination of the neck is crucial. The patient should be observed from the front but also the neck should be palpated, as swollen lymph nodes are sometimes a sign of disease (Fig. 2.15). One-third of the body's lymph nodes are in the neck.

Hands can show a number of features. Deformities can be seen in arthritis (Fig. 2.16). Palmar erythema may occur in liver disease and rheumatoid arthritis. Finger-clubbing may be congenital or is seen in cardiorespiratory disease and liver cirrhosis. Koilonychia (spoon-shaped nails) is seen in iron deficiency; leukonychia (white nails) in liver cirrhosis; nail defects in lichen planus (Fig. 2.17), chronic candidosis and psoriasis; nail haemorrhages in infective endocarditis; and pigmentation in drug use (e.g. zidovudine; Fig. 2.18). Raynaud phenomenon can be a feature of connective tissue disorders. Finger-joint deformities can occur in rheumatoid arthritis. Dupuytren contracture (Ch. 4) may be seen in alcoholic cirrhosis and muscle contractures in cerebral palsy.

Hair can show features in several conditions. Alopecia may be autoimmune, may be seen in lichen planus, or may occur after radiation.

Fig. 2.15 Cervical lymphadenopathy.

Fig. 2.16 Arthritis.

Fig. 2.17 Lichen planus nail deformity.

Hirsutism is a feature of adrenogenital syndrome or Cushing disease, or may be caused by ciclosporin, corticosteroids, minoxidil, phenytoin or androgenic steroids.

The face may be unusual in many syndromes, such as Down syndrome or mucopolysaccharidoses. It may exhibit bruising from trauma

Fig. 2.18 Nail discolouration may be seen after trauma or in local disease, such as fungal infections, in drug use (as here) or in systemic disease.

Fig. 2.19 Subconjunctival haemorrhage associated with zygomatic fracture.

(Fig. 2.19) or purpura; cushingoid facies due to Cushing disease or corticosteroid treatment; and a mask-like facies in scleroderma. Facial telangiectasia is seen in hereditary haemorrhagic telangiectasia, cirrhosis and CREST (calcinosis, Raynaud, oesophageal dysfunction, scleroderma, telangiectasia) syndrome. Facial palsy may indicate stroke or Bell palsy. Neurofibromatosis (Fig. 2.20), tumours (Fig. 2.21) and cysts (Fig. 2.22) may present as lumps. Infection may cause swelling (Fig. 2.23). Myxoedema may indicate hypothyroidism. 'Butterfly rash' over the face may indicate systemic lupus erythematosus, while angiofibromas may underlie tuberous sclerosis (epiloia; Fig. 2.24). A malar flush can be seen in mitral valve stenosis, xanthelasmas in hyperlipidaemia, and cyanosis in hypoxia – cardiac or respiratory disease. Pallor is seen in anaemia or before an imminent faint; purpura may occur in thrombocytopenia or trauma; hyperpigmentation can be racial, or due to suntan, Addison disease or chronic drug (e.g. phenothiazine) use; and hypopigmentation can be caused by vitiligo (Fig. 2.25).

Eyes may show features of disease. Exophthalmos can be seen in hyperthyroidism, and ptosis in myopathy and Horner syndrome. Blue sclerae can be features of infancy and osteogenesis imperfecta.

Fig. 2.20 Neurofibromatosis.

Fig. 2.24 Tuberous sclerosis showing adenoma sebaceum.

Fig. 2.21 Basal cell carcinoma.

Fig. 2.25 Vitiligo.

Fig. 2.22 Sebaceous cyst.

Fig. 2.26 Exfoliative cheilitis.

Fig. 2.23 Cat scratch disease.

Conjunctival haemorrhage can indicate trauma, fractured zygoma or purpura. Jaundice can imply liver disease.

The lips can show cheilitis (e.g. factitious; [Fig. 2.26](#)), lichen planus ([Fig. 2.27](#)) or erythema multiforme. Angular stomatitis can be associated with denture-related stomatitis, anaemia, haematinic deficiency, diabetes, human immunodeficiency virus (HIV) and other diseases ([Fig. 2.28](#)). Lip swelling may be seen after trauma and in infections, neoplasms, allergies, Crohn disease, sarcoidosis or angioedema. Lip pigmentation may underlie Peutz–Jeghers syndrome. ‘Hanging jaw’ is a feature of myasthenia gravis.

Lumps may indicate neoplasms ([Fig. 2.29](#)). *Salivary gland* swellings can represent mumps, Sjögren syndrome, sialosis or tumour (Ch. 4).

Fig. 2.27 Lichen planus on lips.

Fig. 2.28 Angular stomatitis.

Fig. 2.29 Osteoma.

Jaw prognathism and thickened facies can be features of acromegaly. *Cervical lymph node* enlargement is seen in HIV and other infections, malignancy and leukaemia.

Loss of weight or emaciation can be features of anorexia, malignant disease, tuberculosis or HIV infection.

Speech disturbances may suggest drug intoxication, hyposalivation, learning disorder, and neurological or muscle diseases.

Inpatients must always have a full physical examination before an operation, which may include inspection, palpation, percussion and auscultation, and covers examination of at least the following systems:

- Lymph nodes
- Cardiovascular – pulse, blood pressure, heart sounds
- Respiratory – respiratory rate, lung expansion, tracheal position, lung sounds
- Gastrointestinal – any swelling or restriction of movement or tenderness, together with palpation for masses and tenderness
- Neurological – especially the cranial nerves.

Most evidence shows that the history and physical examination often reveal most, if not all, of the clinically useful data. Before any investigations are initiated, the patient's consent must be obtained. Confidentiality must be respected; the history, examination and investigation findings should not be divulged except when there is expressed consent.

INVESTIGATIONS

Investigations are useful only when the appropriate tests are requested, and interpreted in the light of the history, clinical findings, knowledge and experience. It is useless and potentially dangerous to request investigations, the results of which will have no influence on the diagnosis or management.

Screening for latent medical problems is *sometimes* appropriate, mainly when effective action can be taken on the basis of the results. Several relevant treatable conditions, particularly hypertension and diabetes, are frequently unsuspected. For example, blood and urine glucose levels may be abnormal in 5% or more of dental patients. However, it is important not to undertake testing that may cause unnecessary anxiety, trauma, delay or expense.

Many studies have shown the *disadvantages* of 'routine' and 'screening' tests, even preoperatively, carried out with little focus; too often, trivial or inexplicable findings are revealed and unnecessary anxiety and stress caused.

PREOPERATIVE TESTS

Preoperative tests may provide information to reduce possible harm or increase benefit to the patient by altering surgical or sedation/anaesthetic management, and may help risk assessment and guide discussion with the patient that is relevant to informed consent. They may predict postoperative complications and establish a baseline measurement for later reference. Before any investigation is requested, however, it is important for there to be a high enough likelihood of finding an abnormal result and for an abnormal result genuinely to change the patient's management. Most preoperative tests (typically, a full blood count, prothrombin time [PT] or international normalized ratio [INR], activated partial thromboplastin time [APTT], basic metabolic panel and urinalysis) performed on elective surgical patients prove to be normal: findings influence management in under 3% of patients tested. In almost all cases, no adverse outcomes are observed when clinically stable patients undergo elective surgery, irrespective of whether an abnormal test is identified. Preoperative testing is appropriate in symptomatic patients and those with risks factors for which diagnostic testing can provide clarification of a patient's surgical risk. The National Institute for Health and Care Excellence (NICE; formerly the National Institute for Health and Clinical Excellence) guidelines are generic and lack consensus (<http://publications.nice.org.uk/preoperative-tests-cg3>; accessed 25 May 2013); hospitals may have their own guidelines and individual clinicians remain ultimately responsible.

Table 2.12 Grades of surgery

Grade	Examples of procedures
1	Excision of lumps and bumps, incision of abscesses, tooth removal
2	Arthroscopy, herniorrhaphy, tonsillectomy, varicose veins
3	Hysterectomy, thyroidectomy, endoscopic prostatectomy
4	Major bowel, head and neck, lung and joint surgery, and joint replacement Neurosurgery Cardiovascular surgery

(adapted from NICE).

For the purpose of preoperative tests, NICE categorizes surgical procedures into four grades on the basis of complexity and physiological insult (Table 2.12).

The NICE recommendations are in the form of 'look-up' tables set out by surgery grade and ASA grade (<http://www.nice.org.uk/nicemedia/live/10920/29090/29090.pdf>; accessed 30 September 2013):

- Plain chest X-ray (radiograph)
- Resting electrocardiogram (ECG)
- Full blood count
- Haemostasis – including PT, APTT and INR
- Renal function – including tests for potassium, sodium, creatinine and/or urea levels
- Random blood glucose
- Urine analysis (urine dipstick tests – test for pH, protein, glucose, ketones, blood/haemoglobin).

There are also recommendations for sickle cell test and pregnancy tests, and:

- blood gases – for ASA grades II and III only
- lung function (peak expiratory flow rate, forced vital capacity and forced expiratory volume) – for ASA grades II and III only.

Chest radiograph (X-ray)

The likelihood of identifying undiagnosed cardiorespiratory disease and the desirability of re-evaluating patients with known conditions need to be balanced against the radiation exposure. In general, ASA I patients do not require preoperative chest X-rays (CXRs), with the possible exception of smokers over the age of 60 who are undergoing grade 3 or 4 surgery. Certain types of surgery may warrant a CXR at some point in the patient's work-up (e.g. cardiothoracic, oesophageal, and major head and neck surgery). ASA III patients with cardiovascular disease undergoing anything more than grade 1 surgery should probably have a CXR. This should not be repeated if one has been done within 6 months unless the patient's symptoms or signs have changed; in many cases, it could be argued that echocardiography provides more useful information and avoids radiation exposure. Respiratory disease that has changed in its nature or severity with time is a probable indication for CXR, with the exception of patients between the ages of 16 and 40 undergoing grade 1 surgery.

Electrocardiogram

An electrocardiogram (ECG) may on occasion provide evidence of asymptomatic cardiovascular disease and, in those with known cardiac

disease, is useful in estimating risks of GA and surgery. An ECG should be obtained for smokers, for patients with a history or symptoms of cardiac, respiratory or renal disease undergoing grade 4 surgery, and for all patients over the age of 60, regardless of the grade of surgery.

Full blood count (full blood picture)

Full blood count (FBC) may identify and quantify pre-existing anaemia and help assessment of the patient's likely tolerance of any blood loss. FBC is probably indicated in all patients undergoing grade 3 or 4 surgery, particularly in patients with cardiovascular or respiratory disease, for all patients with renal disease, and for all patients over 60 undergoing grade 2 surgery. The white cell count (WCC) may be useful if infection is suspected, and the platelet count where there is suspicion or a history of bleeding tendency.

Haemostasis tests

Haemostatic tests include the platelet count, PT, INR and APTT (Ch. 8). Indications for such tests preoperatively are patients taking anticoagulants; those on haemodialysis; those with a past history or family history of abnormal bleeding, bruising, or liver, kidney or vascular disease; before surgery with the potential to cause a large blood loss so that the need for transfusion is likely; before surgery for cancer, especially where liver metastases may have resulted in a bleeding tendency; and before arterial reconstructive surgery. Investigations should also be considered when regional anaesthesia is planned, particularly using spinal and epidural techniques.

Renal function tests (urea and electrolytes)

Renal function should be assessed in all patients with known renal disease, diabetes, liver dysfunction, and those with an ileus, who are parenterally fed or who are likely to have intravenous fluid administration and perioperative fluid loss.

All adults and children should have urea and electrolyte tests (U&Es) before grade 4 surgery (U&Es are otherwise not generally required in children). These tests are needed in all adults of ASA III or those undergoing grade 3 surgery. Older patients may have asymptomatic deteriorating renal function, so U&Es should be obtained for those aged 60 and over, and before grade 3 surgery. In patients with cardiovascular disease, U&Es are needed in those aged 60 and over undergoing grade 2 surgery.

Sickle test

A sickle test should be requested for all patients of African and West Indian origin, and probably also for those of Mediterranean and Indian origin.

IMAGING

X-RAYS (RADIOGRAPHY)

Radiography, fully discussed elsewhere (see <https://www.gov.uk/government/publications/the-ionising-radiation-medical-exposure-regulations-2000>), is particularly helpful diagnostically since it is inexpensive, rapidly achieved and widely available. Conventional radiography is useful for imaging: bone and joint disease, fractures and dislocations, antral and dental disease (Table 2.13). Plain X-rays have a relatively low radiation dose and special procedures can achieve soft-tissue imaging, albeit with a higher radiation dose.

Table 2.13 Radiographs recommended for demonstrating various head and neck sites

Region required	Standard views	Additional views
Skull ^a	Postero-anterior (PA) 20 Lateral Townes (1/2 axial view)	Submento-vertex (SMV) Tangential
Facial bones	Occipito-mental (OM) OM 30 Lateral	Zygoma Reduced exposure SMV
Paranasal sinuses	OM for maxillary antra	Upper occlusal or lateral SMV Dental panoramic tomography (DPT), tomography
Orthodontics	DPT Cephalometric lateral skull	
Pre- and post-osteotomy	DPT Cephalometric lateral skull Cephalometric PA skull	
Nasal bones	OM 30 Lateral Soft tissue lateral	
Mandible	DPT	Lateral obliques PA mandible Mandibular occlusal
Temporomandibular joints	Transcranial lateral obliques or DPT (mouth open and closed)	Transpharyngeal Arthrography Reverse Townes Reverse DPT Consider CT scan/ MRI

^a CT scanning is valuable in craniofacial injuries.

Radiography requests are essential to enable the radiographic staff to provide the best or most appropriate radiographs for the region under investigation:

1. Fill in the request form as fully as possible with full, relevant, clinical findings.
2. Request the region required rather than specific views, except for dental panoramic tomography, when the term 'DPT' will suffice.

COMPUTED (AXIAL) TOMOGRAPHY

A computed tomography (CT) or computed axial tomography (CAT) scan is a type of repeated special radiograph taken across 'slices' of the body to build up a complex image, using several beams simultaneously from a number of different angles (Fig. 2.30). Cone beam CT (CBCT) is a variant, increasingly used in dentistry for implant work especially (see below).

Advantages

- CT provides good anatomical representation of hard tissues (bone and cartilage).
- It is generally better than magnetic resonance imaging (MRI) for examining lymph nodes.
- It provides good cross-sectional representation.

Fig. 2.30 Computed tomography scan of chest.

- Multiplanar reconstruction is possible from the raw data of the initial examination.
- Three-dimensional reconstruction is possible.
- It provides guidance for biopsies.
- Compared with MRI: imaging is more rapid (in seconds – compared with MRI, which takes minutes) it is less affected by motion artefact, since it is quicker it can be used on patients for whom MRI is inappropriate (e.g. claustrophobics, or people with pacemakers or ferrous or paramagnetic aneurysm clips).

Disadvantages

- CT gives a significant radiation dose.
- It provides phasic imaging of vascular structures and tumours.
- It is an expensive procedure.
- The whole CT procedure may take up to 1 hour, but often takes less than 30 minutes.
- Some patients experience claustrophobia in the CT scanner.

Indications

CT allows visualization of 3–10-mm sections of the body in two dimensions with enough clear distinction between black, grey and white areas of the image to allow pathological diagnosis in many cases.

It is particularly useful in examining the chest or abdomen. CT using contrast media makes it possible to visualize abnormalities more clearly.

Contraindications

Contraindications include pregnancy and history of severe allergies; this may preclude the use of a contrast agent.

Procedure

1. Patients may be asked not to eat beforehand.
2. Patients may have to swallow or be injected intravenously with contrast material that will show up against the tissue on the final pictures.

3. Patients must lie on a couch, which will move through the scanner.
4. The radiographer can see, hear and communicate with the patient (by means of a two-way microphone and speaker system) at all times.
5. The scanner will take a series of pictures.
6. Patients must lie still while images are being taken in order to ensure that they are in focus, and may be asked to hold their breath so the scan is not blurred.

CONE BEAM CT (CBCT)

This is CT in which the X-rays are divergent, forming a cone. CBCT is useful in implantology, endodontics and orthodontics, for accurate visualization of the jaws, teeth and roots (erupted and non-erupted) and of anomalous structures that conventional 2D radiography cannot capture.

SCINTIGRAPHY/NUCLEAR MEDICINE

Radionuclide (radioisotope) scans can be particularly useful for detecting abnormalities in bone, salivary glands, thyroid gland and lymph nodes. The common radionuclide agents used include technetium-99m (Tc-99m) – labelled diphosphonates for bone scans, and gallium for imaging lymph nodes.

Radionuclide scanning involves administration of a radionuclide with an affinity for the organ or tissue of interest, and recording of the distribution of radioactivity. A very small amount of a mildly radioactive liquid is injected into a vein, usually in the arm; after the injection, the patient will have to wait up to 3 hours before the scan can be taken. The distribution of the radionuclide is detected in the tissue/organ under examination where the isotope is concentrated, by a gamma camera, which produces the images or scans after processing by a computer. Detectors record activity in retaining organs at the time of acquisition. Time/activity curves can be plotted to provide functional analysis. The images can then be produced on film or coloured paper, or as graphs or numerical data. The amount of radioactivity given to a patient is small, not dangerous either to the patient or to anyone nearby, and usually clears from the body within 24 hours.

POSITRON EMISSION TOMOGRAPHY

Radioactive molecules made from radionuclides (radioactive isotopes) with short half-lives, such as ^{11}C , ^{15}O or ^{13}N , are injected intravenously. Depending on the type of molecule injected, positron emission tomography (PET) can provide information on different biochemical functions. For example, if glucose is used, the PET scan will show an image of glucose metabolism, or how much energy the body is using in a specific area (such as the brain or a tumour).

MAGNETIC RESONANCE IMAGING (NUCLEAR MAGNETIC RESONANCE)

Magnetic resonance imaging (MRI) is a safe, non-invasive procedure that allows three-dimensional images of internal organs to be created with radio waves and large powerful electromagnets to align hydrogen atoms (protons) within the body (Fig. 2.31).

Advantages

- There is no ionizing radiation.
- MRI provides new, rapidly developing, good multiplanar imaging.

Fig. 2.31 Magnetic resonance image of head and neck.

- It provides good soft-tissue differentiation, which is better than that with CT.
- It provides good imaging of bone marrow.
- It provides good imaging of perineural infiltration.
- Pictures can be taken from multiple angles.
- It can be performed through clothing and through dense tissue such as bone.
- There is less distortion from dental restorations than with CT.

Disadvantages

MRI is dangerous for people with pacemakers or defibrillators and inappropriate for those with ferrous or paramagnetic aneurysm clips (Ch. 5). Currently, MRI is relatively expensive and time-consuming (it can take anything from 30 minutes to 1 hour and 30 minutes, or even 2 hours), and is rather noisy; some ———patients experience claustrophobia. It can also be affected by motion artefact, since it is slow. Gadolinium contrast medium is injected intravenously in up to 30% of MRI scans to improve the clarity.

Indications

MRI, like CT, can be used to produce cross-sectional views of the body or a body part, but can also obtain other views such as sagittal. It allows a clear distinction between black, grey and white areas of the image to aid pathological diagnosis in many cases.

Again like CT, MRI can be used on any part of the body but is frequently employed to examine the head and brain, since it is in this region that it produces clearer results than CT. MRI is also useful for detecting abnormalities in soft tissues and in chest or abdominal examination.

Contraindications

These include:

- presence of a cardiac pacemaker, defibrillator or monitor
- presence of vascular or surgical clips
- presence of any type of orthopaedic prosthesis, rods or pins
- presence of dentures or appliances of any type in the mouth, which must be removed before the scan (implants, fixed crowns or restorations are not contraindications; see below)

- presence of an intrauterine contraceptive device (IUD)
- pregnancy – any effects of MRI on pregnancy are unclear
- history of allergies – may preclude the use of contrast agent.

Procedure

1. Patients may be asked not to eat for 1 hour before the scan; not to smoke for 2 hours before; and not to drink tea, coffee, alcohol or soft drinks containing caffeine (cola, etc.) for 2 hours before. These can influence blood flow and so affect the scan. Iron interferes with MRI and thus iron-containing medications should not be taken.
2. As the MRI scan uses magnetism, metals may affect it. Persons with certain types of metal surgical clips, metal pins or plates, cardiac monitors, defibrillators or pacemakers cannot, therefore, have an MRI scan. The patient must remove everything metal, including watches, any jewellery including piercings, metal clothes closures, belts, metal-containing prostheses, hair clips, shoes, mobile phones, personal organizers, keys, purses and wallets containing magnetic strip credit cards. These must all be left outside the room.
3. MRI scans are noisy, so the patient wears ear plugs.
4. The patient must lie on a couch that can move backwards and forwards through the cylinder.
5. Patients must lie still while images are being taken in order to ensure that they are in focus, and may be asked to hold their breath so the scan is not blurred.
6. The radiographer can see, hear and communicate with the patient (by means of a two-way microphone and speaker system) at all times.
7. The MRI is in a special room that excludes radio waves, as these interfere with the scan.

ULTRASOUND (ULTRASONOGRAPHY)

Ultrasound is the use of high-frequency sound waves (at a frequency of over 20 000 Hz [20 kHz]), which are reflected at interfaces between tissues. An ultrasound scan uses very high-frequency sound waves not audible to the human ear, which are passed through the body using a transmitter or scanner that is normally placed on the skin surface. The pattern of the reflected sound waves or 'echoes' is used to create an outline of the organ in question, so ultrasonography is used for soft tissues rather than bony structures. It can measure size, detect structural abnormalities, determine whether a lump is solid or fluid-filled, and monitor growth of the fetus during pregnancy.

Advantages

- Ultrasound examination is completely painless and safe.
- It produces no ionizing radiation.
- It is inexpensive and provides a good screening test.
- The equipment is mobile.
- It provides good differentiation between cystic and solid soft-tissue masses.
- Advanced technique (Doppler) assesses flow characteristics in vessels.

Indications

- To diagnose disease in liver, gallbladder, pancreas, urinary bladder, prostate, kidney, thyroid gland, lymph nodes, salivary glands, ovaries or testicles, and breast
- In obstetrics, to check that there are no fetal abnormalities, and to monitor fetal growth
- For ophthalmic imaging

- To examine blood flow
- To diagnose aneurysms
- For echocardiography.

Contraindications

None known.

Procedure

1. Ultrasound examination takes between 15 minutes and 1 hour.
2. Usually, a lubricating silicone gel applied to the skin is used to help conduct the sound waves into the body.
3. Patients must lie still during the examination.
4. For some more specialized kinds of ultrasound examination, the probe is inserted into the body.
5. In abdominal ultrasound scanning, large amounts of gas in the intestine can interfere with the images. Therefore, in these instances, low-fibre foods should be taken for 24–36 hours before the examination. Some examinations of the intestines, for example, require a preparatory enema and fasting for several hours before the appointment. Others, as used in obstetrics, may require a full bladder.

LABORATORY INVESTIGATIONS

HISTOPATHOLOGY

A biopsy that is of adequate size and representative of the lesion should be taken, placed in a fixative and sent to the pathology laboratory carefully labelled and with the appropriate form of request for histopathological examination.

- Specimens for *routine histological examination* should be fixed in 10% formol saline; at least ten times the volume of the specimen is needed for adequate fixation.
- Specimens for *immunofluorescent investigations* are not usually carried out on formol saline-fixed tissue, but should be sent in a suitable transport medium for immediate freezing at -70°C and direct immunofluorescence. Serum should also be sent for indirect immunofluorescence.

If tuberculosis or a systemic mycosis is suspected, a fresh tissue specimen should be sent for culture.

MICROBIOLOGY

Specimens should be collected before antimicrobials are started. If pus is present, a sample should be sent in a sterile container, in preference to a swab. Requests for culture and antibiotic sensitivity should indicate possible aetiology, present antimicrobial therapy and any drug allergies. If tuberculosis is suspected, this must be clearly indicated on the request form.

If the microbiological specimen cannot be dealt with within 2 hours, the swab should be placed in transport medium and kept in the refrigerator at 4°C (not a freezer) until dealt with by the microbiology department.

Actinomycosis

It is preferable to send pus for culture but, in the absence of adequate pus, send a dressing that has been in contact with the wound for several hours.

Candidosis

Swabs from the lesions and from the fitting surface of the denture may be sent for Gram stain or culture.

Viral hepatitis or HIV infection

Many centres have defined protocols for the collection of specimens from patients with suspected hepatitis or HIV infection. Particular care must be taken to avoid needlestick injuries and contamination of the outside of the containers, and to indicate that hazard may be posed by the infection. Special coloured plastic bags (usually red) to indicate this hazard can be used for transporting the specimen. Consent is required when testing.

Other viral infections

Swabs must be sent in viral transport medium; dry swabs are no use. Nucleic acid testing is increasingly common. Acute and convalescent serum samples (10 mL blood in a plain container) may be taken; convalescent serum is collected 2–3 weeks after the acute illness.

Syphilis

Oral lesions should be cleaned with saline to remove oral treponemes before a smear is made for dark-ground examination; 10 mL of serum should be sent for Venereal Disease Research Laboratory (VDRL) testing (Ch. 21).

HAEMATOLOGY

Blood for film and red cell indices must be collected in a tube containing potassium ethylenediamine tetra-acetic acid (EDTA; 4 mL into an EDTA tube). EDTA inhibits clotting through its action on cation-dependent proteolytic enzymes critical to the clotting cascade. The blood must be gently mixed to ensure that the anticoagulant is well distributed; clotted samples are useless. Blood for assay of corrected whole blood folate levels is also collected in an EDTA tube. Most other necessary investigations are performed on serum (Appendix 2.3). Any venepuncture episode requires consent, both for the insertion of the needle and for the investigations being carried out on the blood sample. See Table 2.14 for potential complications.

BIOCHEMISTRY

There is currently some variation as to whether serum or plasma is needed for certain biochemical tests, depending on the laboratory involved. Special containers may be required for automated multi-channel analysers, which give a full biochemical profile on a single blood specimen. However, most biochemical estimations can be carried out on serum (collect blood in a plain container), although plasma (collect in a lithium heparin tube) may be needed for estimation of electrolytes, cortisol and proteins. Blood glucose assays are carried out on a sample in a fluoride bottle. Urinalysis is also available (Appendices 2.4 and 2.5).

IMMUNOLOGY

Most tests of humoral immunity and complement components are carried out on serum (plain tube). Autoantibodies are detected in serum. In order to prevent the rapid decay of complement components, the

Table 2.14 Complications of venepuncture

Complication	Remarks
Failure in a young normal adult	Relax. Correct application of tourniquet. Warm arm/hand. Check syringe and needle will aspirate Try other arm; use sphygmomanometer cuff at just below diastolic pressure; make sure you can palpate vein before trying again
Difficult patients	
Fat arm: veins difficult to locate	Remember that veins are there. Palpate antecubital fossa over usual vein site (see text) If unsuccessful, try veins on radial side of wrist or on back of hand (painful)
Thin arm: veins move away from the needle	Most annoying! Insert needle deliberately alongside vein, preferably at a Y-junction, and immobilize vein with your other hand before penetrating vein from side
Haematoma formation	Most annoying to patient! Caused by poor technique, inadequate pressure to puncture site or removal of needle before removal of tourniquet. May cause venous thrombosis. Try not to penetrate through other side of vein. Keep firm pressure with swab on vein after venepuncture until haemostasis secured. In the elderly, maintain this pressure for several minutes

serum should be separated as soon as possible and frozen at -20°C at least and preferably at -70°C . Serum for immune complexes and cryoglobulins may need special handling, details of which can be obtained from the relevant laboratory.

Tests of cell-mediated immunity are expensive and often can be carried out only once special preparations have been made (consult the laboratory; Appendix 2.6).

See above for direct immunofluorescence specimens.

The presence of autoantibodies does not always indicate disease and absence does not necessarily exclude it. The type of autoimmune disorder or disease that occurs and the amount of destruction depend on which systems or organs are targeted by the autoantibodies, and how strongly. Disorders caused by organ-specific autoantibodies, those that primarily target a single organ, such as the thyroid in Graves disease and Hashimoto thyroiditis, are often the easiest to diagnose as they frequently present with organ-related disease.

Once a diagnosis has been made and a treatment plan has been decided on, it must be explained to the patient and informed consent must be obtained.

APPENDIX 2.1 SUGGESTED MEDICAL QUESTIONNAIRE FOR PATIENTS TO COMPLETE^a

	Question	Yes	No	Details
1	Have you had an operation or general anaesthetic before?			
2	Have you had any problems with anaesthetics?			
3	Have any of your relatives had any problems with anaesthetics?			
4	Are you taking any drugs or other medications (inhalers, Pill)?			
5	If female, are you or could you be pregnant?			
6	Have you had any corticosteroid drugs in the past? If yes, when?			
7	Do you have any allergies (drugs, plasters, latex, antiseptics, foodstuffs)?			
8	Do you have heart disease or have you had a heart attack?			
9	Do you ever have to take antibiotics routinely prior to dental surgery?			
10	Do you get chest pains, indigestion or tummy acid in the throat?			
11	Do you have a hiatus hernia?			
12	Do you have high blood pressure?			
13	Do you get breathless walking, climbing stairs or lying flat?			
14	Do you have asthma, bronchitis or chest disease?			
15	Have you ever had a convulsion or fit?			
16	Do you have arthritis or muscle disease?			
17	Do you have anaemia or any other blood disorder?			
18	Do you know your sickle status (if relevant)?			
19	Have you ever had liver disease or been jaundiced?			
20	Have you ever had kidney disease?			
21	Do you have diabetes (sugar in your urine)?			
22	Do you smoke? If yes, how many cigarettes a day (also last 6 months)?			
23	Do you take recreational drugs or drink alcohol? If yes, how many units per week?			
24	Do you have any crowns, loose teeth or artificial teeth? Indicate:			
25	Do you wear contact lenses?			
26	Is there anything else you think the surgeon or anaesthetist should know?			

^aOther useful formats are available, such as that referenced in the Resuscitation Council UK document 2006 on *Medical emergencies for dental practitioners*.

APPENDIX 2.2 COMPLEX MEDICAL HISTORY AS PROVIDED BY A DENTAL PATIENT

Medical Information Sheet	
Name: Blood Group: A + Situation: Lives alone	
Address:	
Phone:	
Only in real emergency:	1st contact: 2nd contact: 3rd contact:
Allergies:	To medication – Trimethoprim, preservatives and lanolin in eye ointments/drops. Airborne – Pollens, moulds. Photosensitivity reactions (Polymorphic light eruption). Oral allergy syndrome, sticky dressings, dogs, cats
Vaccinations:	Tetanus 1994, BCG 1986, Hep B booster 1997, Polio booster 1999, Hep A booster 2001, H1N1 swine flu vaccinations 2009, annual influenza vaccination, pneumococcal vaccine Nov 2010
Conditions:	Current: Systemic autoimmune disease (atypical primary Sjögren syndrome) with associated complications: Ophthalmological (Keratoconjunctivitis sicca (KCS)), CNS (Autoimmune myelitis: inflammatory non-compressive cervical cord myelopathy/Sjögren myelopathy), Renal (Chronic kidney disease (CKD) Stage 3 (lowest eGFR 49)), Urological (Interstitial cystitis (IC)/Painful bladder syndrome), Dermatological (Intermittent 'sterile neutrophilic folliculitis' rash poss associated with autoimmune disease, generalized mucosal and skin dryness), generalized (Periodic lymphadenopathy/flu-like symptoms, severe fatigue), Gynaecological (vestibulodynia). Other conditions: Pineal region brain tumour (histological type not known), GI: Severe idiopathic slow-transit constipation, Psychiatric: Major depressive disorder, severe generalized anxiety, Urological: Urethral stenosis, Dermatological: Polymorphic light eruption, seborrhoeic dermatitis, intermittent acne, intermittent mild eczema, Gynaecological: Bartholin cyst (recurrence). Resolved: Healed pyoderma gangrenosum (PG) R. leg, costochondritis, Recently: Unexplained severely painful, possibly reactive, condition of tongue (intrinsic and ulcerative, desquamating) for 2 weeks between multiple infections requiring 3 antibiotics (URTIs and acute labyrinthitis and streptococcal tonsillitis). Ongoing investigation/monitoring: Brain tumour, myelitis, renal function.
Prescribed Drugs:	Long-term: For autoimmune disease: Salagen (oral pilocarpine) 5 mg every 3 h (max 6 daily) (always kept with me for quick self-administration as wears off fast), Plaquenil (hydroxychloroquine) 200 mg every other morning with food, Viscotears preservative-free single-dose vials of carbomer 974P artificial tears at least 4 times a day, more freq as needed, diazepam (and for neuro motor symptoms) 5 mg p.r.n. For depression: Seroquel (quetiapine) 100 mg night, Stilnoct (zolpidem) 10 mg night, trazadone 150 mg night. For seborrhoeic dermatitis: ketoconazole shampoo daily, aqueous cream, E45 bath oil, Lotiderm p.r.n. For neutrophilic rash: Dermovate p.r.n. For IC and myelopathic paraesthesia: imipramine 25 mg night. For chronic idiopathic constipation: Resolor 2 mg daily, docusate sodium 3 times a day. For acne when returns: Tetralysal 300 (lymecycline) 1–2 tabs. Periodically: For pain: Arcoxia sparingly (as contraindicated with CKD), co-codamol. For vestibulodynia: 5% lidocaine ointment p.r.n. Discontinued: For KCS: Restasis (cyclosporin 0.05% emulsion single-unit eye drops) every 12 h (on named-patient basis) for appx 4 y, Circadin (melatonin) 1 tab nocte. For depression: lithium, Cipralex. Steroids previously received: For myelitis: 3 pulsed steroid IV infusions in Feb '06 (1000 mg methylprednisolone each time), For PG: oral EC prednisolone (3 mths in '06), For Sjögren lymphadenopathy/flu-like syndrome: IM DepoMedrone steroid injection 120 mg Nov '09, For neutrophilic rash and lymphadenopathy: oral EC prednisolone (4 days 30 mg Aug '10, 8 days 15 mg and 6 days 20 mg Sep '10), For neutrophilic rash: IM DepoMedrone steroid injection 120 mg Sep '10. For costochondritis: local cortisone injection into chest Sep '10. (General note about prescribing – consider potential of medications to exacerbate symptoms of Sjögren syndrome – e.g. caution with anticholinergics, etc.).
In case of General Anaesthetic:	To avoid exacerbation of Sjögren syndrome symptoms: AVOID prolonged NPO, allow clear liquids till 2 h prior, omit drying agents, add humidifier to rebreathing system, lubricate ETTs/LMAs well, place w caution, use humidified O ₂ , lubricate eyes with preservative-free carbomer artificial tears, i.e. Viscotears, maintain warmth

APPENDIX 2.3 INTERPRETATION OF HAEMATOLOGICAL RESULTS

Blood	Normal range ^a	Level ↑	Level ↓
Haemoglobin (Hb)	Male 13.0–18.0 g/dL Female 11.5–16.5 g/dL	Polycythaemia (rubra vera or physiological); myeloproliferative disease; dehydration	Anaemia
Haematocrit (packed cell volume [PCV])	Male 40–54% Female 37–47%	Polycythaemia; dehydration	Anaemia
Mean cell volume (MCV) MCV = PCV/RBC	78–99 fl	Macrocytosis in vitamin B ₁₂ or folate deficiency; liver disease; alcoholism; hypothyroidism; myelodysplasia; myeloproliferative disorders; aplastic anaemia; cytotoxic agent	Microcytosis in iron deficiency, thalassaemia, chronic disease
Mean cell haemoglobin (MCH) MCH = Hb/RBC	27–31 pg/cell	Pernicious anaemia	Iron deficiency; thalassaemia; sideroblastic anaemia
Mean cell haemoglobin concentration (MCHC) MCHC = Hb/PCV	32–36 g/dL		Iron deficiency; thalassaemia; sideroblastic anaemia; anaemia in chronic disease
Red cell count (RBC)	Male $4.2\text{--}6.1 \times 10^{12}/\text{L}$ Female $4.2\text{--}5.4 \times 10^{12}/\text{L}$	Polycythaemia	Anaemia; fluid overload
White cell count (WCC; total)	$4\text{--}10 \times 10^9/\text{L}$	Infection; inflammation; leukaemia; intense exercise; trauma; stress; pregnancy	Early leukaemia; some infections; bone marrow disease; drugs, including corticosteroids and chemotherapy; idiopathic
Neutrophils	Average $3.3 \times 10^9/\text{L}$	Pregnancy; exercise; infection; bleeding; trauma; malignancy; leukaemia; corticosteroids	Some infections; drugs; endocrinopathies; bone marrow disease; idiopathic
Lymphocytes	Average $2.5 \times 10^9/\text{L}$	Physiological; some infections; leukaemia; lymphoma	Some infections; some immune defects (e.g. HIV, AIDS); lymphoma; corticosteroids; systemic lupus erythematosus (SLE)
Eosinophils	Average $0.15 \times 10^9/\text{L}$	Allergic disease; parasitic infestations; skin disease; malignancy, including lymphoma	Some immune defects
Platelets	$150\text{--}400 \times 10^9/\text{L}$	Thrombocytosis in bleeding; myeloproliferative disease; chronic inflammatory states	Thrombocytopenia related to leukaemia; drugs; HIV; other infections; idiopathic; autoimmune; disseminated intravascular coagulopathy (DIC)
Reticulocytes	0.5–1.5% of RBC	Haemolytic states; during treatment of anaemia	Chemotherapy; bone marrow disease
Erythrocyte sedimentation rate (ESR)	0–15 mm/h	Pregnancy; infections; anaemia; inflammation; connective tissue disease; temporal arteritis; trauma; infarction; tumours	–
Plasma viscosity	1.4–1.8 cp	As ESR	

^aAdults unless otherwise stated. Check values with your laboratory.

APPENDIX 2.4 INTERPRETATION OF BIOCHEMICAL RESULTS^a

Biochemistry ^b	Level ^c ↑	Level ^c ↓
Acid phosphatase	Prostatic malignancy; renal disease; acute myeloid leukaemia	–
Alanine transaminase (ALT) ^d	Liver disease; infectious mononucleosis	Hypothyroidism; hypophosphatasia; malnutrition
Alkaline phosphatase	Puberty; pregnancy; Paget disease; osteomalacia; fibrous dysplasia; malignancy in bone; liver disease; hyperparathyroidism (some); hyperphosphatasia	–
Alpha ₁ -antitrypsin	Liver cirrhosis	Congenital emphysema
Alpha-fetoprotein (AFP)	Pregnancy; gonadal tumour; liver disease	Fall in level in pregnancy indicates fetal distress
Amylase	Pancreatic disease; mumps; some other salivary diseases	–
Angiotensin-converting enzyme (ACE)	Sarcoidosis	–
Antistreptolysin O titre (ASOT)	Streptococcal infections; rheumatic fever; drugs ^f	–
Aspartate transaminase (AST) ^e	Liver disease; biliary disease; myocardial infarct; trauma; drugs ^f	–
Bilirubin (total)	Liver or biliary disease; haemolysis	–
Brain natriuretic peptide (BNP)	Cardiac failure	–
Caeruloplasmin	Pregnancy; cirrhosis; hyperthyroidism; leukaemia	Wilson disease
Calcium	Primary hyperparathyroidism; malignancy in bone; renal tubular acidosis; sarcoidosis; thiazides; calcium supplements; excess vitamin D	Hypoparathyroidism; renal failure; rickets; nephrotic syndrome; chronic renal failure; lack of vitamin D; low magnesium levels; acute pancreatitis
Cholesterol	Hypercholesterolaemia; pregnancy; hypothyroidism; diabetes; nephrotic syndrome; liver or biliary disease	Malnutrition; hyperthyroidism
Complement (C3)	Trauma; surgery; infection	Liver disease; immune complex diseases (e.g. systemic lupus erythematosus [SLE])
Complement (C4)	–	Liver disease; immune complex diseases; hereditary angioneurotic oedema (HANE)
Cortisol (see Steroids)	–	–
Creatine kinase (CK)	Myocardial infarct; trauma; muscle disease; rhabdomyolysis; statins	–
Creatinine	Renal failure; urinary obstruction	Pregnancy
C-reactive protein (CRP)	Inflammation; trauma; myocardial infarct; malignant disease	–
C1 esterase inhibitor	–	Hereditary angiodema
Cyclic citrullinated peptide (CCP)	Rheumatoid arthritis	–
Erythrocyte sedimentation rate (ESR)	Inflammation; trauma; myocardial infarct; malignant disease	–
Ferritin	Liver disease; haemochromatosis; leukaemia; lymphoma; other malignancies; thalassaemia	Iron deficiency
Fibrinogen	Pregnancy; pulmonary embolism; nephritic syndrome; lymphoma	Disseminated intravascular coagulopathy (DIC)
Folic acid	Folic acid therapy	Alcoholism; dietary deficiency; haemolytic anaemias; malabsorption; myelodysplasia; phenytoin; methotrexate; trimethoprim; pyrimethamine; sulfasalazine; cycloserine; oral contraceptives; pregnancy
Free thyroxine index (FTI; serum T4 and T3 uptake)	Hyperthyroidism	Hypothyroidism
Gamma-glutamyl transpeptidase (GGT)	Alcoholism; obesity; liver disease; myocardial infarct; pancreatitis; diabetes; renal diseases; tricyclics	–
Globulins (total; see also Protein)	Liver disease; multiple myeloma; autoimmune disease; chronic infections	Chronic lymphatic leukaemia; malnutrition; protein-losing states
Glucose	Diabetes mellitus; pancreatitis; hyperthyroidism; hyperpituitarism; Cushing disease; liver disease; post head injury	Hypoglycaemic drugs; Addison disease; hypopituitarism; hyperinsulinism; severe liver disease
Hydroxybutyrate dehydrogenase (HBD) immunoglobulins	Myocardial infarct	–
Total immunoglobulins	Liver disease; infection; sarcoidosis; connective tissue disease	Immunodeficiency; nephrotic syndrome; enteropathy
IgG	Myelomatosis; connective tissue disorders	Immunodeficiency; nephrotic syndrome
IgA	Alcoholic cirrhosis; Berger disease	Immunodeficiency

(Continued)

Biochemistry ^b	Level ^c ↑	Level ^c ↓
IgM	Primary biliary cirrhosis; nephrotic syndrome; parasites; infections	Immunodeficiency
IgE	Allergies; parasites	–
Lactate dehydrogenase (LDH)	Myocardial infarct; trauma; liver disease; haemolytic anaemias; lymphoproliferative diseases	Radiotherapy
Lipase	Pancreatic disease	–
Lipids (triglycerides)	Hyperlipidaemia; diabetes mellitus; hypothyroidism; hyper-vitaminosis D	–
Magnesium	Renal failure	Cirrhosis; malabsorption; diuretics; Conn syndrome; renal tubular defects
Nucleotidase	Liver disease	–
Percent carbohydrate-deficient transferrin	Alcoholism	–
Phosphate	Renal failure; bone disease; hypoparathyroidism; hyper-vitaminosis D	Hyperparathyroidism; rickets; malabsorption syndrome; insulin
Potassium	Renal failure; Addison disease; ACE inhibitors; potassium supplements	Vomiting; diabetes; Conn syndrome; diuretics; Cushing disease; malabsorption; corticosteroids; salbutamol
Protein (total)	Liver disease; multiple myeloma; sarcoid; connective tissue diseases	Pregnancy; nephrotic syndrome; malnutrition; enteropathy; renal failure; lymphomas
Albumin	Dehydration	Liver disease; malnutrition; malabsorption; nephrotic syndrome; multiple myeloma; connective tissue disorders
Alpha ₁ -globulin	Oestrogens	Nephrotic syndrome
Alpha ₂ -globulin	Infections; trauma	Nephrotic syndrome
Beta-globulin	Hypercholesterolaemia; liver disease; pregnancy	Chronic disease
Gamma-globulin	(see Immunoglobulins)	Nephrotic syndrome; immunodeficiency
Serum GGT (SGGT; see GGT)	–	–
Serum glutamic oxaloacetic transaminase (SGOT; see AST)	–	–
Serum glutamic pyruvic transaminase (SGPT; see ALT)	–	–
Sodium	Dehydration; Cushing disease	Cardiac failure; renal failure; syndrome of inappropriate antidiuretic hormone (SIADH); Addison disease; diuretics
Steroids (corticosteroids)	Cushing disease; some tumours	Addison disease; hypopituitarism
Thyroxine (T4)	Hyperthyroidism; pregnancy; oral contraceptive	Hypothyroidism; nephrotic syndrome; phenytoin
Troponin	Myocardial infarct	–
Urea	Renal failure; dehydration; gastrointestinal bleed	Liver disease; nephrotic syndrome; pregnancy; malnutrition
Uric acid	Gout; leukaemia; renal failure; multiple myeloma	Liver disease; probenecid; allopurinol; salicylates; other drugs
Vitamin B ₁₂	Liver disease; leukaemia; polycythaemia rubra vera	Pernicious anaemia; gastrectomy; Crohn disease; ileal resection; veganism; metformin

^aAbsolute value ranges may differ from laboratory to laboratory. There are also many more causes of abnormal results than are outlined here. SI values: 10⁻¹, deci (d); 10⁻², centi (c); 10⁻³, milli (m); 10⁻⁶, micro (μ); 10⁻⁹, nano (n); 10⁻¹², pico (p); 10¹⁵, femto (f).

^bSerum or plasma.

^cAdult levels; always consult your own laboratory.

^dALT = SGPT (serum glutamate–pyruvate transaminase).

^eAST = SGOT (serum glutamate–oxaloacetic transaminase).

^fAmpicillin, cefalotin, cloxacillin, erythromycin, indometacin, methotrexate, opioids.

APPENDIX 2.5 URINALYSIS: INTERPRETATION OF RESULTS^a

Colour	Protein	Glucose ^b	Ketones	Bilirubin ^c	Urobilinogen ^c	Blood ^d
<u>Comment</u>						
–	Tetrabromphenol blue dye binds to some proteins in urine – mainly albumin. Not all proteins are detected and the sensitivity is not high	–	–	–	–	Tests for intact red cells and free haemoglobin (Hb)
<u>Health</u>						
Yellow	Usually no protein, but a trace can be normal in young people	Usually no glucose, but a trace can be normal in 'renal glycosuria' and pregnancy	Usually no ketones but ketonuria may occur in vomiting, fasting or starvation	Usually no bilirubin	Usually present in normal healthy patients, particularly in concentrated urine	Usually no blood
<u>False positives</u>						
Red: beet	Alkaline urine. Container contaminated with disinfectant (e.g. chlorhexidine). Blood or pus in urine. Polyvinyl pyrrolidone infusions	Cefamandole. Container contaminated with hypochlorite	Patients on L-dopa or any phthalein compound	Chlorpromazine and other phenothiazines	Infected urine. Patients taking ascorbic acid, sulphonamides or paraminosalicylate	Menstruation. Container contaminated with some detergents
<u>Disease</u>						
Brown: homogentisic acid, bilirubin, urobilin, porphyrins	Renal diseases. Also cardiac failure, diabetes, endocarditis, myeloma, amyloid, some drugs, some chemicals	Diabetes mellitus. Also in pancreatitis, hyperthyroidism, Fanconi syndrome, sometimes after a head injury, other endocrinopathies	Diabetes mellitus. Also in febrile or traumatized or starved patients on low-carbohydrate diets	Only where conjugated bilirubin is increased – hepatocellular and obstructive liver disease	Haemolytic or hepatic, hepatocellular or obstructive disease. Prolonged antibiotic therapy	Genitourinary diseases. Also in bleeding tendency, haemolysis, rhabdomyolysis, some infections where bacteria contain hydroperoxidase, some drugs, endocarditis
Red: Hb Milky: chyluria						

^aUsing test strips (e.g. Ames reagent strips, BM-Test-5L, Diastix or Diabur strips). Normal or non-fresh urine may be alkaline; normal urine may be acid. Nitrites and leukocyte esterase positivity suggests a urinary tract infection.

^bDopa, ascorbate or salicylates may give false negatives.

^cMay be false negative if urine not fresh.

^dAscorbic acid may give false negative.

APPENDIX 2.6 SOME IMPORTANT AUTOANTIBODIES^a

Autoantibodies	Main associations
Anti-actin	Autoimmune hepatitis, coeliac disease
Anti-epithelial	
Anti-basement membrane zone	Pemphigoid
Intercellular cement (desmoglein)	Pemphigus
Anti-ganglioside antibodies	
Anti-GD3	Guillain–Barré syndrome
Anti-GM1	Travellers' diarrhoea
Anti-GQ1b	Miller–Fisher syndrome (see Guillain–Barré syndrome)
Anti-gastric parietal cell	Pernicious anaemia
Anti-glomerular basement membrane (anti-GBM) antibody	Goodpasture syndrome
Anti-Hu	Neuroblastoma
Anti-intrinsic factor	Pernicious anaemia
Anti-islet cell	Diabetes type 1
Anti-Jo 1 (GAD65)	Polymyositis, dermatomyositis
Anti-liver/kidney microsomal 1 (anti-LKM 1 antibodies)	Chronic hepatitis C
Anti-Ku	Polymyositis/scleroderma (PM/Scl) overlap syndrome
Anti-mitochondrial	Primary biliary cirrhosis
Anti-neutrophil cytoplasmic (ANCA)	
pANCA (perinuclear; anti-myeloperoxidase)	Ulcerative colitis, polyarteritis nodosa
cANCA (cytoplasmic proteinase 3; anti-PR3)	Wegener granulomatosis
Antinuclear (ANA) anti-extractable nuclear antigen (anti-ENA)	
Anti-p62	Primary biliary cirrhosis
Anti-sp100	Primary biliary cirrhosis
Anti-glycoprotein210	Primary biliary cirrhosis
Anti-double-stranded (ds) DNA	Antibody with the highest specificity for systemic lupus erythematosus (SLE) and found in most patients
Anti-Ro (Robair)	Sjögren syndrome
Anti-La (Lattimer)	Sjögren syndrome
Anti-RNP	Mixed connective tissue disease (MCTD)
Anti-Sm	SLE
Anti-PM/Scl (anti-exosome)	PM/Scl overlap syndrome
Anti-Scl 70	
Anti-topoisomerase	Scleroderma
Anti-centromere	CREST (calcinosis, Raynaud, oesophageal dysfunction, scleroderma, telangiectasia) syndrome
Anti-smooth muscle	Autoimmune hepatitis
Anti-steroid 21-hydroxylase (21-OH)	Addison disease
Anti-thyroid	
Thyroid peroxidase (TPOAb)	Hashimoto thyroiditis, Graves disease
TSH receptor (TRAb)	Graves disease
Thyroglobulin antibodies	Autoimmune thyroid disease
Anti-transglutaminase	
Anti-tTG (tissue transglutaminase)	Coeliac disease
Anti-eTG (epidermal transglutaminase)	Dermatitis herpetiformis
Rheumatoid factor (RF)	Rheumatoid arthritis (high rate of false positives in SLE and other conditions)
Lupus anticoagulant	
Anti-thrombin antibodies	SLE

^aSee also Table 18.3.

KEY POINTS

- Informed consent is crucial
- Communicate with other health-care professionals

Assessment of the patient, consent and the question of preoperative screening are discussed in Chapter 2 and much of that discussion is relevant to this chapter. Integrated care pathways are increasingly used in many countries. In the UK, the National Patient Safety Agency (NPSA) and NHS Quality Improvement Scotland (NHS QIS) are responsible for overseeing this area.

TREATMENT COMPLICATIONS

Any form of surgery or invasion of bone or soft tissues causes inflammation, with variable pain and swelling and sometimes other sequelae; therefore it is crucial that benefits outweigh the risks and that the patient has given valid consent. Even a local anaesthetic (LA) injection can be followed by complications. LA complications and medico-legal complaints arising from them are rare but include persisting anaesthesia or paraesthesia. Most cases involve lingual and/or inferior alveolar nerve sensory loss. In one study of over 12000 inferior alveolar nerve block injections, 0.15% resulted in some lingual sensory disturbance and 7% caused patients to experience an 'electric shock'-type feeling in the tongue at the time of LA injection –almost certainly indicating needle nerve damage. However, all but 1 patient regained normal sensation within 6 months. Most LAs, in particular articaine and prilocaine, are also potentially neurotoxic, and a Danish study suggested that the main cause of injury was neurotoxicity resulting from administration of the LA rather than from needle penetration. Clinicians should consider avoiding high-concentration (4%) LA for block anaesthesia and avoiding articaine for block anaesthesia. Complications from conscious sedation (CS) and general anaesthesia (GA) are considered below.

Drug use can cause adverse reactions; some of the main adverse reactions, interactions and contraindications to drugs used in dentistry are shown in Chapter 29, [Tables 3.1 and 3.2](#), and [Appendices 3.1–3.3](#). It is important for clinicians only to undertake a procedure or use a drug when they are aware of the attendant interactions and adverse effects (as discussed in Ch. 29), and to be able to manage any emergency (Ch. 1) or other complications. Clinicians should work only within their field of competence.

Finally, never alter a patient's medication personally, even aspirin given by another health-care professional (HCP), as this is considered, at the least, discourteous and, at worst, to be practising medicine without a licence. Always consult the patient's HCP.

PAIN MANAGEMENT

Pain is an unpleasant sensory and/or emotional experience associated with actual or potential tissue damage. Pain is a complicated process that involves an intricate interplay between chemicals (neurotransmitters),

which bind to neurotransmitter receptors (nociceptors) on cell surfaces. These function as gates or ports, enabling pain messages to pass through to cells. Normally, nociceptors only respond to strong, potentially harmful stimuli; however, chemicals from injured or inflamed tissues ([Box 3.1](#)) sensitize nociceptors, causing them to transmit pain signals in response to lesser stimuli. This is referred to as allodynia, a state in which pain is produced by innocuous stimuli such as light touch.

Pain is initiated with the activation of nociceptors at the free nerve endings of A-delta and C fibres, followed by transduction, whereby one form of energy (mechanical, thermal, chemical) is converted into another (electrical – nerve impulse). Lightly myelinated A-delta nerve fibres are responsible for sharp stabbing pain usually resulting from stimulation of mechanoreceptors (e.g. primary pain following acute injury). Stimulation of unmyelinated C-polymodal nerve fibres gives rise to pain described as dull, aching and poorly localized (e.g. infection, secondary pain following acute injury, visceral pain). Pain may be superficial or deep, and somatic, visceral or neuropathic, based on the site of action of the noxious stimulus.

Following transduction, neural impulses are carried along peripheral nerves to spinal cord and brainstem, which act as relay centres (where the pain signal can potentially be blocked, enhanced or otherwise modified). They continue through the thalamus (which also serves as the storage area for body images and plays a key role in relaying messages between the brain and various parts of the body) to the cerebral cortex, where pain perception occurs.

The main excitatory neurotransmitters for pain are substance P and glutamate. Inhibitory neurotransmitters include gamma-aminobutyric acid (GABA), serotonin, noradrenaline (norepinephrine) and opioid-like chemicals such as endorphins and enkephalins (which block pain by locking on to opioid receptors and switching on pain-inhibiting pathways or circuits). Endorphins (mu-opioids) may also be responsible for the 'feel-good' effects experienced after vigorous exercise.

It must be borne in mind that pain has emotional, sensory, behavioural and cognitive components, and can be influenced by temperament, context, experience, pain sensitivity, coping skills and cognitive development, and also by biological, psychological and cultural factors.

Prevention and treatment of pain and suffering are essential. Furthermore, adequate pain control during a clinical procedure may also make management and pain control far easier for future health-care procedures. Pre-emptive analgesia is the clinical concept of introducing analgesic management before the onset of noxious stimuli, which helps to prevent pain potentiation. Reassurance, explanation, a calm environment and gentle handling will help but frequently need to be supplemented with analgesics, hypnosis, LA, CS (oral, inhalational or intravenous) or GA.

ANALGESICS

Analgesics may act at different levels of the pain transmission pathway. Aspirin and other non-steroidal anti-inflammatory agents (NSAIDs), paracetamol (acetaminophen), corticosteroids and LA act peripherally, while some other agents, such as opioids, act on the central nervous system (CNS). Neurogenic pain, originating in damaged C fibres, may also respond to membrane-stabilizing drugs, such

Table 3.1 More common drug interactions with analgesics and local anaesthetics of significance in oral health care^a

Specific drugs used in dentistry	Interacting drug	Main uses of interacting drug	Possible outcomes (check text and Ch. 29)
Acetaminophen (paracetamol)	Alcohol (ethanol)	Abuse	Liver toxicity
Adrenaline (epinephrine)-containing LA	Beta-blockers (non-selective)	Hypertension	Hypertension and bradycardia
	Cocaine	Abuse	Arrhythmias
	Catechol-O-methyl transferase (COMT) inhibitors (tolcapone, entacapone)	Parkinsonism	Hypertension, tachycardias, arrhythmias
	Halothane	GA	Arrhythmias
	Tricyclics	Depression	Hypertension, tachycardias, arrhythmias
Aspirin	Alcohol	Alcoholism	Risk of gastrointestinal bleeding
	Corticosteroids	Immune suppression	Risk of gastrointestinal ulceration
	Hypoglycaemics	Diabetes	Enhanced hypoglycaemia
	Warfarin	Cardiac disease	Risk of gastrointestinal bleeding
		Depression	Hypertension
Articaine (N.B. adrenaline [epinephrine] is included in some preparations, so care with drugs that increase QT)	Antidepressants (monoamine oxidase inhibitors [MAOIs])	Hypertension	Reduced antihypertensive effect
Non-steroidal anti-inflammatory drugs (NSAIDs)	Antihypertensives	Hypertension	Reduced antihypertensive effect
	Corticosteroids	Immune suppression	Risk of gastrointestinal ulceration
	Lithium	Manic depression	Lithium toxicity
	Methotrexate	Rheumatoid disease	Methotrexate toxicity
	Warfarin	Cardiac disease	Risk of gastrointestinal bleeding
Benzocaine	Sulphonamides	Antibacterials	Methaemoglobinaemia
Benzodiazepines	Alcohol (ethanol)	Abuse	Benzodiazepine toxicity
	Cimetidine	Gastric disorders	Benzodiazepine toxicity
	Digoxin	Cardiac disease	Digitalis toxicity
	Fluoxetine	Depression	Benzodiazepine toxicity
	Isoniazid	Tuberculosis	Benzodiazepine toxicity
	Oral contraceptives	Contraception	Benzodiazepine toxicity
	Phenytoin	Epilepsy	Phenytoin toxicity
	Protease inhibitors	HIV/AIDS	Benzodiazepine toxicity
	Antiarrhythmics	Arrhythmias	Cardiac depression
	Propranolol	Hypertension	Bupivacaine toxicity
Bupivacaine	Acetazolamide	Diuretics	Lidocaine antagonized
Lidocaine	Antiarrhythmics	Arrhythmias	Cardiac depression
	Atazanavir	Antiviral	Lidocaine enhanced
	Cimetidine	Ulcer-healing agent	Lidocaine enhanced
	Fosamprenavir	Antiviral	Arrhythmias
	Loop diuretics	Diuretics	Lidocaine antagonized
	Lopinavir	Antiviral	Lidocaine enhanced
	Olanzapine or other antipsychotics	Antipsychotics	Arrhythmias
	Propranolol or other beta-blockers	Beta-blockers	Cardiac depression
	Saquinavir	Antiviral	Lidocaine enhanced
	Suxamethonium	Muscle relaxant	Neuromuscular blockade enhanced
Prilocaine	Thiazides	Diuretics	Lidocaine antagonized
	Antiarrhythmics	Arrhythmias	Cardiac depression
	Sulphonamides	Antibacterial	Methaemoglobinaemias

^aN.B. There are many others; check text and appendices on drugs. ALWAYS check the *British National Formulary* or an equivalent source, as these lists cannot be complete; nor can their accuracy be guaranteed.

Table 3.2 Main contraindications and cautions for dental analgesic agents

Dental drugs	Avoid (as well as allergy)	Cautions apart from allergy or pregnancy/lactation
LA	Benzocaine and methaemoglobinaemia Bupivacaine in cardiacs Prilocaine in methaemoglobinaemia	Adrenaline (epinephrine) in people with cardiac disease
Anxiolytics/sedatives	Benzodiazepines with glaucoma or respiratory depressants	Children, older patients Liver or kidney disease Drug or alcohol abuse Head injury
Analgesics	Aspirin in bleeding tendency, young children or peptic ulcer Codeine in children	Non-steroidal anti-inflammatory drugs (NSAIDs) in bleeding tendency, cardiac failure, chronic kidney disease, children, diabetes, gastrointestinal ulcer, hypertension Paracetamol (acetaminophen) with alcohol

as anticonvulsants (e.g. carbamazepine). Tricyclic antidepressants (e.g. amitriptyline) also have a role in the modulation of pain pathways. Muscle relaxants, such as benzodiazepines and hypnosis, may be indicated for pain related to muscle spasm. Analgesic drug use, contraindications and potential adverse reactions and interactions are fully discussed in Chapter 29 (see also Appendices 3.1, 3.2 and 3.3) but Table 3.1 summarizes the main problems relevant to dentistry. Box 27.9 shows drugs whose action may be affected by grapefruit, and Box 27.10 drugs enhanced by pomegranate.

Adjuncts to analgesia include transcutaneous electrical nerve stimulation (TENS), dorsal column stimulation (DCS), acupuncture, rubbing the skin locally (counter-irritation), psychological techniques and neurosurgical procedures.

CONTROL OF MILD PAIN

Non-opioid analgesics are commonly used (Tables 3.3 and 3.6). NSAIDs act peripherally and are equi-analgesic with centrally acting weak opioids such as codeine. NSAIDs act by blocking cyclo-oxygenase (COX), which converts arachidonic acid to prostaglandins (PGs) that are involved in inflammation and pain. Other PGs stimulate protective gastric mucus secretion, blood platelet formation and renal excretion – and thus there can be dysfunction in these. A wide range of NSAIDs is available (Table 3.4). Most block COX-1 in particular, which is responsible for the PGs affecting stomach, platelets and kidneys – and they can thus also damage the stomach and interfere with haemostasis and renal function (Fig. 3.1 and Box 3.2). All NSAIDs can cause serious gastrointestinal effects; azapropazone confers the highest risk and ibuprofen the lowest. NSAIDs cause gastric irritation, ulceration and bleeding, especially in older individuals and patients taking corticosteroids. Piroxicam use is thus now limited to treatment by specialists – of osteoarthritis, rheumatoid arthritis and ankylosing spondylitis. Ketoprofen and ketorolac also have significant gastrointestinal adverse effects. NSAIDs should not be used in patients with current or past peptic ulcers, and not given in combinations. They can also worsen asthma and are contraindicated in pregnancy and in older patients. They inhibit platelet function, but most do so reversibly and therefore prolong the bleeding time only for the life of the drug (typically 48–72 hours). NSAIDs can interact with lithium to cause lithium toxicity. They also block renal PG synthesis and may

Table 3.3 Non-opioid analgesics				
Analgesic	Tablet contains	Route	Adult dose	Comments
Non-NSAIDs				
Acetaminophen (paracetamol)	500 mg	Oral or injection	500–1000 mg up to six times a day (max. 4 mg daily)	Mild analgesic. Not anti-inflammatory. Hepatotoxic in overdose or prolonged use. Contraindicated in liver or renal disease, anorexia, or those on zidovudine. Available with methionine to prevent liver damage in overdose, as co-methiamol
Nefopam	30 mg	Oral or i.m.	30–60 mg up to three times daily	Moderate analgesic. Contraindicated in convulsive disorders. Caution in pregnancy, older patients, renal or liver disease. May cause nausea, dry mouth, sweating
NSAIDs^a				
Aspirin	300 or 325 mg	Oral	300–600 mg up to six times a day after meals (use soluble or dispersible or enteric-coated aspirin) (max. 4 g daily)	Mild anti-inflammatory analgesic. Causes gastric irritation. Interferes with haemostasis. Contraindicated in bleeding disorders, children, asthma, late pregnancy, peptic ulcers, renal disease, aspirin allergy
Diflunisal	250 or 500 mg	Oral	250–500 mg twice a day	Anti-inflammatory analgesic for mild to moderate pain. Long action: twice-daily dose only. Effective against pain from bone and joint. Contraindicated in pregnancy, peptic ulcer, allergies, renal and liver disease
Ibuprofen	200 mg	Oral	200–400 mg up to four times a day	Mild analgesic. Fewer adverse effects than other NSAIDs. Causes gastric irritation. Interferes with haemostasis. Contraindicated in bleeding disorders, children, older people, asthma, cardiac failure, diabetes, hypertension, late pregnancy, peptic ulcers, renal disease, aspirin allergy
Ketorolac	10 mg	Injection or oral	10 mg up to three times a day	Mild anti-inflammatory analgesic. Adverse effects as other NSAIDs. May affect platelets. Allergic reactions (anaphylactoid reactions, asthma, bronchospasm, Stevens–Johnson syndrome, toxic epidermal necrolysis). Fluid retention and oedema – therefore use with caution in cardiac failure or hypertension.
Mefenamic acid	250–500 mg	Oral	250–500 mg up to three times a day	Mild anti-inflammatory analgesic. May be contraindicated in asthma, gastrointestinal, renal and liver disease, and pregnancy. May cause diarrhoea or haemolytic anaemia
Parecoxib	40 mg	Injection	40 mg prn	Mild anti-inflammatory analgesic. Adverse effects as other NSAIDs. May be contraindicated in sulphonamide sensitivity, liver or inflammatory bowel disorders. Non-approval from FDA as with other COX-2 selective inhibitors

^aThere are many other NSAIDs (see Table 3.4).

Table 3.4 Non-steroidal anti-inflammatory drugs (NSAIDs)

Group	Subgroup	Examples
Carboxylic acids	Carbo- and heterocyclic acids	Etodolac
		Indometacin
		Ketorolac
		Sulindac
		Tolmetin
	Fenamic acids	Flufenamic acid
		Meclofenamic acid
		Mefenamic acid
	Phenylacetic acids	Alcofenac
		Diclofenac
		Fenclofenac
	Propionic acids	Fenbufen
		Fenoprofen
		Flurbiprofen
		Ibuprofen
		Ketoprofen
		Naproxen
		Oxaprozin
		Tiaprofenic acid
		Aspirin (acetyl salicylic acid)
		Diffunisal
Selective cyclooxygenase-2 inhibitors	Cox inhibitor	Paricoxib
		Valdecoxib
	Oxicams	Isoxicam
		Piroxicam (restricted use because of gastrointestinal effects and rashes)
		Tenoxicam
Enolic acids	Pyrazolones	Butazones
		Propazones
Non-acidic compounds		Nabumetone

lead to acute renal failure, particularly in older patients with cardiac failure and those with renal damage, such as diabetic nephropathy. In these groups, renal function should be monitored. Aspirin is a typical NSAID, which has the effects described above but also irreversibly inhibits platelet function and therefore causes a prolonged bleeding time for the life of the platelets (about 7–8 days minimum).

Misoprostol, H2 antagonists or proton pump inhibitors can help protect the stomach in NSAID use. However, NSAIDs that act as COX-2 inhibitors, such as celecoxib and rofecoxib, spare the COX-1 enzyme and thus cause less gastric damage; they do not affect platelets and are preferred for patients with peptic ulceration, but are contraindicated in cardiac disease and should not be used together with aspirin. COX-2 inhibitors have much less effect on the stomach, platelets and kidneys but, unfortunately, are also associated with a thrombotic risk (e.g. myocardial infarction and stroke), as are non-selective NSAIDs such as diclofenac and ibuprofen, especially when used at high doses and for long periods. Rofecoxib increases the risk of myocardial infarction and has thus been withdrawn.

Paracetamol (acetaminophen; N-acetyl-para-aminophenol; APAP) has approximately the same analgesic activity as aspirin; it is a useful analgesic and antipyretic (reduces fever) but has no anti-inflammatory activity. Paracetamol appears to act by reducing the oxidized form of the COX enzyme, preventing it from forming pro-inflammatory cytokines, and it also modulates the endogenous cannabinoid system. Paracetamol is metabolized by the liver and by P450 enzymes, responsible for its toxic effects due to a minor alkylating

metabolite (*N*-acetyl-*p*-benzoquinone imine, abbreviated as NAPQ1). Paracetamol causes no gastric irritation and is remarkably safe but, in overdose, it can cause liver damage. It accounts for most drug overdoses in the resource-rich world. Up to 4 g daily is the maximum dose for an adult, but toxicity is increased by starvation and by alcohol, anticonvulsants, barbiturates and possibly zidovudine. *Co-methiamol* is a combination tablet of paracetamol with methionine included to ensure that sufficient levels of glutathione in the liver are maintained in order to minimize the liver damage if an overdose is taken.

CONTROL OF MODERATE PAIN

If an NSAID or paracetamol (acetaminophen) fails to control pain, an opioid may be indicated (Tables 3.5 and 3.6). Opioids activate the μ 1 receptor in the CNS that is responsible for analgesia. Weak oral opioids, such as codeine (methymorphine), act centrally to provide useful analgesia. The analgesic efficacy of codeine is partly dependent on its O-demethylation to morphine via cytochrome P450, which exhibits genetic polymorphism, and therefore the degree of pain relief

Table 3.5 Opioids^a

Analgesic	Tablet contains	Route	Adult dose (always check with BNF)	Comments (avoid all in known hypersensitivity to the drug or known intolerance to other opioid agonists)
Codeine phosphate	15 mg	Oral	10–60 mg up to six times a day (or 30 mg i.m.)	Analgesic for moderate pain. Contraindicated in late pregnancy, children and liver disease. Avoid alcohol. May cause sedation and constipation. Weakens cough reflex
Dextropropoxyphene	65 mg	Oral	65 mg up to four times a day	Analgesic for moderate pain. Risk of respiratory depression in overdose, especially if taken with alcohol. Can cause dependence. Occasional hepatotoxicity. No more effective as an analgesic than paracetamol/acetaminophen or aspirin alone. Available with acetaminophen as co-proxamol
Dihydrocodeine tartrate	30 mg	Oral	30 mg up to four times a day (or 50 mg i.m.)	Analgesic for moderate pain. May cause nausea, drowsiness or constipation. Contraindicated in children, hypothyroidism, asthma and renal disease. Interacts with MAOI. May increase post-operative dental pain. Reduce dose for elderly. Available with paracetamol as co-drydamol
Fentanyl	50 micrograms	Injection. Patch and buccal tablet, lozenge and spray available	50 micrograms as required	Analgesic for moderate to severe pain. 100 times more potent than morphine. Danger of respiratory depression/death. Contraindicated in hypovolaemia, hypotension, raised intracranial pressure, respiratory insufficiency.
Alfentanil	50 micrograms	Injection	50 micrograms as required	Analgesic for moderate to severe pain. Can cause muscle rigidity. Contraindications liver disease, bradycardia, phaeochromocytoma and as for fentanyl
Remifentanyl	0.1 micrograms/kg	Injection	0.1 micrograms/kg	Analgesic for moderate to severe pain but not in conscious patients. Contraindications as for alfentanil
Pentazocine	25 mg	Oral	50 mg up to four times a day (or 30 mg i.m. or i.v.)	Analgesic for moderate pain. May produce dependence. May produce hallucinations. May provoke withdrawal symptoms in narcotic addicts. Contraindicated in pregnancy, children, hypertension, respiratory depression, head injuries or raised intracranial pressure. There is a low risk of dependence
Buprenorphine	0.2 mg	Sublingual	0.2–0.4 mg up to four times a day (or 0.3 mg i.m.)	Potent analgesic. More potent analgesic than pentazocine, longer action than morphine, no hallucinations, may cause salivation, sweating, dizziness and vomiting. Respiratory depression in overdose. Can cause dependence. Contraindicated in children, pregnancy, MAOI, liver disease and respiratory disease
Meptazinol	No tablet available	i.m. or i.v.	75–100 mg up to six times a day	Potent analgesic. Claimed to have a low incidence of respiratory depression. Side-effects as buprenorphine
Phenazocine	5 mg	Oral or sublingual	5 mg up to four times a day	Potent analgesic for severe pain. May cause nausea
Pethidine	No tablet available	s.c. or i.m.	25–100 mg up to four times a day	Potent analgesic. Less potent than morphine. Contraindicated with MAOI. Risk of dependence
Morphine	As required	s.c., i.m., oral or suppository	5–10 mg	Potent analgesic. Often causes nausea and vomiting. Reduces cough reflex, causes pupil constriction, risk of dependence
Diamorphine	10 mg	s.c., i.m. or oral	2–5 mg by injection, 5–10 mg orally	Potent analgesic. More potent than pethidine and morphine. Euphoria and dependence

^aNot usually appropriate for dental pain.

Table 3.6 The analgesic ladder

Mild pain	Moderate pain	Severe pain
Paracetamol (acetaminophen)	Paracetamol (acetaminophen) ± oral opioid (codeine, dihydrocodeine or non-steroidal anti-inflammatory drug [NSAID])	Paracetamol (acetaminophen) + injected opioid (morphine)

and the adverse effects may vary significantly between individuals. It is thus contraindicated in children (<http://www.fda.gov/Safety/MedWatch/default.htm>; accessed 30 September 2013). Despite this, codeine is widely used for postoperative pain relief in adults, at a dose of 30–60 mg, often in combination with paracetamol.

Activation of the mu₂ receptor by opioids can lead to the undesired effects of respiratory depression, sedation, constipation, nausea

and vomiting. Opioids also depress ventilation by muting the brain response to carbon dioxide. They may therefore be contraindicated in patients who have acute or chronic respiratory disease and seizures.

Tramadol is another mild opioid that acts as an opioid receptor agonist; it also inhibits spinal monoamine reuptake and is an effective analgesic. It causes less sedation and respiratory depression than other opioids, though nausea and vomiting can be troublesome. Use of 5-hydroxytryptamine 3 (5HT₃) antagonists to prevent the nausea and vomiting associated with tramadol may reduce its analgesic efficacy. Tramadol is contraindicated in epilepsy and porphyria, and in patients on antidepressants or antipsychotics. It may precipitate the serotonin-ergic syndrome – a potentially life-threatening drug reaction that may arise mainly in combination with recreational drugs and antidepressants (monoamine oxidase inhibitors [MAOIs], selective serotonin reuptake inhibitors [SSRIs] and selective serotonin–noradrenaline reuptake inhibitors [SSNRIs]).

Table 3.7 Hypnotics

Hypnotic	Duration of action	Examples	Comments
Benzodiazepines	Long	Diazepam, flunitrazepam, flurazepam, nitrazepam	Residual effects on following day (hangover effect). Dependence can result
	Shorter	Loprazolam, lorazepam, temazepam	–
Pyrazolopyrimidine	Very short	Zaleplon	–
Cyclopyrrolone	Short	Zopiclone	Dependence is possible
Imidazopyridine	Short	Zolpidem	Dependence is possible
Clomethiazole	Medium	Clomethiazole	Pronounced hangover. Anticholinergic effects such as dry mouth
Antihistamines	Medium	Diphenhydramine, promethazine	–

CONTROL OF SEVERE PAIN

Severe pain requires treatment with potent opioids (e.g. morphine, pethidine, oxycodone, fentanyl, alfentanil or remifentanyl; [Tables 3.4, 3.5 and 3.6](#)). Opioids control pain, and reward addictive behaviours, exerting their actions through opioid receptors whose genes have been cloned (*Oprm*, *Oprd1* and *Oprk1*, respectively). Opioid receptors are activated by a family of endogenous peptides (enkephalins, dynorphins and endorphin), or exogenously by alkaloid opiates, the prototype of which is morphine. Mu receptors mediate both the therapeutic and the adverse activities of morphine; mu-opioid receptors are a key molecular switch triggering brain reward systems and potentially initiating addictive behaviours. Delta-receptors regulate emotional responses.

Oxycodone and fentanyl are no more effective than morphine but may have fewer adverse effects. Opioids can be addictive and can cause respiratory depression, which can be reversed with naloxone; supplemental oxygen may be indicated. Other effects include pinpoint pupils, sedation, nausea, constipation and pruritus. The benefits of opioids must be weighed against their adverse effects. Choice of drug and route of administration depends on the particular clinical situation and care must be taken when converting from one form of drug or administration route to another, as doses will vary.

Postoperatively, morphine may be administered orally but, as some patients may need to be kept nil by mouth, or gastrointestinal absorption may be reduced or unpredictable, intramuscular or subcutaneous administration may be needed. Nevertheless, intramuscular injections are painful, absorption is unpredictable and dangerous, and analgesia cannot be accurately titrated to clinical need. Intravenous morphine is the only way to establish a suitable degree of analgesia reliably, but issues about the timing of administration and who may safely administer it have led to the development of more demand-dependent systems of analgesic delivery.

Patient-controlled analgesia

The disadvantages of giving morphine as required (p.r.n.) are due to the peak effects, which may oversedate and cause nausea and vomiting while, during the trough, the patient may have inadequate analgesia. Patient-controlled analgesia (PCA), which consists of an infusion pump which delivers a small bolus whenever a demand button is pressed within the confines of a set 'lock-out' time, solves some of these problems.

CONTROL OF CHRONIC AND NEUROPATHIC PAIN

Sustained-release oral formulations of morphine or oxycodone or transdermal administration of fentanyl may help some patients with chronic pain. Antidepressants and anticonvulsants can also be useful.

Psychological therapies, as well as alternative techniques such as TENS, may also help, as may one of several neurosurgical procedures.

CHOICE OF ANAESTHETIC TECHNIQUE FOR DENTAL PROCEDURES

Dental professionals should ensure that due regard is given to all aspects of behavioural management and anxiety control before deciding to treat under LA, CS or GA. The choice of an appropriate method for a particular patient undergoing a specific procedure depends on several factors, including the type of procedure or operation indicated, the physical and mental health of the patient ([Appendix 3.4](#)), the effects of the agents used and the patient's wishes. Attempts have been made to grade patients as regards physical fitness for operation ([Ch. 2](#)) and these may help in decision-making ([Appendix 3.5](#)). The degree of cooperation must be taken into account; this may be lacking in some children and other people. Other factors that may influence the decision include social circumstances (e.g. is the patient able to be accompanied, and cared for at home?), urgency and facilities available at the time.

Hypnotics can be useful preoperatively, to help the patient relax and sleep ([Table 3.7](#)); most, apart from antihistamines and clomethiazole, act on receptors for GABA. However, all can impair decision-making and driving.

LA should be used wherever possible for outpatient dentistry ([Table 3.8](#)), with CS if necessary. GA and so-called 'sedation with intravenous barbiturates' are significant causes of morbidity or even mortality, and should be given only in a hospital with critical care facilities.

LOCAL ANAESTHESIA (LOCAL ANALGESIA)

The first use of cocaine as LA in surgery is credited to an Austrian ophthalmologist, Koller, who, in 1884, used cocaine at the suggestion of Freud. Subsequently, dozens of LA compounds have been developed and used in solution to block nerve conduction temporarily. LA molecules bind specifically to sodium channel proteins in axonal membranes of neurons near the injection site, with essentially no effects centrally unless given in overdose. LAs used in dentistry are mostly amides ([Box 3.3](#)) (e.g. articaine, bupivacaine, lidocaine, mepivacaine, prilocaine, ropivacaine). Earlier ester-type agents (e.g. procaine, benzocaine) are only rarely used. A vasoconstrictor is usually included to maintain the duration of anaesthesia. Adrenaline (epinephrine) is the most commonly used vasoconstrictor; felypressin (Octapressin®) is an alternative and is used with prilocaine.

Adverse reactions to LAs may also include dose-related toxic responses (cardiovascular and CNS) in normal individuals (especially

Table 3.8 Possible indications for and contraindications to local anaesthesia (LA)

May be contraindicated	May be indicated
Patients on beta-blockers if very large doses are given	After a recent meal
Patients with sensory loss in the trigeminal region	Inadequate facilities for general anaesthesia (GA)
Local infection	No GA available
LA 'allergy'	Poor-risk patients for GA
Liver disease: doses should be reduced	Minor surgery or procedure
Very young children	
Needle-phobics	
Haemangioma in field

if the agents enters the vasculature), and idiosyncratic or allergic responses. Most adverse reactions to LA administration are unrelated to the drug and are caused by fainting or by inadvertent entry of the drug into the circulation. One study showed blood aspiration into the LA cartridge in nearly 3% of injections. LA injections should be given with an aspirating syringe to avoid intravascular injection of adrenaline (epinephrine) in particular. It is also wise to use a safety syringe in order to reduce the risk of needlestick (sharps) injury. The LA should then be injected slowly. Reactions unrelated to LA agents include psychomotor responses and sympathetic or other nerve stimulation. The common adverse reactions of inadvertent intravenous administration of LA should be appropriately recognized and explained to the patient. Arrhythmias and electrocardiogram (ECG) changes, such as ST-segment depression, may be detectable during dental extractions or operations under LA, presumably due to trigeminal stimulation. Patients being treated with digoxin for atrial fibrillation or congestive heart failure are more prone to these arrhythmias.

Overdosage has caused deaths associated with LA but otherwise mortality is very rare indeed. Over a 10-year period, there were only three deaths in persons receiving dental care under LA in Britain when last recorded (1980–1989). *All* were related to the use of prilocaine. This fact does not suggest that prilocaine is dangerous but serves to emphasize that it is not necessarily safer than lidocaine. *Amide LAs have been given to millions of patients, many of whom must have been medically compromised, for nearly half a century, with few serious untoward reactions.* It is difficult, therefore, to believe that, in moderated doses, they can cause significant toxic or allergic reactions.

It is questionable whether there have been many genuine (immunoglobulin E [IgE]-mediated) allergic reactions to lidocaine. However, there have been occasional reactions to other components, such as the

Fig. 3.2 Skin vasoconstriction after dental local anaesthetic injection.

preservative, since vasoconstrictor solutions may also contain antioxidants such as bisulphites (Ch. 17).

The overall incidence of complications of all types from LA is reportedly around 4.5% but most of these are of a trifling nature. Local adverse effects may include blanching of the facial skin (Fig. 3.2), transient facial palsy (LA misplaced and entering the parotid gland, where it affects the facial nerve), visual disturbance (misplaced posterior superior alveolar nerve LA can produce diplopia, mydriasis, palpebral ptosis and abduction difficulties of the affected eye), persistent anaesthesia (prilocaine and articaine in particular are mildly neurotoxic, and any LA injection can physically damage nerves), trismus (damage to nerve supply or medial pterygoid muscle, or bleeding into the area) or lip trauma (due to the patient biting an anaesthetized lip). None of these is common or permanent.

Drug interactions with LA solutions are rare, if at least theoretically possible (see Table 3.1 and Ch. 29). Adrenaline (epinephrine) was alleged to be potentiated in patients taking tricyclic antidepressants but this has been disproved. In patients on beta-blockers, interactions may be possible because of the unopposed beta-sympathomimetic activity of adrenaline, but this only happens when excessively large doses of an adrenaline-containing LA are given. Other interactions are exceedingly rare (see below) and contraindications may include some cardiac disorders (especially heart block or other conduction disturbances), porphyria and myasthenia gravis (see individual LA agents below).

Local anaesthetic creams (e.g. Ametop; tetracaine [amethocaine] or Emla; lidocaine plus prilocaine) effectively reduce the pain of needle pricks and are thus useful for skin injections in children.

LOCAL ANAESTHETIC AGENTS

Most LAs are metabolized in the liver.

Articaine (articaine)

Articaine is an amide-type LA that has an onset and duration of anaesthesia similar to those of other intermediate-acting amide LAs. The most significant benefit of articaine over lidocaine is that it may have somewhat faster onset and greater depth of action. Articaine is 1.5 times as potent and only 0.6 times as toxic as lidocaine and has

Table 3.9 Indications for and contraindications to LA with articaine*

May be contraindicated	May be indicated
Porphyria	Patients on beta-blockers
Heart block	
Cholinesterase deficiency	
Narrow-angle glaucoma	

*Some advise against use in block anaesthesia.

been shown to be superior in achieving successful anaesthesia following infiltration. It is not for injection in children under 4 years of age. However, the use of inferior alveolar nerve blocks can be almost eliminated in children by using articaine due to its ability to anaesthetize teeth effectively by infiltration up to the first permanent molar region. In addition, diffusion of articaine on to the palatal surface may also eliminate the discomfort of palatal infiltration. It can also be used in patients taking beta-blockers.

Articaine may be mildly neurotoxic and can cause prolonged anaesthesia, but its other adverse effects, toxic reactions and drug interactions (solutions containing a vasoconstrictor) are the same as those of other amide LAs (Table 3.9). The maximum recommended adult dose for articaine is 7mg/kg. It should possibly not be given in porphyria.

Bupivacaine

Bupivacaine is an amide-type LA with a slow onset but long duration of action. It is therefore useful intraoperatively for patients under GA, to reduce the trigeminal nerve stimulation that can cause arrhythmias, and to give prolonged pain control postoperatively. It binds to plasma proteins and has a plasma half-life of 1.5–5.5 hours. Bupivacaine is largely metabolized in the liver. Maximum dose is 2.5 mg/kg.

Bupivacaine is the most cardiotoxic of the LAs (Table 3.10), the cardiotoxic effects being enhanced by hypoxia, hypercapnia, acidosis and hyperkalaemia. It inhibits cardiac conductivity and contractility, and may induce ventricular fibrillation. Bupivacaine therefore should not be used for patients with cardiac disease. Levobupivacaine, the L-isomer of bupivacaine, is of similar potency to bupivacaine but has the advantage of being significantly less cardiotoxic and neurotoxic than racemic bupivacaine.

Lidocaine

Lidocaine is the most widely used LA in many countries. Because of its effectiveness and the paucity of significant adverse reactions to it after half a century of use, lidocaine with adrenaline (epinephrine) is the standard against which other LAs are judged. It is an amide type with a rapid onset of action, providing LA of intermediate to long duration. Less than 10% of lidocaine is excreted unchanged in the urine. Lidocaine is metabolized mainly by the liver with an elimination half-life of 1–2 hours, and rapidly undergoes first-pass metabolism. The main metabolites also have LA activity and contribute to the effects of lidocaine as they have longer half-lives. Lidocaine can cross the placenta and may enter breast milk.

Serious adverse effects of lidocaine are exceedingly rare and most adverse reactions are due to misplacement of the needle, incompetent administration or overdose. There may not, however, be a linear relationship between the dose of lidocaine and the resultant blood level. In general, toxicity is more likely in children, older people and some acutely ill patients. Early features of overdose include tinnitus,

circumoral paraesthesia, metallic taste, light-headedness, nausea, vomiting and double vision. At higher levels, nystagmus, slurred speech, auditory and visual hallucinations, localized muscle twitching and tremors of the hands and feet are possible. Convulsions followed by loss of consciousness, respiratory arrest and eventual cardiovascular collapse may also occur. Lidocaine may cause some degree of depression of atrial and atrioventricular nodal activity, intraventricular conductivity and ventricular contraction. Excessive doses of lidocaine have been followed by death.

Lidocaine should not be given in a dose exceeding 4.4mg/kg body weight. The maximum dose of lidocaine for the average adult is therefore 300 mg. If lidocaine is used in combination with adrenaline (epinephrine), the safe dose is up to 7 mg/kg, increasing the maximum dose of lidocaine to 500mg for an average adult. A dental LA cartridge of 2.2 mL containing lidocaine 2% with adrenaline contains 44 mg of lidocaine, and thus the maximum safe number of cartridges for a normal adult would be 11 cartridges (7 cartridges if used without adrenaline). Lidocaine solution with adrenaline contains sodium metabisulphite to prevent oxidation of adrenaline; it should not be given to patients allergic to sulphites. Lidocaine may be contraindicated (Table 3.11) in patients with some cardiac disorders (especially hypovolaemia, heart block or other conduction disturbances), porphyria and myasthenia gravis. Lidocaine should be used in lower doses in children and older patients, and in cardiac, hepatic or renal disease. Impaired lidocaine metabolism may be found in severe cardiac failure and liver disease. Factors that affect hepatic blood supply and/or enzyme function can also significantly influence lidocaine metabolism.

Adrenaline can cause unopposed alpha-adrenergic activity in patients taking beta-blockers but only if LAs are given in far larger doses than appropriate for dentistry. Beta-blockers may also reduce hepatic blood flow and inhibit hepatic microsomal enzymes. By contrast, phenytoin, benzodiazepines and barbiturates may induce hepatic enzymes, lowering levels of free lidocaine.

Mepivacaine

Mepivacaine is an amide-type LA with a more rapid onset and shorter duration of action than lidocaine, and is rapidly metabolized in the liver. It binds to plasma proteins and has a plasma half-life of 2–3 hours. About 50% of the metabolites of mepivacaine are excreted in urine. Mepivacaine can cross the placenta.

Prilocaine

Prilocaine is an amide-type LA of fast onset and intermediate duration of action. Prilocaine metabolism is similar to that of lidocaine,

Table 3.12 Indications for and contraindications to LA with prilocaine

May be contraindicated	May be indicated
Glucose-6-phosphatase deficiency: greater risk of methaemoglobinaemia	In some patients with cardiovascular disease
Porphyria	
In patients on antimalarials: greater risk of methaemoglobinaemia	
In patients on sulphonamides: greater risk of methaemoglobinaemia	

being rapidly metabolized by the liver and excreted in the urine as *o*-toluidine. The main adverse effect of prilocaine is a dose-dependent production of methaemoglobinaemia resulting in impaired oxygen-carrying capacity. Cyanosis may occur 2–3 hours following administration. The local and systemic adverse effects of prilocaine on the CNS and heart are similar to those of lidocaine. Prilocaine may occasionally cause local neurotoxicity. The maximum adult dose is 400 mg. Prilocaine is contraindicated in methaemoglobinaemia and possibly in porphyria or children (Table 3.12).

Ropivacaine

Ropivacaine is an amide LA that may have a faster onset of action and longer duration of action than lidocaine but lesser pulpal anaesthesia; it can increase blood pressure (BP) and heart rate. It was found to be less cardiotoxic than bupivacaine in animal models. The local and systemic adverse effects of ropivacaine on the CNS and heart are similar to those of lidocaine. Use is prohibited in children of less than 12 years of age, the elderly, people with severe liver disease, and those with hypersensitivity.

VASOCONSTRICTORS

Adrenaline (epinephrine)

The addition of adrenaline to an LA improves haemostasis and anaesthesia; 1 in 80 000 to 1 in 100 000 adrenaline enhances pulpal anaesthesia ninefold and soft-tissue anaesthesia fourfold. It also increases the duration of action of lidocaine and enhances its safety margin. There is controversy about the possible systemic effects of adrenaline in an LA solution (Table 3.13). Adrenaline is a potent sympathomimetic, having significant beta-adrenergic activity (β_1 action raises cardiac rate and contraction force while β_2 activity causes bronchodilatation); it can thus cause a rise in BP, and some alpha activity, which causes vasoconstriction of vessels of the skin and mucosae.

The cardiac effects of adrenaline-containing LA solutions are usually slight but can be significant. Even with the use of aspirating techniques, up to 20% of all LA injections made into the highly vascular head and neck region may result in a significant rapid, albeit transient, rise of peripheral blood levels of adrenaline. There is also a slow rise in peripheral blood levels of adrenaline as a consequence of the gradual release of LA solution from the site of injection into local blood vessels. Adrenaline in LAs can raise cardiac output or BP. This is seen in healthy persons and others with cardiovascular disease. This does not happen when adrenaline is omitted. There is a very small rise in systolic BP (up to 8 mmHg) and a slight fall in diastolic pressure when lidocaine with 1:100 000 adrenaline is used, and up to a 14-mmHg rise with 1:25 000 adrenaline. By virtue of the enhanced anaesthesia, adrenaline may reduce the release of endogenous catecholamines. This is shown by data using tritiated adrenaline, where the rise in peripheral blood

Table 3.13 Indications for and contraindications to LA containing adrenaline

May be contraindicated	May be indicated
After radiotherapy to the area	For maximally effective anaesthesia
Liability to dry socket	
Asthma: patients can be sensitive to sulphites	
In patients on digoxin: may precipitate arrhythmias	
Cardiac bypass grafts: may precipitate arrhythmias	
In patients on beta-blockers: hypertensive crises may result but only in overdose	
In patients on norepinephrine-uptake blockers, St John's wort, atomoxetine, antipsychotic drugs or other psychoactive agents	
In patients who have used drugs of abuse, especially cannabis, ephedrine, clenbuterol or cocaine, in the previous 24 h: additive sympathomimetic effects may develop	
In patients on antiemetics	
Untreated hyperthyroidism	
Phaeochromocytoma	

catecholamine levels associated with intraoral injection of adrenaline-containing LA was mainly due to endogenous adrenaline. Patients with hypertension have greater elevation of systolic pressures after administration of LAs, but patients with ischaemic heart disease or prosthetic cardiac valves have changes similar to those of healthy people. However, systolic and diastolic pressures and cardiac rate can be raised even before the patient attends for dental treatment. The mere sight of a clinician can cause a slight rise in BP ('white-coat hypertension'). Immediately before the injection of LA, there can be significant rises in cardiac rate, systolic pressure and, to a lesser extent, diastolic pressure. Cardiac rate may fall but systolic pressure may rise slightly during administration of the LA. Similar cardiovascular changes may be seen when saline is injected or even if a syringe is placed in the mouth but the needle does not touch the mucosa. Anxiety clearly underlies these changes.

The clinical significance, if any, of the above remains unclear, but some argue that adrenaline is best avoided in cardiac patients or those on beta-blockers. However, this remains debatable. If a less effective LA is used, pain may not be completely abolished and this can have significant adverse effects on the heart. Also, in the case of patients on beta-blockers, interactions have only resulted when excessively large doses of an adrenaline-containing LA have been given.

Adrenaline-containing LAs may cause a significant but transient fall in plasma potassium, an effect particularly noticeable in patients on non-potassium-sparing diuretics (e.g. thiazide and loop diuretics). This hypokalaemic action appears due to a β_2 -adrenergic action on membrane-bound adenosine triphosphatase (ATPase). Adrenaline-containing LAs may also cause a transient rise in plasma glucose levels, due to α_2 -adrenergic inhibition of insulin release, but these changes appear to have no clinical significance.

In the case of cocaine intoxication, adrenaline-containing LAs and other adrenergic vasoconstrictors are completely contraindicated. Adrenaline-containing LAs may also slightly delay wound healing after dental surgery and may increase the frequency of post-extraction alveolar osteitis ('dry socket').

Adrenaline is rapidly inactivated by the liver via both catechol-*O*-methyl transferases (COMTs) and monoamine oxidases (MAOs). The metabolites are excreted in urine, mainly as glucuronides or ethereal sulphate conjugates.

Table 3.14 Possible indications for and contraindications to prilocaine with felypressin

May be contraindicated	May be indicated
In cardiac patients	For better anaesthesia than with prilocaine alone
In patients with a liability to dry socket	
Theoretically, in pregnant patients	

Table 3.15 Indications and contraindications for LA by intraligamentary injection

May be contraindicated	May be indicated
Possibly in patients predisposed to infective endocarditis	Bleeding tendencies

Table 3.16 Indications for and contraindications to electronic dental analgesia

May be contraindicated	May be indicated
Demand-type pacemakers	–
Cerebrovascular disease	
Epilepsy	

Felypressin

Felypressin is a synthetic analogue of vasopressin with little of its anti-diuretic or oxytocin-like actions. Theoretically, it can cause coronary artery vasoconstriction and might affect the uterus in pregnancy, but these effects are unlikely with dental LA preparations. The administration of large amounts of felypressin to patients receiving GA with halothane may result in cyanosis and a slight rise in BP, but these changes are not serious. Felypressin has little toxicity, even if given intravenously in amounts far in excess of those used for LA (Table 3.14).

Over the years however, prilocaine with felypressin has not been shown to be safer than lidocaine with adrenaline (epinephrine), which generally provides deeper and more effective pain control.

OTHER METHODS OF LOCAL ANALGESIA

Intraligamentary (intraligamental) injections

Intraligamentary injections given after topical anaesthesia are recommended for restorative procedures in mandibular teeth in haemophilic patients. The intraligamentary injection administered with a computer-controlled local anaesthetic delivery system (wand) is successful, particularly in palatal injections and when an inferior alveolar nerve block fails to provide profound pulpal anaesthesia in mandibular posterior teeth of patients presenting with irreversible pulpitis. Indications and contraindications are shown in Table 3.15.

Electronic dental analgesia

A number of dedicated electronic dental analgesia (EDA) systems are available. Some studies found that many patients (60%) preferred EDA to LA for restorative dentistry; however, others found that the levels of effectiveness of EDA were similar to those of topical anaesthesia, reducing the discomfort of LA injections in only 26% of cases. Indications and contraindications are shown in Table 3.16.

CONSCIOUS SEDATION

Changes in the provision of GA for UK dental services, and recommendations by repeated working groups that GA for dental treatment should only be used when there is no other method of pain and anxiety management appropriate for that patient, have led to the growing use of conscious sedation (CS). This is defined as:

a technique in which the use of a drug or drugs produces a state of depression of the central nervous system enabling treatment to be carried out, but during which verbal contact with the patient is maintained throughout. No interventions are required to maintain a patent airway, spontaneous ventilation is adequate and cardiovascular function is maintained. The drugs and techniques used to provide conscious sedation for dental treatment should carry a margin of safety wide enough to render loss of consciousness unlikely. (Department of Health. Conscious sedation in the provision of dental care: report of an expert group on sedation for dentistry – see Useful websites.)

The Indicator of Sedation Need (IOSN) is increasingly used to assess needs.

PROCEDURAL SEDATION

Procedural sedation is ‘a technique of administering sedatives or dissociative agents with or without analgesics to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function’. Procedural sedation and analgesia (PSA) is intended to depress conscious level but to allow the patient to maintain oxygenation and airway control independently.

Degree of conscious level loss

ASA has defined the various sedation depths:

Minimal sedation (anxiolysis)

- Response to verbal stimulation is normal
- Cognitive function and coordination may be impaired
- Ventilatory and cardiovascular functions are unaffected.

Moderate sedation/analgesia (also called conscious sedation)

- Depression of consciousness is drug-induced
- Patient responds purposefully to verbal commands
- Airway is patent and spontaneous ventilation is adequate
- Cardiovascular function is usually unaffected.

Deep sedation/analgesia

- Depression of consciousness is drug-induced
- Patient is not easily aroused but responds purposefully following repeated or painful stimulation
- Independent maintenance of ventilatory function may be impaired
- Patient may require assistance in maintaining a patent airway
- Spontaneous ventilation may be inadequate
- Cardiovascular function is usually maintained.

General anaesthesia

- Loss of consciousness is drug-induced, where the patient cannot be aroused, even by painful stimulation
- Patient’s ability to maintain ventilatory function independently is impaired
- Patient requires assistance to maintain patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function
- Cardiovascular function may be impaired.

Monitoring sedation

- Monitor vital signs before, during and after the procedure
- Monitor the ECG continuously in high-risk patients, during prolonged procedures or during deep sedation
- Consider continuous pulse oximetry for patients with co-morbidities (e.g. chronic obstructive pulmonary disease [COPD], asthma, congestive heart failure) or when high doses of sedatives or multiple drugs that may depress respirations are used
- Monitor the patient’s appearance
- Monitor airway patency
- Monitor response to physical stimuli and verbal command
- Remember that measurement of blood gas level may be required
- Consider capnography for high-risk patients.

Suitability for CS

Only patients who are in ASA categories I and II are suitable for treatment under CS outside a hospital department. CS can be helpful for treating patients with needle phobia or other fears, pronounced gag reflex or anxiety, and for complex procedure such as endodontic and surgical work. It is normally used in conjunction with appropriate LA.

Most anxious patients can be treated with oral sedation (with benzodiazepines such as temazepam) or intravenous techniques with benzodiazepines (e.g. midazolam), or transmucosal sedation with benzodiazepines (usually nasal or sublingual midazolam) or inhalational sedation (with nitrous oxide and oxygen). Others may respond to a combination of alternative techniques, such as intravenous sedation with propofol or more than one drug.

Particular care is necessary in patients who are old, pregnant or very young, or who have cardiovascular, respiratory, liver, kidney or psychiatric disorders (Table 3.17). All patients should have thorough medical, dental and social histories taken and their dental examinations should be recorded for each course of treatment. BP measurement (Fig. 3.3), colour, pulse and respiration are important, as they determine patient selection and monitoring of the procedure. The ASA status should be determined.

Written informed consent must be obtained before each operation. Suitable consent forms are supplied by the medical defence societies. It is desirable, and there is increasing pressure, to provide patients with written information relevant to their treatment. Due consideration should be given to the patient’s regular medication, if any (Table 3.18).

Sedated and anaesthetized patients may lose their cough reflex and the ability to protect their airway adequately. Material from the mouth or elsewhere can thus be aspirated into the larynx or lungs. Thus the airway must be protected by the anaesthetist/sedationist.

Table 3.17 Indications for and contraindications to conscious sedation

May be contraindicated	May be indicated
Intravenous sedation	
Psychotic personalities	Involuntary movements (e.g. chorea, parkinsonism)
Severe (disabling) heart disease	Uncooperative patients (e.g. learning impairment)
Respiratory infections	Patients who faint with local anaesthesia
Airways obstruction	Patients with a tendency to retch
Fascial space infections	Where stress may induce attacks of angina
Chronic obstructive pulmonary disease	Where stress may induce attacks of epilepsy
Unescorted patients	Where stress may induce attacks of asthma
Pregnancy	Where stress may induce attacks of hypertension
Children	Patients too anxious to accept treatment under LA
Needle-phobics	Many prolonged operations, such as removal of third molars or preparation for multiple implants for which GA would otherwise be needed
Liver disease	Upper airways obstruction
Myasthenia gravis	Claustrophobic patients
Glaucoma	
Inhalational sedation	
Psychoses	Children
Pregnancy during the first trimester	Drug users
Claustrophobic patients (mask phobia)	Myasthenia gravis
Respiratory infections	Asthma
After some eye surgery	Needle-phobics
In patients with vitamin B ₁₂ deficiency or on methotrexate	Patients with tendency to retch
Where access to the nose is required	Epilepsy

Fig. 3.3 Blood pressure measurement using sphygmomanometry.

PRE-MEDICATION

Pre-medication may still be administered for the purposes of diminishing anxiety, decreasing secretions, and reducing pain and vomiting (Table 3.19).

CONDUCTING CONSCIOUS SEDATION

In conducting sedation in the UK, the requirements of the Code of Practice issued by the General Dental Council must be fulfilled (Box 3.4;

Table 3.18 Preoperative modification of regularly used medications before operation under conscious sedation or general anaesthesia

Medication	Action (always discuss with the physician responsible for the patient)
Alpha-blockers	Continue
Analgesics	Continue
Angiotensin-converting enzyme inhibitors (ACEIs)	Continue
Antiarrhythmics	Continue
Anticholinesterase eye drops	May theoretically prolong the effect of suxamethonium and mivacurium; usually continue
Anticoagulants	Continue or consult haematologist
Anticonvulsants	Continue
Antimicrobial	Continue
Aspirin	Continue except for some surgery (e.g. urological and neurosurgery)
Beta-blockers	Continue
Calcium-channel blockers	Continue
Contraceptive pill	Continue
Corticosteroids	Continue, and raise dose (Ch. 6)
Digoxin	Continue
Diuretics (potassium-sparing)	Omit on morning of operation
Diuretics (thiazides or loop)	Continue
Heparin	Last prophylactic dose must be 6 h before operation
Insulin or antidiabetics	Consult diabetologist; usually change to a sliding scale (Ch. 6)
Lithium	Stop 1 day before major surgery
Monoamine oxidase inhibitors (MAOIs)	Dangerous hypertensive interaction with certain opioid drugs. Preferably stop a few weeks before surgery if opioids are to be used
Non-steroidal anti-inflammatory drugs (NSAIDs)	Continue
Oral hypoglycaemics	Last dose is administered the night before a morning operating list, or the morning of an afternoon list
Selective serotonin reuptake inhibitors (SSRIs)	May interact with other drugs that facilitate serotonin (e.g. tramadol and other antidepressants): possibility of serotonin syndrome (dangerous neuromuscular and autonomic overactivity); consult anaesthetist
Statins	Continue
Tricyclic antidepressants	Exaggerate the effects of catecholamines; consult anaesthetist
Warfarin	Continue usually; consult haematologist

Table 3.19 Pre-medication

Aim	Drugs used
Reduction of anxiety	Temazepam 10–30 mg p.o. (adults); oral midazolam 0.5 mg/kg or alimemazine (trimeprazine) 2 mg/kg p.o. (children)
Decrease in secretions	Glycopyrrolate
Analgesia	NSAIDs are commonly administered in adults; paracetamol in children
Antiemetic	Promethazine or alimemazine

see Appendix 3.4). Suitable resuscitative equipment, including a defibrillator, must always be available.

The dental surgery should be large enough to allow adequate access for the dental team all around the patient. The dental chair must be capable of being placed in the horizontal position. Dedicated purpose-

Box 3.4 Requirements before using conscious sedation

- Written medical history
- Previous dental history
- Written instructions have been provided pre- and postoperatively
- The presence of an accompanying adult
- The patient has complied with pre-treatment instructions
- The medical history has been checked and acted on
- Records of drugs employed, dosages and times given, including site and method of administration
- Previous conscious sedation/general anaesthesia history
- Pre-sedation assessment
- Any individual specific patient requirements
- Suitable supervision has been arranged
- Written documentation of consent for sedation (consent form)
- Records of monitoring techniques
- Full details of dental treatment provided
- Post-sedation assessment

designed relative analgesia (inhalational sedation; IS) machines for dentistry should be used. Such machines should be maintained according to manufacturers' guidance with regular documented servicing. Gas supply lines for IS machines must be connected by non-interchangeable colour-coded pipelines to the medical gas supply or a mobile four-cylinder stand. On installed pipelines there must be a low-pressure warning device and an audible alarm. Nitrous oxide and oxygen cylinders must be stored safely with regard to current regulations. Cylinders must be secured safely to prevent injury. There should be adequate scavenging of waste gases. Inadequate scavenging may result in unacceptable risks to the health of the dental team. Scavenging of gases should not rely on window-opening or air-conditioning alone, and in the UK should conform to current Control of Substances Hazardous to Health (COSHH) Regulations (2002; <http://www.hse.gov.uk/coshh/>, accessed 30 September 2013). The long-term exposure limit (LTEL) represents a time-weighted average (TWA) over an 8-hour reference period defined in COSHH Regulation EH40 as the procedure whereby the occupational exposures in any 24-hour period are treated as equivalent to a single uniform exposure for 8 hours – the TWA exposure; recommended LTELs range from 25 to 100 ppm. Breathing systems should have separate inspiratory and expiratory limbs to allow proper scavenging. Active and passive systems are available for scavenging. Nasal masks should be close-fitting to provide a good seal without air entrainment valves. All the appropriate equipment for the administration of sedation must be available in the surgery. This includes syringes, needles, cannulae, surgical wipes/tapes/dressings, tourniquets and labels. Purpose-designed, calibrated and appropriately maintained equipment is essential for all infusion techniques. It is mandatory to be able to administer supplementary oxygen or oxygen under intermittent positive pressure ventilation (IPPV) to the patient, should the need arise.

There must be at least one other person present at all times, who is suitably qualified and experienced enough to monitor the level of sedation and well-being of the patient. The levels of theoretical and practical training required by team members, regulations regarding standard and emergency equipment, monitoring, recovery facilities, consent, and instructions to patients and carers have been described in two UK Department of Health reports (see Further reading). An overview of the practical techniques only is provided here.

The clinical record for CS should include the reason for it and evidence of the consent process (Box 3.5). Instructions should be given in

Box 3.5 Inhalation sedation (IS) technique

1. Check that the IS (relative analgesia) machine and scavenging are functioning properly and that an alternative supply of oxygen (O_2) is available
2. Recline the patient with legs uncrossed and position the mask over the patient's nose
3. Close the air entrainment valve on the mask (if present) and start administering 100% O_2 at a flow rate to approximate the patient's minute volume. This has been achieved when the reservoir bag moves with each breath without collapsing or overinflating and the patient does not have to mouth-breathe. (Correct flow rates are typically 5–8 L/min for an adult. Paediatric minute volumes vary with age)
4. Turn the nitrous oxide (N_2O) inspired concentration to 10% and advise the patient that they may start to feel warm or light-headed, or experience tingling of the extremities
5. After ensuring that the patient's speech (which may be slurred) is maintained for 1 min, increase the N_2O in increments of 5–10% at 1-min intervals until a relaxed state is reached. Inspired N_2O concentrations of 25–35% are typically used; concentrations exceeding 50% should be avoided
6. Supplement the inhalational sedation throughout with positive comments of reassurance and instructions
7. Delayed verbal or motor responses, visual or auditory changes, warmth and paraesthesia are all signs of an adequately sedated patient. Inability to maintain mouth-opening, snoring (indicating some degree of airway compromise) or moving into a state of restlessness are signs of oversedation and the concentration of N_2O should thus be decreased
8. Protect the airway with a rubber dam or butterfly sponge in the sedated patient
9. Monitor clinical signs (e.g. pulse and respiratory rate, unobstructed breathing and lack of cyanosis) throughout the surgery. Pulse oximetry may help
10. Turn the O_2 concentration to 100% at the end of the procedure

written form when sedation is proposed. Patients often fail to take in what they are told or quickly forget. The patient's name and the reason for having sedation must be confirmed. This apparently obvious precaution avoids embarrassing confusion between patients coming from a crowded waiting room. The operation site should be confirmed and, if appropriate, marked in ink by the operator. This must be done while the patient is conscious, and checked with the patient. One of the most effective methods of lessening anxiety is by reassurance and brief discussion of a patient's particular anxieties.

Appliances such as orthodontic removable appliances or dentures should be removed preoperatively. The sedationist must be aware of the presence of crowned, fragile or loose teeth, bridges that could be damaged, contact lenses, hearing aids or colostomy bags. The bladder should be emptied preoperatively.

It is essential that a dental professional does not administer sedation in the absence of a second trained person. The latter is required not merely to assist and help deal with any mishaps, but also to act as a chaperone. Fantasies of sexual assault may arise during benzodiazepine sedation. Further, the patient may become disinhibited and make advances to the dentist.

Monitoring for intravenous sedation must include constant monitoring of conscious state, colour, BP, respiration and pulse. Use should be made of a BP monitor and pulse oximeter (Fig. 3.4); this provides a measure of the degree of haemoglobin oxygen saturation by means of spectrophotometry. Pulse oximeters are usually accurate and are a valuable safety measure. They pass red light at 660 nm (absorbed by oxygenated haemoglobin) and infrared light at 920 nm (absorbed by deoxygenated haemoglobin) across the vascular bed (usually of a finger or ear lobe), which permits display of the percentage of haemoglobin saturated with oxygen. This is safe when above 90%. A stethoscope and, ideally, an ECG monitor too (Fig. 3.5) should be used. However,

Fig. 3.4 Pulse oximetry to monitor blood oxygen saturation (nail varnish should be removed!).

Fig. 3.5 Cardiac monitor.

this is rarely practicable in the absence of expert interpretation of the tracing, such as in a hospital, unless an automatic read-out of possible diagnoses is available. Disadvantages of using ECG are that it can generate anxiety in the patient and is disturbed by movements, so its use is often restricted to patients with serious cardiac disease being treated in a hospital.

CHECKS AND INSTRUCTIONS FOR PATIENTS

Routine checks before conscious sedation for dental treatment

Always check the following:

1. Patient's name (and hospital number)
2. Nature, side and site of operation
3. Medical history, particularly of cardiorespiratory disease or bleeding tendency
4. Consent has been obtained in writing from the patient or, in a person under 16 years of age, from parent or guardian, and that the patient adequately understands the nature of the operation and sequelae
5. Necessary oral investigations (e.g. radiographs) are available
6. What the patient has had by mouth, including drugs, over the previous 4 hours
7. Patient has emptied the bladder
8. Patient's dentures have been removed and bridges, crowns and loose teeth have been noted by the anaesthetist

9. Pre-medication (and, where indicated, regular medication such as the contraceptive pill, anticonvulsants or antidepressants) has been given but not usually within the previous 4 hours
10. Anaesthetic and suction apparatus are working satisfactorily and that emergency drugs are available and not date-expired
11. Patient is escorted by a responsible adult
12. Patient has been warned not to drive, operate unguarded machinery, drink alcohol or make important decisions for 24 hours postoperatively.

Instructions to patients before conscious sedation

These instructions should preferably be given in writing:

1. You must be accompanied by a responsible adult, over the age of 18 years, who will undertake to escort you home and remain with you for 24 hours after treatment. You must not be accompanied by children under 14 years of age.
2. Do not wear nail varnish or make-up.
3. After sedation, you must not on the same day:
 - A. drive a motor vehicle
 - B. ride a bicycle or motorcycle, even as a passenger
 - C. cook or use unguarded machinery
 - D. take alcohol
 - E. take sedative drugs without medical advice
 - F. make important decisions or sign any documents.
4. If you develop a cold before your appointment, please telephone the hospital or dental surgery for advice.

Patients who fail to comply with these simple safety precautions will not be given sedation.

STANDING DENTAL ADVISORY COMMITTEE: REPORT OF AN EXPERT GROUP ON SEDATION FOR DENTISTRY

Conscious sedation in the provision of dental care: executive summary

- Despite the publication of a number of authoritative documents on pain and anxiety control for dentistry, it has become evident that there remain areas of confusion and lack of consensus.
- This document is designed to lay down specific recommendations to all practitioners providing conscious sedation for the provision of dental care in general dental practice, community and hospital settings.
- The effective management of pain and anxiety is of paramount importance for patients requiring dental care and conscious sedation is a fundamental component of this.
- Competently provided conscious sedation is safe, valuable and effective.
- It is absolutely essential that a wide margin of safety be maintained between conscious sedation and the unconscious state of general anaesthesia. Conscious sedation must under no circumstances be interpreted as light general anaesthesia.
- A high level of competence based on a solid foundation of theoretical and practical supervised training, progressive updating of skills and continuing experience is the key to safe practice.

- Education and training must ensure that all members of the dental team providing treatment under conscious sedation have received appropriate supervised theoretical, practical and clinical training.
- Training in the management of complications, in addition to regularly rehearsed proficiency in life-support techniques, is essential for all clinical staff. Retention and improvement of knowledge and skills rely upon regular updating.
- Operating chairs and patient trolleys must be capable of being placed in the head-down tilt position and equipment for resuscitation from respiratory and cardiac arrest must be readily available.
- Dedicated purpose-designed machines for inhalational sedation should be used.
- It is essential to ensure that hypoxic mixtures cannot be delivered.
- There should be adequate active scavenging of waste gases.
- All equipment for the administration of intravenous sedation, including appropriate antagonist drugs, must be available in the treatment area and appropriately maintained.
- Supplemental oxygen delivered under intermittent positive pressure, together with back-up, must be immediately available.
- It is important to ensure that each exposure to conscious sedation is justified. Careful and thorough assessment of the patient ensures that correct decisions are made regarding the planning of treatment.
- A thorough medical, dental and social history should be taken and recorded prior to each course of treatment for every patient.
- There are few absolute contraindications for conscious sedation, though special care is required in the assessment and treatment of children and elderly patients.
- Patients must receive careful instructions and written valid consent must be obtained.
- Fasting for conscious sedation is not normally required but some authorities recommend the same fasting requirements as for general anaesthesia.
- Recovery from sedation is a progressive step down from completion of treatment through to discharge. A member of the dental team must supervise and monitor the patient throughout this period.
- The decision to discharge a patient into the care of the escort following any type of sedation must be the responsibility of the sedationist.
- The patient and escort should be provided with details of potential complications, aftercare and adequate information regarding emergency contact.
- The three standard techniques of inhalation and oral and intravenous sedation employed in dentistry are effective and adequate for the vast majority of patients. The simplest technique to match the requirements should be used.
- The only currently recommended technique for inhalation sedation is a titrated dose of nitrous oxide with oxygen and it is absolutely essential to ensure that a hypoxic mixture cannot be administered.
- The standard technique for intravenous sedation is the use of a titrated dose of a single drug: for example, the current use of a benzodiazepine. This can be given into a vein on the dorsum of hand or elsewhere in the arm (Fig. 3.6)

Fig. 3.6 Intravenous line.

- Oral pre-medication with an effective low dose of a sedative agent may be prescribed.
- No single technique will be successful for all patients.
- All drugs and all syringes in use in the treatment area must be clearly labelled and each drug should be given according to accepted recommendations.
- Stringent clinical monitoring during the procedure is of particular importance and all members of the clinical team must be capable of undertaking this.
- Conscious sedation for children must only be undertaken by teams which have adequate training and experience.
- Nitrous oxide/oxygen should be the first choice for paediatric dental patients.
- Intravenous sedation for children is only appropriate in a minority of cases.
- The management of any complication, including loss of consciousness, requires the whole dental team to be aware of the risks, appropriately trained and fully equipped. It is vitally important for the whole team to be prepared and regularly rehearsed.
- Attention must be given to risk awareness, risk control and risk containment.
- Evidence of active participation in continuing professional development (CPD) and personal clinic audit is an essential feature of clinical governance.

PREPARATION AND CHOICE OF TECHNIQUE

Only patients of ASA classes I and II are suitable for sedation as outpatients. ASA III patients should be referred to at least an appropriate secondary care unit and ASA IV patients to the hospital service, ideally with an anaesthetist present. Unlike sedation in the hospital operating-theatre setting, fasting is not required for CS in the dental practice when resorting to GA in the event of failure is not an option. There are few absolute contraindications but special care should be taken with children and the elderly. Treatment during pregnancy should be avoided where possible, certainly as regards the use of nitrous oxide and probably benzodiazepines in the first trimester.

'Standard' sedation techniques involve the use of *one only* of the options outlined below.

Oral sedative drug alone

This method is ideal where it is not possible to use one of the titratable techniques (e.g. needle-phobic patients for whom nitrous oxide is unlikely to provide sufficient relaxation). Oral sedation should only be used by those capable of intravenous cannulation. Benzodiazepines may cause paradoxical hyperexcitability in some children or oversedation in older people, and the level of sedation cannot be altered.

Pre-medication before conscious sedation

Pre-medication may be desirable to lessen anxiety. However, this is not usually feasible in general dental practice as it delays recovery. Any pre-medication is typically given 30–35 minutes preoperatively. If pre-medication has to be given, benzodiazepines are useful because of their anxiolytic and amnesic actions, their relative freedom from side-effects and their wide safety margin. Diazepam, lorazepam and temazepam are used more and more widely for pre-medication. Beta-blockers may also be employed and may help to prevent arrhythmias induced by surgery. Opioids such as pethidine are traditional pre-medicants because of their sedative action. However, they frequently cause nausea, vomiting and respiratory depression. Promethazine or alimemazine (trimeprazine) may be used for its sedative and antiemetic effect, for pre-medication of children, but these drugs have a prolonged action and are often ineffective. They also raise blood sugar levels – a consideration when treating diabetics. Patients vary widely in their requirements for pre-medication and this may be discussed with the anaesthetist/sedationist.

Inhalational sedation with nitrous oxide and oxygen

This technique does not cause significant cardiorespiratory or respiratory depression in patients who are well enough to have outpatient treatment. Nitrous oxide diffuses into body cavities and thus is contraindicated after recent eye retinal surgery where parfluoropropane sulphur hexafluoride has been used, and where there is bowel obstruction or cysts on pathological cavities. The gases persist in the eye for up to 3 months after surgery. Chronic exposure may interfere with vitamin B₁₂. An 'IS machine' with built-in safety features is used to titrate nitrous oxide and non-hypoxic (30%+) flows of oxygen (see [Box 3.5](#)). The oxygen concentration is set to 100% at the end of surgery to minimize diffusion hypoxia. Patients are monitored using clinical signs (i.e. responsiveness, adequate breathing, pulse and colour). Before being allowed to leave professional supervision, the patient should be able to walk unaided without stumbling or feeling unstable. Adults who have received inhalation sedation may leave unaccompanied.

Intravenous sedation with midazolam alone

Midazolam is currently the accepted benzodiazepine of 'standard' intravenous sedation and has displaced diazepam ([Box 3.6](#)). Benzodiazepines may cause disinhibition in children, and intravenous sedation for children under 12 is only appropriate for a minority of cases. Outpatient sedation is contraindicated for patients with cardiorespiratory disease of ASA grade IV and in those with significant renal or hepatic dysfunction.

Patients must be accompanied postoperatively and receive advice similar to that issued after GA. Flumazenil is a specific antagonist at the benzodiazepine binding site on the GABA receptor and will reverse sedation in emergencies.

Advanced techniques

More experienced and suitably trained teams working in tightly controlled clinical settings with additional facilities as outlined by the UK Department of Health may use 'alternative techniques' such as:

- sedation for children under 12 other than with nitrous oxide
- inhalational sedation using anything other than nitrous oxide (e.g. sevoflurane)

Box 3.6 Intravenous sedation (IS) technique

1. Establish reliable intravenous access
2. Inject 2–3 mg of midazolam over 30 s and assess the patient's response over the next 2–3 min
3. Administer further 0.5–1 mg increments of midazolam at 2-min intervals until adequate sedation is achieved, as indicated by a relaxed but cooperative patient with slight speech slurring (eyelid signs, as formerly used in diazepam sedation, are not reliable)
4. Careful titration is necessary because some patients may require more and some may require a lot less than the average dose requirement of 0.07 mg/kg (i.e. 5 mg for a 70 kg person)
5. Protect the airway with the use of a rubber dam or butterfly sponge; this is particularly important in the patient sedated with midazolam
6. Note that sedation will realistically be maintained for about 30 min of operating time. Monitor the patient clinically as for inhalational sedation (see earlier) and also with pulse oximetry
7. Remember that signs of oversedation are as for inhalation sedation (see earlier). In addition, if oxygen (O₂) saturation is seen to fall, reassess the patient's airway and respiratory effort. Simply instructing the patient to take deeper breaths and administering supplemental nasal or face-mask O₂ may be all that is necessary for surgery to continue, provided verbal contact is also still maintained. However, in the presence of other signs of oversedation (see earlier), it may be advisable not to start surgery
8. Use flumazenil (200 mcg bolus then 100-mcg increments at 1-min intervals until improvement) only if this fails; flumazenil should never be used solely to hasten postoperative recovery
9. Continue direct postoperative observation for 15 min and discharge with an escort after 1 h

- intravenous sedation with propofol
- the use of additional intravenous drugs, an opioid or ketamine
- combined inhalational and intravenous sedation (except use of nitrous oxide to site a cannula).

Where techniques involve the continuous intravenous administration of a drug, or where three or more drugs are used together regardless of their routes, a dedicated non-operator sedationist must be present. This may be a dentist or doctor, registered for 4 years with experience of at least 100 procedures, who has undergone recognized training in conscious sedation in the context of the dental environment. It has been suggested that an anaesthetist with 2 years' experience would comply with *most* of these requirements.

DRUGS USED FOR CONSCIOUS SEDATION

Sedative agents for sedation include mainly the benzodiazepines (midazolam and diazepam), propofol and nitrous oxide. Before their use, the administrator's experience, the facilities and the relative safety of the different agents must be taken into consideration (see also Table 3.20).

Benzodiazepines

- Benzodiazepines are potent sedative drugs, acting on the limbic system to block reuptake of GABA.
- They have been widely used for conscious sedation.
- They are usually given intravenously, but some can be given orally, rectally or intranasally.
- Their effects include amnesia, anticonvulsant activity, anxiolysis, muscle relaxation and sedation but they can also cause respiratory depression.
- Benzodiazepines do not affect the cardiovascular system.
- Achievement of the depth of sedation necessary is established when the patient shows Eve's sign (the inability to touch the end of the nose accurately).

Table 3.20 Agents for conscious intravenous sedation^a

Drug	Proprietary names (UK)	Adult dose	Comments
Diazepam	Valium	Up to 20 mg	Benzodiazepine: gives sedation with amnesia but no analgesia. Give slowly intravenously in 2.5-mg increments until ptosis begins (i.e. eyelids begin to droop; Verrill's sign) – rapid injection may cause respiratory depression. Then give local analgesia. Disadvantages: • May cause pain or thrombophlebitis • Drowsiness returns transiently 4–6 h postoperatively due to metabolites desmethyl diazepam, triazolam and oxazepam, and enterohepatic recirculation • May cause mild hypotension and respiratory depression.
	Diazemuls	Up to 20 mg	Preferred to Valium. Has most of the actions above but causes less thrombophlebitis and therefore can be given into veins on dorsum of hand. Expensive. Do not give intramuscularly.
Midazolam	Hypnovel	0.07 mg/kg (up to 7.5 mg total dose)	Benzodiazepine. Compared to diazepam: • onset of action is quicker (30 s) • amnesia is more profound, starting 2–5 min after administration and lasting up to 40 min (with no retrograde amnesia) • recovery is more rapid; midazolam is virtually completely eliminated within 5 h without the recurrence of drowsiness that may follow the use of diazepam • incidence of venous thrombosis is lower than with diazepam • at least twice as potent • signs of sedation are less predictable – very slow injection required. Occasional deaths in elderly.
Propofol	Propofol, Diprivan	2 mg/kg	Contraindicated in children under 18 years. May cause pain on injection. Contraindicated in patients taking anticonvulsants. Occasional fits or apnoea.

^aMidazolam is the main agent used.

- The effect of benzodiazepines is reversed by flumazenil.
- Benzodiazepines may be ineffective in children, in whom they may paradoxically cause hyperactivity, and in persons on long-term medication with psychoactive drugs. Be very careful about prescribing benzodiazepines in combination with an opioid, as both are respiratory depressants.
- Diazepam has a long half-life (0.8–2.25 days) that is markedly increased in obese or elderly patients (3.9 days and 3.29 days, respectively), and its active metabolites have long half-lives (i.e. *N*-desmethyldiazepam [1.6–4.2 days]; nordiazepam [about 8 days]).
- Diazepam is a mild respiratory depressant with minimal risk to healthy persons, but is potentially dangerous to those with cardiorespiratory disease, particularly COPD. Diazepam is metabolized to products that have sedative actions (desmethyldiazepam, temazepam and oxazepam) and thus effects can persist, with a half-life of 20–72 hours.
- Midazolam is now the most commonly used agent for procedural sedation. It is considerably (two or three times) more potent than diazepam, amnesia is more profound and recovery more rapid (Tables 3.21 and 3.22). The maximal effect of midazolam on the brain appears to be about 10–15 minutes after intravenous administration. Intranasal midazolam has a faster onset of sedation than oral diazepam, with better sedation and faster recovery.
- Intravenous midazolam produces a faster onset of sedation, less pain on injection, and improved awakening when compared with diazepam. Midazolam is cleared by hepatic hydroxylation to 1-hydroxymidazolam (which has only 10% of the pharmacological activity of midazolam).
- Lorazepam has a peak onset of action 15–20 minutes after administration and the duration of action is longer (i.e. 6–8 hours) than that of midazolam (30–60 minutes). In addition, lorazepam has roughly double the potency of midazolam. Because of this, lorazepam is more typically used for long-term sedation, such as in the intensive care unit.
- A short-acting benzodiazepine (e.g. midazolam), usually alone or in combination with an opioid analgesic (e.g. fentanyl, morphine), is commonly selected but the combination increases risks of oxygen desaturation and cardiorespiratory complications. Specific reversal agents for benzodiazepines (flumazenil) and opiates (naloxone) must be readily available throughout the procedure. The sedative and respiratory-depressant effects and the risk of cardiovascular depression conferred by all benzodiazepines are

Table 3.22 Midazolam: possible adverse reactions and contraindications

Adverse reactions	Contraindications
Hiccough	Hypersensitivity to midazolam
Cough	Erythromycin use (potentiates midazolam)
Oversedation	Concomitant use of barbiturates, alcohol, narcotics or other CNS depressants, cimetidine, omeprazole, kava or valerian
Pain at the injection site	Glaucoma
Nausea and vomiting	Depressed vital signs, shock or coma
Headache	
Blurred vision	
Fluctuations in vital signs	
Hypotension	
Respiratory depression	
Respiratory arrest	

Table 3.21 Procedural sedation^a

Drug	Dose (adult)	Onset of action (min)	Duration (min)	Comments
Midazolam (Versed)	0.02–0.1 mg/kg i.v. initially; if further sedation is required, may repeat with 25% of initial dose after 3–5 min; do not exceed 2.5 mg/dose (1.5 mg for elderly persons) and 5 mg cumulative dose (3.5 mg for elderly persons)	1–2	30–60	Respiratory depression or hypotension possible, particularly when rapidly administered or given with fentanyl; does not provide analgesia. Flumazenil can reverse
Fentanyl	1–2 mcg/kg slow i.v. push over 1–2 min; may repeat dose after 30 min	1–2	30–60	May cause chest wall rigidity, apnoea, respiratory depression or hypotension; elicits minimal cardiovascular depression; may cause dysphoria, nausea, vomiting or EEG changes. Naloxone can reverse
Etomidate (Amidate)	0.1–0.2 mg/kg slow i.v. push over 30–60 s	<1	3–5	Often causes pain on injection, myoclonus or adrenal suppression (typically no clinical significance unless repeated doses are used within a limited time span). May cause nausea and vomiting, and lowers seizure threshold; causes a slight-to-moderate decrease in intracranial pressure lasting for several minutes; does not cause histamine release; useful for patients with trauma and hypotension
Ketamine	1–4.5 mg/kg i.v. over 60 s; total dose 0.5–2 mg/kg	1	10–15	Emergence delirium in approximately 12% of patients, which may last from 1–3 h but not usual in children <15 y or in older patients (i.e. >65 y)
Dexmedetomidine	0.7 mcg/kg/h; if further sedation is required, may repeat	5–30	60–120	Slow onset. Produces a sedation level similar to the other agents noted here but no respiratory depression and no major cardiac depression; patients are able to follow commands and respond to verbal and tactile stimulus
Propofol (Diprivan)	0.5–1 mg/kg i.v. loading dose; may repeat by 0.5-mg increments every 3–5 min	<1	3–10	Provides rapid onset, brief duration of action and quick recovery; has anticonvulsant properties; can rapidly cause deepening sedation; causes cardiovascular depression and hypotension

^aMedscape Reference. Dosage guidelines for adults. <http://emedicine.medscape.com/article/109695-overview#aw2aab6b8> (accessed 27 May 2013).

greatly increased if these drugs are combined with alcohol or opioids (opiates). Opiates may be used to provide analgesia and sedation during painful procedures. Fentanyl is favoured because of its prompt onset and short duration of action, with minimal cardiovascular depressive effects and hypotension. Fentanyl binds with stereospecific receptors at many sites within the CNS and increases pain threshold, alters pain reception and inhibits ascending pain pathways. In addition to analgesia, opioid agonists suppress the cough reflex and cause respiratory depression, drowsiness and sedation. The half-life is 2–4 hours.

Propofol

- Propofol provides potent, ultra-short-acting sedation or anaesthesia but has no analgesic properties. It is associated with a deep sedation level approaching that of GA. Because of this, an anaesthetist or sedation team often administers it and monitors its use outside the operating room.
- It appears to have the advantages of a rapid sedative response, with a quicker recovery and better effects on mood compared with midazolam. Propofol's onset of action is rapid at 90–100 seconds. Duration of action is dose-dependent and ranges from 5 to 10 minutes after bolus administration.
- Propofol is rapidly metabolized by the liver.
- It leads to a dose-dependent decrease in arterial BP and cardiac output.
- It has a relatively high rate of discomfort, including severe pain, with injection in up to 28–90% of patients. Transient local pain can be minimized if the larger veins of the forearm or antecubital fossa are used.
- Propofol is slightly more cost-effective than midazolam because of its shorter recovery times, and is safer than benzodiazepines and opiates. There are no antagonists.
- Long-term treatment with high doses can cause a propofol infusion syndrome (PRIS) – a rare but often lethal reaction characterized by rhabdomyolysis, acidosis, and renal and cardiac failure.
- It is therefore contraindicated for children under the age of 18 years, either during surgical or diagnostic procedures or in the ICU.
- It is sometimes used with remifentanyl (short-acting and not affected by obesity or liver or kidney disease) for maintenance of total intravenous anaesthesia.

Nitrous oxide

- Nitrous oxide (NO) produces analgesia and sedation with a far quicker recovery than most sedatives/analgesics. Nitrous oxide with oxygen is overall the safest agent for CS because of its rapid reversibility and lack of respiratory or cardiodepressant effects.
- For needle-phobics, children, epileptics, some drug users or those with asthma and myasthenia gravis, inhalational sedation is preferable to intravenous sedation because it provides better control of the patient. For inhalation sedation, clinical monitoring of the patient is adequate.
- For claustrophobic patients or those with upper airways obstruction, inhalation sedation may be contraindicated.

Other agents

Other agents may occasionally include etomidate, ketamine and dexmedetomidine.

Etomidate

- Etomidate produces minimal haemodynamic effects and has a reliable onset of action.
- It is an ultra-short-acting, non-barbiturate hypnotic used mainly for GA. It produces rapid induction without histamine release and with minimal cardiovascular and respiratory effects. Etomidate transiently lowers cerebral blood flow by 20–30% and slightly reduces intracranial and intraocular pressure. It has no analgesic properties. Onset of action is 5–30 seconds with peak action at 1 minute. Etomidate has a duration of 2–10 minutes, depending on the dose.
- The major adverse effect is transient adrenal suppression secondary to inhibition of 11- β -hydroxylase and 17- α -hydroxylase enzymes, which are important in cortisol synthesis. There is also a high incidence of pain on injection, and nausea and vomiting associated with bolus administration.

Ketamine

- Ketamine produces a dissociative state and patients may not be able to speak or respond purposefully to verbal commands. Onset of action for intravenous administration is within 1 minute, and duration of action about 10–15 minutes.
- It is usually not recommended for adults because it often causes emergence delirium (i.e. vivid imagery, hallucinations, confusion, excitement, irrational behaviour). Emergence delirium is not typical in children younger than 15 years or in older patients (i.e. over 65 years).
- Emergence reactions are estimated to occur in approximately 12% of patients and can be expected to last from 1–3 hours. The incidence may be reduced by decreasing the recommended dose of ketamine and using it in conjunction with a benzodiazepine. A small hypnotic dose of a short-acting barbiturate or benzodiazepine is recommended to terminate severe emergence reactions.
- In doses typically used for procedural sedation, ketamine does not affect pharyngeal–laryngeal reflexes and thus allows a patent airway as well as maintaining spontaneous respiration. Therefore it is useful for emergency procedures when fasting cannot be assured. The unique dissociative action and partial agonism at opiate mu receptors permit painful procedures to be performed in a consistent state of sedation and patient comfort. Ketamine is contraindicated when an increased BP would pose a risk of complications. An increase in oropharyngeal secretions is often triggered and laryngospasms are possible.
- At a 1:1 mixture with propofol, ketamine can be used in adults for procedural sedation and analgesia. This mixture has been associated with a reduced incidence of emergence delirium and may negate the need for concomitant benzodiazepine use.

Dexmedetomidine (DEX)

- Dexmedetomidine produces a level of sedation similar to the other agents mentioned but no respiratory depression and no major cardiac depression. Patients are able to follow commands and respond to verbal and tactile stimulus but fall quickly asleep when not stimulated. It does provide some pain relief. Minimal cardiovascular effects are seen and include mild bradycardia and a decrease in systemic vascular resistance.
- It is an α_2 -adrenergic agonist that provides sedation, anxiolysis, hypnosis, analgesia and sympatholysis. Onset of action is

relatively slow and the context-sensitive half-life is approximately 4 minutes after a 10-minute infusion. It is 1600 times more selective for α_2 than α_1 receptors and therefore has very few adverse effects and provides predictable results.

- Dexmedetomidine has a minimal respiratory depressive effect, which is beneficial for dentistry; however, it has the disadvantage of permitting an intraoperative arousal response such that the patient suddenly appears to be no longer sedated, and it has a variable amnestic effect.

POSTOPERATIVE CARE

The immediate postoperative period is a particularly dangerous time and the patient must be closely supervised with pulse oximetry, until completely conscious, by the dental surgeon; supervision by the nurse or other responsible adult should continue until the patient is alert and able to stand without dizziness or ataxia. A member of the dental team should supervise the patient during recovery. The first stage of recovery is normally in the dental chair. Once patients have recovered sufficiently to move to a resting area, they should be carefully guided and supported. During recovery, patients should be laid on their side in the semi-prone (tonsillar) position and the airway must be protected. Up to 20% of patients may become hypoxic after intravenous sedation and therefore supplemental oxygen should be given during recovery. Equipment and drugs for dealing with medical emergencies must be on hand. The sedationist must be constantly available to see the patient for any emergency.

Monitoring discharge

Patients cannot be considered fully recovered until they have returned to their preoperative physiological state. Early recovery (phase I) lasts from discontinuation of the procedure until patients have recovered protective reflexes and motor function. This requires close monitoring and supervision, normally in a high-dependency atmosphere with suitably trained nursing staff. In deciding when patients have recovered enough to allow their safe transfer to phase II recovery, the Aldrete scoring system may be used (Table 3.23). This assigns a score of 0, 1 or 2 to activity, respiration, circulation, consciousness and colour, giving a maximal score of 10. A score of 9 indicates recovery sufficient for the patient to be transferred from high dependency. However, with the advent of pulse oximetry, a more reliable indicator of oxygenation than clinical observation, the ability to maintain O_2 saturation $>92\%$ on room air is regarded as a satisfactory end-point. After patients are discharged, they can then undergo full recovery at home (phase III recovery).

The decision to discharge a patient into the care of the responsible adult escort after any type of sedation must be the responsibility of the dentist or anaesthetist/sedationist (see also Appendices to this chapter). The patient must be accompanied home by a responsible adult. If this is not possible, sedation is contraindicated. Exceptions may be made occasionally in the case of inhalation sedation with nitrous oxide and oxygen when, at the discretion of the sedationist, the patient may leave unaccompanied if medically fit and responsible. Arrangements should be made for the patient to travel home by private car driven by the escort or by taxi rather than on public transport. When this is not possible, the escort must be made aware of the added responsibilities of caring for the patient during the journey home. If either the patient or the escort appears to be unwilling or unable to comply with these requirements, sedation should not be given. It is desirable that the escort should look after the patient for the rest of the day.

Table 3.23 Aldrete score

	2	1	0
Respiration	Able to take deep breath and cough	Dyspnoea/shallow breathing	Apnoea
O_2 saturation	Maintains $>92\%$ on room air	Needs O_2 inhalation to maintain O_2 saturation $>90\%$	Saturation $<90\%$ even with supplemental oxygen
Consciousness	Fully awake	Arousable on calling	Not responding
Circulation	BP ± 20 mmHg preoperatively	BP ± 20 – 50 mmHg preoperatively	BP ± 50 mmHg preoperatively
Activity	Able to move 4 extremities	Able to move 2 extremities	Able to move 0 extremities

Table 3.24 Indications for and contraindications to general anaesthesia

May be contraindicated	May be indicated
Pregnancy	Refusal of or allergy to local anaesthesia
Unescorted patients	Acute local infections (but not Ludwig angina)
Severe infections in the floor of the mouth	Injection phobia
Severe anaemia (especially sickle cell anaemia)	Learning impairment
Severe renal disease	Major surgery
Severe hepatic disease	Multiple extractions
Severe respiratory disease	
Severe cardiac disease	

Alternatively, arrangements should be made for a reliable adult to undertake that care.

GENERAL ANAESTHESIA

It is inappropriate in this book to discuss general anaesthetic agents or intraoperative care in detail, since GA is the remit of specialist anaesthetists and, in the UK, must be given only in a hospital (see *A conscious decision: a review of the use of general anaesthesia and conscious sedation in primary dental care*, Department of Health, 2003).

However, dental surgeons working in hospital may have to care for such patients perioperatively. Indications for GA are shown in Table 3.24. Due consideration should be given to the patient's medication, if any (see Table 3.7), which should be discussed with the anaesthetist.

PREOPERATIVE PREPARATION

It is the anaesthetist's responsibility to assess suitability for, and the best approach to, GA but a thorough clerking by the surgical team makes this process more efficient. Information about previous GA (tolerance and associated problems), induction or airway management (e.g. starvation, mouth-opening, dentition, heartburn and reflux), and history or family history of conditions relevant to GA (e.g. cholinesterase deficiency, malignant hyperpyrexia) are important.

Preoperative starvation guidelines

If gastric contents are regurgitated, they risk being aspirated into the lungs and causing asphyxiation or Mendelsohn syndrome. This risk has traditionally been reduced, whenever possible, by minimizing

intake of food and drink before GA. In reality, however, many patients are starved for excessive times. Prolonged fast of fluid is illogical since, in fasting patients, the stomach can secrete up to 50mL of gastric juice an hour. Further, ingested clear fluids rapidly leave the stomach of healthy people, with about half the volume disappearing in 10–20 minutes. Prolonged fluid deprivation has also been shown to raise the volume and decrease the pH of gastric juice, which increases the likelihood and consequences of gastric acid aspiration. Although patients who are likely to have delayed gastric emptying through underlying disease or drug treatment should not drink before GA, there is now overwhelming evidence in favour of allowing other patients with ASA grades I or II to drink clear fluids up to 2 hours before the procedure. If medication needs to be administered preoperatively, tablets and capsules can be swallowed with a small quantity of water at any time before GA.

The risks apply mainly (and rarely) to GA. Protective reflexes should remain largely intact in CS, and so the risks of aspiration should be lower. The available guidelines are somewhat equivocal but there are no hard data to support starvation before CS.

If aspiration is likely, metoclopramide hastens gastric emptying and may contribute to risk reduction. Ranitidine or sodium citrate can neutralize the acidity of gastric secretions in those at risk of aspiration.

Rapid sequence induction

It may not be appropriate to wait for adequate starvation when emergency surgery is required. In such circumstances, a rapid sequence induction of GA is required. In addition, certain conditions may render starvation times less effective (Box 3.7).

Patients with significant reflux or gastro-oesophageal incompetence are also at risk of aspirating the contents of their stomach, whether filled with food or not; in general, they should also be considered for a rapid sequence induction. The patient breathes 100% oxygen for at least 3 minutes to extend the time during which they may remain well saturated while apnoeic if there are difficulties intubating (pre-oxygenation). A predetermined dose of induction agent is delivered as a bolus while an assistant applies backward pressure to the cricoid cartilage. The latter manoeuvre occludes the oesophagus and further reduces the likelihood of regurgitation. A fast-acting muscle relaxant (suxamethonium or rocuronium) is given, the patient intubated, and cricoid pressure only released when endotracheal tube position is confirmed and its cuff inflated.

INTRAVENOUS ANAESTHETICS

Most intravenous sedative and GA agents are modulators of the GABA_A receptor, facilitating inhibitory neurotransmission at a site on the receptor away from that of GABA itself. Ketamine, however, is an *N*-methyl-D-aspartate (NMDA) receptor blocker and clonidine-like agents are α_2 -receptor agonists (Table 3.25).

Etomidate

Etomidate, an imidazole derivative, causes less cardiovascular depression than either propofol or thiopental, although its use, even in hypotensive patients, has declined owing to other undesirable effects such as nausea and vomiting, pain on injection and excitatory movements. It inhibits the enzymes 11- β -hydroxylase and 17- α -hydroxylase, suppressing adrenal function, an effect which may occur even after a single dose.

Box 3.7 Conditions rendering preoperative starvation ineffective

- Trauma at less than the usual starvation time after eating
- Use of potent opioids preoperatively
- Acute abdominal condition (particularly bowel obstruction)
- Active labour

Table 3.25 Drugs for intravenous anaesthesia

Drug	Proprietary names (UK)	Adult dose	Comments
Etomidate	Hypnomidate	0.2 mg/kg	Good for outpatient anaesthesia. Pain on injection: use large vein and give fentanyl 200 mcg first. After operation give naloxone 0.1–0.2 mg and oxygen. Little cardiovascular effect. Often involuntary movements, cough and hiccough. Hepatic metabolism. Avoid in repeated doses in traumatized patient – may suppress adrenal steroid production
Ketamine	Ketalar	0.5–2 mg/kg	Rise in BP, cardiac rate and intraocular pressure. Little respiratory depression. Often hallucinations. Contraindicated in hypertension, psychiatric, cerebrovascular or ocular disorders. Rarely used in dentistry
Propofol	Diprivan	2 mg/kg	May cause pain on injection. Occasional fits or anaphylaxis. Contraindicated in children under 18
Thiopental	Intraval	2.5 mg/kg (2.5% solution)	Ultra-short-acting barbiturate. No analgesia. Danger of laryngospasm. Rapid injection may cause apnoea. Irritant if injected into artery or extravascularly

Ketamine

Ketamine anaesthesia is dissociative, separating the electrical activity of the thalamocortical system from that of the limbic system. There is a delay preceding the onset of anaesthesia. Unlike other induction agents, ketamine stimulates the sympathetic nervous system, increasing heart rate and BP (but also cerebral blood flow, intracranial pressure, and both myocardial and cerebral oxygen demand). Ketamine should be avoided in patients with raised intracranial pressure and open eye injuries, and used with caution in hypertension. It is a bronchodilator and useful in patients with severe bronchospasm refractory to other bronchodilators. Vivid and unpleasant dreams may follow its use.

Propofol

Propofol is the most commonly used intravenous induction agent (see above). It is a highly lipid-soluble, weak organic acid, formulated as a 1% or 2% lipid emulsion with soya bean oil and egg phosphatide. Patients with egg allergy are usually sensitive to egg *albumin* and therefore may still be given propofol.

Propofol suppresses upper airway reflexes, making coughing and laryngospasm rare, and it is therefore particularly suited to the use

of the laryngeal mask airway (LMA). Propofol causes systemic vascular resistance to fall and is associated with less reflex tachycardia than other induction agents. BP invariably falls and propofol should be administered slowly and cautiously to older or haemodynamically compromised patients. Awakening is due largely to redistribution rather than metabolism. Pain on injection may be decreased by the addition of lidocaine or formulation in an alternative base.

Thiopental

Thiopental is a barbiturate that leaves airway reflexes relatively preserved, but airway manipulation without a muscle relaxant (i.e. the LMA) can cause laryngospasm. Thiopental was the agent originally described for rapid sequence induction and is often (by convention only) the agent of choice in these circumstances. Thiopental is contraindicated in patients with porphyria. Accidental extravascular injection causes pain and necrosis, and intra-arterial injection may result in gangrene.

Total intravenous anaesthesia

Anaesthesia may be maintained by repeated boluses or an infusion of intravenous agents – total intravenous anaesthesia (TIVA). Infusion pumps can deliver propofol by a continuous infusion that maintains a constant level in the plasma – target-controlled infusion (TCI).

AIRWAY MANAGEMENT

Effective GA abolishes pain and awareness during surgery, and also the tone of head and neck muscles that normally maintain the airway patency and the cough and gag reflexes crucial to protecting the airway from aspiratable material. Some form of airway-opening technique is thus always required, with an additional need to protect the patient's respiratory tract from aspiratable material.

Airway manœuvres with or without a face mask

The patency of the airway of an unconscious patient may be maintained using a head-tilt and chin-lift or jaw-thrust technique. Where GA is being administered, a face mask is usually necessary to deliver both oxygen and GA to keep the patient alive and asleep, respectively. An oropharyngeal and/or nasopharyngeal airway may be used to aid manual airway maintenance. Although a head-down lateral position with vigilant observation and suction may help minimize the risk of airway soiling from aspiratable material, more reliable means of airway protection are generally needed. Furthermore, the insertion of a more substantial airway-opening device means the anaesthetist is free to deliver an appropriate GA at the same time.

Laryngeal mask

The laryngeal mask airway is an inflatable 'mask' that acts as a face mask but is connected to a tube or stem so that it may be inserted into the oropharynx just at the laryngeal entrance. An airway seal is achieved by inflation of the 'mask' cuff, which also provides some degree of isolation from the oesophagus. The LMA requires less skill to insert than an endotracheal tube and usually presents a smaller risk of trauma to tissues and teeth. Once inserted, it does not need to be held in place and it is possible to maintain an airway probably for as long as necessary. Although the classic LMA (cLMA) offers

Box 3.8 Indications for intubation

- Restricted access to airway or whole patient (ear, nose and throat; neurosurgery; prone patient)
- Protection against contamination of airway from above
- Protection against contamination of airway from below
- Requirement for muscle relaxation where resulting airway pressure may exceed that suitable for a laryngeal mask airway

Box 3.9 Intubation technique

1. Check equipment and monitoring
2. Induce anaesthesia and manually ventilate the patient before a muscle relaxant is administered
3. Flex the patient's neck with the atlanto-occipital joint extended ('sniffing the morning air'), allowing direct visual alignment of the larynx with the open mouth at laryngoscopy
4. Hold the laryngoscope blade (in the left hand) and pass along the right side of the floor of the mouth, displacing the tongue to the right
5. When the epiglottis is seen, advance the tip of the blade into the space between it and the base of tongue
6. Lift the laryngoscope up and away, bringing the vocal cords into view and allowing the introduction of the endotracheal tube, either directly or after first inserting a bougie and 'rail-roading' the endotracheal tube over it
7. Commence ventilation and inflate the tube cuff until the leak disappears. Confirm the tube position by auscultating both lung bases and apices, looking for chest movement and preferably demonstration of carbon dioxide in the exhaled gases with a capnograph. An endotracheal tube inserted too far will tend to go down the right bronchus, in which case partially deflate the cuff and withdraw the tube slightly. If in doubt, remove the tube, ensure the patient is well oxygenated and anaesthetized, and start again

reasonable protection from material coming from the airway above, it does not guarantee airway protection from gastric material; therefore, where there is a risk of regurgitation, endotracheal intubation is usually required. The ProSeal LMA™ has a second lumen that 'sits' at the opening of the oesophagus, creating a channel through which gastric contents may be vented away from the trachea or through which a nasogastric tube may be inserted; it may thus reduce the risk of inadvertent aspiration. The intubating LMA (iLMA) is another variation of the cLMA that may be used to aid the intubation of the trachea, either when this has proved difficult or where there is a need to avoid positioning the head and neck for intubation in the usual manner (e.g. cervical spine injury or rheumatoid arthritis). The cLMA, though a bulky device that limits surgical access to the mouth, has become an acceptable alternative to intubation for many dental, oral, maxillo-facial and ear, nose and throat procedures.

Intubation

Use of a tracheal tube with an inflated cuff is the only way to *guarantee* protection of the respiratory tract from soiling. Indications for intubation are shown in [Box 3.8](#).

A cuffed tracheal tube may be inserted orally, nasally or as a surgical airway (tracheostomy or cricothyroidotomy). A muscle relaxant is usually used for intubation (see [Box 3.9](#) for intubation technique).

Endotracheal intubation may be difficult in some instances; this difficulty may be suggested by a high Mallampati score ([Table 3.26](#)) and a number of other factors ([Box 3.10](#)).

Table 3.26 Mallampati scoring

Class	Definition
1	Full visibility of tonsils, uvula and soft palate
2	Visibility of hard and soft palate, upper portion of tonsils and uvula
3	Visibility of soft and hard palate and base of the uvula
4	Visibility of hard palate only

Box 3.10 Observations that suggest difficulty in intubation

- Neck – reduced distance from thyroid cartilage to mandibular symphysis, short and/or fat, thyroid goitre, neck masses
- Mandible – retrognathic with class II malocclusion, particularly class II division 1
- Ankylosing spondylitis
- Rheumatoid arthritis
- Trismus

Fibreoptic intubation

For patients at known or high risk of difficult intubation, an awake fibreoptic procedure allows intubation without loss of the protective airway reflexes and ability to breathe. Anaesthesia of the entire upper airway from nasopharynx to glottis is established using topical LA in a variety of concentrations with or without some carefully titrated sedation. A short narrow endoscope with endotracheal tube mounted is introduced via the nose or mouth into the trachea by direct visualization and the tube is rail-roaded over it. GA is subsequently induced in the normal way and the cuff inflated. Fibreoptic intubation is often performed in patients who are asleep (not at risk of aspiration and unlikely to be difficult to ventilate), for the purpose of avoiding a traumatic direct laryngoscopy where a nasal tube is required, to avoid neck manipulation in those with cervical spine pathology, and to teach and develop the skill of fibreoptic intubation.

MUSCLE RELAXANTS

With the exception of the rapid sequence induction situation, an ability to ventilate the patient manually with a bag and face mask should always be verified prior to the administration of a muscle relaxant. These are neuromuscular-blocking drugs. There are two main categories – non-depolarizing and depolarizing. Non-depolarizing agents (mivacurium, rocuronium, vecuronium and atracurium) act by blocking acetylcholine (ACh) receptors at the motor endplate. Depolarizing agents (suxamethonium) are ACh agonists that, after an initial stimulation, desensitize muscle fibres to further ACh stimulation, preventing nearby Na⁺ channels from repolarizing and producing a neuromuscular block.

Suxamethonium

Suxamethonium is the only depolarizing muscle relaxant in use. Its usefulness lies in its rapid action and very brief effects. The rapid onset and short duration of action make it useful for induction of GA. Suxamethonium may stimulate muscarinic receptors in the sinoatrial node, causing bradycardia (atropine should be given before a repeat dose and considered in all infants). Because of the initial muscle spasm, this can result in hyperkalaemia postoperatively. The small rise

in K⁺ is usually of little significance but may be dangerous in patients with pre-existing electrolyte abnormalities, renal failure, burns, spinal injuries and progressive neuromuscular disorders. Muscle pains also occur postoperatively and intraocular pressure rises. Prolonged neuromuscular block (suxamethonium apnoea) occurs in 4% of patients owing to inherited deficiency in the enzyme plasma cholinesterase, apnoea ranging from 10 minutes to several hours. Suxamethonium may also precipitate malignant hyperpyrexia.

Atracurium

Atracurium is an antagonist at the nicotinic ACh receptor of the neuromuscular junction. Histamine release can occasionally cause hypotension or bronchospasm. Atracurium is eliminated completely, independently of hepatic and renal metabolism, by ester hydrolysis and spontaneous breakdown. *Cis*-atracurium causes less histamine release but has a slower onset time.

Vecuronium

Vecuronium is an aminosteroidal muscle relaxant, which does not affect the cardiovascular system or release histamine. It is metabolized by hepatic de-acetylation and renal excretion.

Rocuronium

Rocuronium is an aminosteroidal muscle relaxant used as an alternative to suxamethonium for rapid sequence intubation.

Mivacurium

Mivacurium is a benzyliisoquinolinium muscle relaxant, which has a shorter duration of action than the other non-depolarizing relaxants. It is metabolized by plasma cholinesterase and therefore patients prone to suxamethonium apnoea should also not receive mivacurium.

Reversal of neuromuscular blockade

Neostigmine is an anticholinesterase that reverses the competitive effects of non-depolarizing muscle relaxants. It also acts at autonomic ganglia and is therefore given with either atropine or glycopyrrolate to prevent bradycardia.

Sugammadex is used for the reversal of rocuronium and vecuronium neuromuscular blockade.

ANAESTHETIC GASES

General anaesthesia acts via effects on proteins in cell membranes, probably ion channels. Several inhalational and intravenous anaesthetic agents appear to facilitate the function of inhibitory ion channels similarly while attenuating the function of excitatory ion channels, to produce a state of anaesthesia. Nitrous oxide has been used for many years for GA. Halothane was the main drug used for inhalational anaesthesia until the 1980s but the rare severe liver injury following repeated exposures to halothane in some patients (Ch. 9) led to the development of other volatile agents such as enflurane, isoflurane, desflurane and sevoflurane. Arrhythmias may accompany halothane use, especially if adrenaline (epinephrine) is given. Cardiac rhythm is also more stable with the other agents, though they cause greater respiratory depression than halothane and induction is less pleasant. Enflurane causes cardiorespiratory depression and can be

Table 3.27 *Inhalational agents*

Drug	Proprietary names (UK)	Comments
Desflurane	Suprane	Less potent than isoflurane. May cause apnoea or coughing and is contraindicated in children
Enflurane	Ethrane/ Alyrane	Less potent anaesthetic than halothane. Non-explosive. Less likely to induce arrhythmias or affect liver than halothane. Induction and recovery are slower than with halothane
Halothane	Fluothane	Non-explosive. Anaesthetic but weak analgesic. Causes fall in blood pressure, cardiac arrhythmias and bradycardia. Hepatotoxic on repeated administration. Post-anaesthetic shivering is common, vomiting rare. Contraindicated for dental procedures in patients younger than 18 years unless treated in hospital
Isoflurane	Forane/ Aerrane	Isomer of enflurane. Causes less cardiac but more respiratory depression than halothane. Induction and recovery are slower than with halothane
Nitrous oxide	–	Analgesic but weak anaesthetic. Non-explosive. No cardiorespiratory effects. May cause eye damage from expansion of intravitreal gases
Sevoflurane	Sevoflurane	Rapid action and recovery. May cause agitation in children

epileptogenic. Immediate recovery is slower after isoflurane than after halothane and there may be some coughing. Recovery after sevoflurane is rapid but it may agitate children. Desflurane may cause apnoea or breath-holding, and increased secretions, and is not for use in children (Table 3.27).

Following induction of GA and the establishment of airway control, anaesthesia is maintained by the continuous administration of either a volatile anaesthetic or intravenous agent, with or without nitrous oxide or another means of analgesia.

The potency of an inhalational agent is determined by its lipid solubility or oil:gas partition coefficient, whereas its speed of action is determined by its blood:gas partition coefficient. Historically, some volatile anaesthetic agents were inflammable or even explosive, but modern agents are not inflammable. The commonly used volatile agents are all bronchodilators but depress ventilation.

Nitrous oxide

Nitrous oxide has a very low blood:gas partition coefficient and thus a very rapid onset and offset, but it approaches anaesthetic potency only in a grossly hypoxic mixture. It has good analgesic properties (useful for inhalational pain relief with oxygen as Entonox). Nitrous oxide with its analgesic properties may also be used as a 'carrier' gas to complement the sleep-inducing properties of a volatile agent. In addition, nitrous oxide, which moves into blood faster than nitrogen moves out, has the ability to increase the alveolar concentration of a volatile agent and speed up its effects. Conversely, at the end of GA, nitrous oxide rapidly leaves the blood, reducing the concentration of available oxygen in the alveoli (diffusion hypoxia). Additional oxygen is thus usually administered to a patient recovering from nitrous oxide anaesthesia to counteract this. Nitrous oxide has additional undesirable properties in some circumstances. It contributes to postoperative nausea and vomiting, and expands enclosed gas spaces and may thus be detrimental to certain bowel, ocular and middle ear procedures.

Prolonged exposure to nitrous oxide affects vitamin B₁₂ metabolism and can result in megaloblastic and neurological syndromes.

Isoflurane

Isoflurane is the longest established and cheapest of the three commonly used volatile anaesthetics (isoflurane, sevoflurane, desflurane). It is irritant and unpleasant to inhale, and is therefore rarely used for induction of anaesthesia, but otherwise has properties that make it a good maintenance agent. It may reduce systemic vascular resistance and cause a reflex tachycardia.

Sevoflurane

Sevoflurane has a faster onset than isoflurane and is more pleasant to inhale. Like halothane, it also causes a fall in systemic vascular resistance but, because it attenuates reflex changes in heart rate, the BP tends to fall further. Compared to isoflurane, a greater proportion of sevoflurane is metabolized to potentially toxic by-products and there are theoretical if controversial concerns regarding its suitability in renal failure. It is considerably more expensive than isoflurane.

Desflurane

Desflurane has a blood:gas partition coefficient lower than that of nitrous oxide, and thus the onset and offset of its effects are rapid. Like isoflurane, it is unsuitable for inhalation induction but its effects wear off rapidly, even after prolonged anaesthesia, and this can be an advantage for long surgical cases where prolonged administration of other agents may be associated with prolonged recovery. Desflurane's unusual physical properties necessitate an electrically heated vaporizer.

Halothane

The risk of cardiac arrhythmias and hepatotoxicity means halothane has been superseded by other volatile agents in most situations. Because of a relatively high blood:gas coefficient, halothane does not wear off as quickly as sevoflurane. Thus induction is slower but also anaesthesia will be deeper for longer when the mask is removed; this may be an advantage where airway manipulation with minimal risk of laryngospasm is necessary.

Enflurane

Enflurane is an isomer of isoflurane. Its cardiovascular side-effects fall between those of halothane and isoflurane, and it has been associated with epileptiform electroencephalogram (EEG) changes. Its use has therefore declined.

ANALGESIA

Opioids are commonly used at induction and act rapidly so that effective analgesia is established before surgery. Alfentanil, fentanyl, morphine and remifentanyl are opioids that are frequently used.

COMPLICATIONS OF GENERAL ANAESTHESIA

Many patients have a relatively smooth postoperative recovery, especially after short procedures. Superficial vein thrombosis may follow intravenous injections that are irritant or entry of cannulae into the tissues. Analgesics usually suffice, though antibiotics are occasionally indicated.

Medical emergencies, such as anaphylaxis, Addisonian crisis and acute severe asthma, among others, may occur perioperatively, as they may at any time.

Local complications after GA

Operative care carried out expeditiously, with careful handling of tissues, asepsis, wound toilet and careful wound closure, will minimize local complications, as will the appropriate use of analgesics and antimicrobials. Nevertheless, some pain is to be expected after surgical procedures, and bleeding or wound infection is not always totally avoidable.

Pain

Pain after surgery usually starts after anaesthetic drugs have worn off and may result from unavoidable operative trauma. Alternatively, it may stem from a complication such as infection. Postoperatively, analgesics should be given as necessary, but if a GA has been given, the anaesthetist should be consulted first. Immediately after oral surgery, it may be necessary to use a long-acting local analgesic or a strong analgesic such as morphine. In some cases, this is best controlled by the patient (PCA). However, after most dental procedures, a combination of ibuprofen and paracetamol (acetaminophen; see [Tables 3.3 and 3.4](#)) should be effective.

Wound infection

Wound infection is uncommon after oral and maxillofacial procedures unless there has been significant contamination, such as in a road traffic accident, or if foreign bodies are present, local vascularity is poor or the patient is immunocompromised. Infection may cause pain, discharge or sepsis and is best managed by drainage, wound toilet, antimicrobials and analgesics as indicated. The diagnosis must first be made, and treatment guided by the likely pathogen (Ch. 21). If streptococci are implicated, the first-choice therapy in the absence of allergy is amoxicillin $\pm$ clavulanic acid. If staphylococci are involved, flucloxacillin is appropriate. For anaerobic infections, metronidazole is the first choice. For Gram-negative infections (e.g. contamination of wound with bowel organisms, urinary tract infection (UTI), hospital-acquired and aspiration pneumonia), it is best to take advice from the microbiologist; useful antibiotics include amoxicillin, piperacillin plus tazobactam, and gentamicin.

Bleeding

Postoperative haemorrhage usually has a local cause (i.e. damaged soft tissues; Ch. 8). It responds to local pressure, insertion of haemostatic agents or suturing of the soft tissues. Patients should be given written as well as verbal guidance on how to care for their wounds (Appendix 3.6). If there is a contributing systemic cause (e.g. anticoagulated patients), appropriate pre- and postoperative measures must be taken.

Systemic complications after GA

Drowsiness, headache, sore throat, muscle pains and vomiting are seen in over 60% of patients after outpatient GA. Headache seems more common in women, especially if halothane has been used. Sore throat is common if the patient was intubated, as are muscle pains if suxamethonium has been given. More important complications are shown in [Box 3.11](#) and discussed below.

Box 3.11 Postoperative complications

- Collapse
- Nausea and vomiting
- Fever
- Jaundice
- Behavioural problems
- Low urine output
- Thrombosis
- Awareness
- Delayed recovery of consciousness
- Cardiac complications
- Laryngospasm
- Respiratory complications
- Malignant hyperpyrexia
- Death

Collapse

There may be signs of weakness, sweating, rapid pulse, pallor, hypotension, shock or loss of consciousness. The causes can be difficult to find but may include haemorrhage, pulmonary embolism, cardiac arrest (usually myocardial infarction), sepsis, anaphylaxis, adrenal insufficiency and adverse reactions to GA agents. These are outlined in Chapters 1 and 5.

Postoperative nausea and vomiting (PONV)

Postoperative vomiting is both unpleasant for the patient and dangerous if protective laryngeal reflexes have not returned after GA or sedation; it may have serious sequelae (risk of aspiration with intermaxillary fixation, wound dehiscence, etc.). Risk factors include female sex, being a non-smoker, a previous history of PONV or travel sickness, and use of postoperative morphine. Volatile agents are thought to be responsible for most vomiting immediately after waking from GA. One possible explanation is that these agents potentiate the function of 5HT₃ receptors in addition to their effect on the GABA_A receptor. Optimum prevention or treatment is by combining drugs with different modes of action. In many cases, the cause of postoperative nausea is unclear, but some patients seem to be particularly susceptible. An antiemetic is usually effective ([Tables 3.19 and 3.28](#)). Metoclopramide and domperidone, however, are best avoided in the young and in older people, as they can induce dystonic reactions. Parenteral administration may be needed if vomiting is severe.

Fever

A transient rise in temperature postoperatively is common within a few hours of GA and major operations, and is regarded as 'physiological'. Persistent fever shortly after an operation may indicate malignant hyperthermia (Ch. 23). Persistent fever for several days postoperatively, especially if spiking, may indicate haematoma, wound infection, deep vein thrombosis (DVT), UTI, infection of an intravenous line or more serious pulmonary infection. Persistent mild fever continuing or appearing several weeks postoperatively may indicate infective endocarditis (Ch. 5).

Jaundice

Postoperative jaundice after GA can result from many causes, including viral and drug-induced hepatitis. Halothane should be avoided if the

Table 3.28 *Antiemetics*

Class	Used mainly for nausea and vomiting related to	Main possible adverse effects
Antihistamines (e.g. cyclizine)	Many causes, including postoperative	May cause sedation
Dexamethasone	Postoperative nausea and vomiting or that associated with cancer chemotherapy	
Domperidone	Cancer chemotherapy	Few problems with sedation or dystonic reactions
Metoclopramide	Gastrointestinal disorders, including postoperative	May cause dystonic reactions
Nabilone	Cancer chemotherapy	A cannabinoid that may cause drowsiness
Phenothiazines	Neoplastic disease, radiation, general anaesthesia or drug use, including postoperative	May cause dystonic reactions
5HT ₃ antagonists (granisetron, ondansetron, tropisetron)	Postoperative nausea and vomiting or that associated with cancer chemotherapy	May cause headaches or hypersensitivity reactions

patient has been exposed to it within the previous 6 months or has had a previous episode of halothane hepatitis. In a series of 300 patients who had been given halothane on more than one occasion within a month and who subsequently developed hepatitis, no fewer than 46% died.

Alcoholic hepatitis can be a problem. GA for high-risk patients cannot be avoided for emergencies, such as maxillofacial injuries, and this group of patients includes an unduly high proportion of alcoholics.

Aggravation of pre-existing liver disease (including gallstones), hepatic necrosis secondary to circulatory failure, transfusion reactions and Gilbert syndrome are other causes.

Behavioural complications

Causes of confusion after GA or sedation may include: drugs (anaesthetic, analgesic, others), hypoglycaemia, alcohol or other drug withdrawal, pre-existing psychiatric states, hypoxia, infection (wound, lungs, urinary tract, abscess, septicaemia), urine retention or disturbed urea and electrolytes. Amnesia that persists for at least 5 hours is common after sedation with diazepam or midazolam. As a result, patients are likely to forget post-sedation instructions, or worse, have an accident as a result of forgetting to take normal precautions when using power tools or other dangerous equipment. Bizarre behaviour has also been described even 24 hours after sedation. It is also important to make sure that the patient is not anticipating going abroad immediately after the GA or sedation. Airports are difficult to navigate even by the fully alert, and complications might develop on board an aircraft or at a destination where medical care is limited.

Low urine output

Absolute anuria is usually caused by urine retention – a common postoperative complication, especially in the older male. The patient should be catheterized unless urine can be passed after a warm bath. If the patient is already catheterized, make sure the catheter is not blocked. Low urine output is a cardinal sign of dehydration, hypovolaemia and shock. The patient should be given fluids orally or intravenously. Start with a fluid challenge and continue according to the response. Care must be taken with patients in heart failure.

Box 3.12 *Causes of delayed recovery from GA*

- Residual intravenous or gaseous agents, sedatives, opioids
- Residual muscle relaxation (use a nerve stimulator)
- Anticholinergic drugs
- Hypoxia, hypercapnia
- Hypothermia
- Hypothyroidism
- Electrolytes (Na⁺, Ca²⁺ particularly)
- Cerebrovascular accident or other pathology

Deep vein thrombosis

DVT is mainly seen after prolonged major operations under GA and affects the leg veins. It may lead to pulmonary embolism (Ch. 5). Always suspect this in a patient whose haemoglobin saturation falls several days after major surgery or who develops hypotension, tachycardia, chest pain, etc. (Ch. 5). Factor V Leiden deficiency and other causes of thrombophilia should be considered (Ch. 8).

Awareness

For patients, the possibility of being awake during GA is a cause of worry. Unfortunately, it is not unheard of; it is an established cause of complaints against anaesthetists and is a precipitant of post-traumatic stress disorder. Awareness most often manifests as recollection of an auditory perception; sensations of pain are less likely. These experiences are more likely to occur when GA may become light, such as during airway manipulation and transfer of the patient into the operating room. Significant awareness is generally felt to be unlikely during surgery where a muscle relaxant has not been used, because movement in response to a noxious stimulus precedes awareness – and depth of anaesthesia may be adjusted accordingly. There is currently much interest in depth of anaesthesia monitoring, which utilizes various calculations from a simplified EEG recording (e.g. bispectral index [BIS]), but whether or not these technologies are likely to reduce the incidence of awareness is unknown.

Delayed recovery of consciousness after GA

Important causes are overdose of GA agents or the use of long-acting opioids for pre-medication, suxamethonium sensitivity, diabetic coma or hypoglycaemia, cardiac complications as mentioned earlier, or cerebrovascular accidents. The latter may occur either in susceptible patients (elderly hypertensives) or as a result of emboli. Occasionally, neurotic patients may feign persistent unconsciousness.

Patients should not be discharged from recovery if they are at risk of laryngospasm or not fully conscious. Certain conditions resulting in an abnormally prolonged time to recovery of either consciousness or ventilation may, however, cause more subtle respiratory problems or postoperative confusion, as shown in [Box 3.12](#).

Cardiac complications

Myocardial infarction, cardiac failure or severe arrhythmias can follow GA and are the main risks in those with pre-existing cardiac disease (Ch. 5). Pre-existing cardiac disease may be aggravated or myocardial infarction can follow at an unpredictable interval after the anaesthetic, especially in those with ischaemic heart disease (Ch. 5). Myocardial infarction is one of the chief causes of deaths associated

with anaesthesia. There is no logical reason why GA *per se* should be expected to cause myocardial infarction or arrhythmias, and evidence is emerging that certain GA agents may have myocardial *protective* properties. Nevertheless, perioperative cardiac complications account for many of the deaths 'under GA', although these can probably be explained by gross haemodynamic abnormalities (blood loss, hypotension, hypertension, bradycardia, tachycardia) and/or metabolic abnormalities (hypoxia, hypercapnia, electrolyte problems) in patients who cannot compensate for them. Cardiac risk factors are notoriously difficult to apply generally, though there have been many scoring systems over the years. Shock (circulatory failure leading to tissue and organ hypoperfusion) is more likely to be a complication of major surgery; contributory factors include pre-existing heart disease, dehydration, haemorrhage, sepsis or anaphylactic reactions.

Laryngospasm

Upper airway stimulation causes coughing in a fully awake patient and no reaction in one who is deeply anaesthetized. Instead of a coordinated cough, the patient in between these states is at risk of their vocal cords closing and failing to open again (laryngospasm). This results in stridor when mild to moderate, but complete airway obstruction when severe. The cords often relax with positive airway pressure (and increasing the inspired volatile concentration when inducing anaesthesia) but occasionally it is necessary to re-administer a muscle relaxant.

Other respiratory complications

Airway obstruction is particularly important in dental surgery because of operating around the airway and the risk of foreign material being inhaled. Facilities such as suction must always be immediately available for locating and clearing any blockage. *The recovery period is the most dangerous time and great care must be taken to keep the airway clear.*

Lung alveoli begin to collapse within minutes of GA, as respiratory muscle tone is lost (atelectasis). This occurs particularly in lower zones and with higher inspired oxygen concentrations when there is less nitrogen to 'splint' open the alveoli. If excessive, it may cause shunting to occur with a tendency to impaired postoperative gas exchange. This is extremely common but quickly compensated for in the healthy patient. At the other end of the spectrum, patients with poor preoperative respiratory function or inadequate pain relief preventing coughing and clearance of secretions may develop pneumonia and respiratory failure. Immobility for any reason leaves patients at risk of thromboembolism and thus GA is a contributory factor. This is reflected in the markedly different risks associated with different types of surgery. After prolonged GA, especially in older people, there is high risk of atelectasis (Ch. 15); therefore, the patient should be strongly encouraged to undertake breathing exercises and to cough up any sputum. Accumulation of secretions is a frequent cause of lower airway obstruction and subsequent chest infection. This can be particularly severe in patients with chronic bronchitis (Ch. 15). A transient rise in temperature is common and is usually caused by atelectasis or localized pulmonary infection that may not be clinically detectable. Physiotherapy may be helpful. In dentistry, inhalation of a tooth or fragments of materials is another possible cause of atelectasis and subsequent lung abscess. Also, if an emergency operation has had to be carried out despite an acute upper respiratory tract infection, lower respiratory tract infection is more likely. Occasionally, bronchospasm can result from a hypersensitivity reaction to an intravenous anaesthetic or other drug used during the operation.

Respiratory weakness may be due to the action of muscle relaxants. Reversal of the action of neuromuscular blocking drugs depends on many factors but, if delayed, results in weak respiratory movements that cannot be made stronger by the patient's conscious efforts. Suxamethonium apnoea is discussed in Chapter 23. Impaired chest movements may be caused by damage to the chest, a common accompaniment of maxillofacial injuries, particularly when they result from road traffic accidents (Ch. 24). This may inhibit respiration and coughing.

Respiratory depression can result from the effects of the anaesthetic and ancillary drugs. Midazolam and pentazocine, for example, form a potent combination of respiratory depressants, which can be aggravated by hypoxia, often from a similar cause, and have caused occasional deaths.

Malignant hyperpyrexia

See Chapter 23.

PARTICULAR CONSIDERATIONS IN OUTPATIENT SEDATION OR GA IN DENTISTRY

Since the operation site is close to the airway, any inflammatory oedema, haemorrhage or foreign bodies can endanger respiration. Appropriate instruction must be given preoperatively, recorded in the case notes and re-emphasized before discharge. Patients must be made aware that, after a GA, it is dangerous to drive a vehicle, ride a bicycle, ride pillion on a motorcycle, work with unguarded machinery or make important decisions. They should also be warned not to drink alcohol or take certain drugs, particularly sleeping tablets. Obviously, it is impossible to control the behaviour of irresponsible patients, but it is essential to point out the dangers in the clearest possible terms. Patients may also fail to take in or forget verbal instructions, particularly after benzodiazepine use. To protect both patient and operator, the patient and escort should be given written instructions (Fig. 3.7). In the case of sedation given in the dental surgery, it is important to use a questionnaire to make sure that nothing has been forgotten and, in the event of any mishap, to provide documentary evidence that this assessment has been carried out.

DEATHS IN PATIENTS RECEIVING GA FOR DENTAL TREATMENT

Although deaths are now uncommon during or immediately after GA for dental treatment, they are more frequent than with other pain and anxiety control methods. Every death is a tragedy for the individual and family. Investigation of deaths has too often highlighted factors that seemed potentially avoidable. In the UK, there has been a fall in the number of deaths associated with GA for dental treatment outside hospital since the 1960s, in line with the decline in the use of GA in dental practice. Tragically, though, there were a number of deaths in children associated with GA for dental treatment outside hospital in the late 1990s. Investigations and inquiries into these deaths have been critical of the standard of care provided in fundamental areas such as preoperative assessment, monitoring of electrical heart activity, BP, oxygen and carbon dioxide levels, start of resuscitation and transfer to specialist critical care. GA for dental treatment is not permitted in the UK outside a hospital with critical care facilities (amendment in 'Maintaining standards' published by the British General Dental Council, 2001). Dentists arranging or providing dental treatment under GA should also make sure they have explored and discussed with the patient all possible alternatives and enquired about possible contraindications. They must also take measures to avoid the need for GA in the future.

Mark each item with a tick or N/A for every sedation given		Patient label

CENTRAL LINES (CATHETERS)

Attempting to give infusions of antimicrobials, antiemetics, blood and blood products, chemotherapeutic drugs, nutrients and other fluids into a small vein may cause pain. Most such infusions should therefore be delivered into a larger vein (**Fig. 3.8**). This is achieved with a central line – a central venous catheter (e.g. Hickman® or Groshong® line) – which can also be used to take blood samples (**Table 3.29**). A central line is a long, hollow, silicone rubber tube inserted into a large vein, leaving the limb free to move. The catheter tube tip is positioned in the vein just above the heart; the other end of the line is usually sealed with a cap or bung that can be attached to an intravenous drip (**Fig. 3.9**) or syringe. Sometimes the tube has more than a solitary lumen, to permit different infusions or

Fig. 3.8 Central catheter.

Table 3.29 Catheters for venous and arterial access

Catheter type	Entry site	Length	Comments
Peripheral venous catheters	Veins of forearm or hand	<7 cm	Phlebitis with prolonged use; rarely associated with bloodstream infection
Peripheral arterial catheters	Usually radial artery; sometimes femoral, axillary, brachial, posterior tibial arteries	<7 cm	Low infection risk; rarely associated with bloodstream infection
Midline catheters	Via antecubital fossa into proximal basilic or cephalic veins; do not enter central veins	7–230 cm	Anaphylactoid reactions reported with catheters made of elastomeric hydrogel; lower rates of phlebitis than short peripheral catheters
Non-tunnelled central venous catheters	Percutaneously into central (subclavian, internal jugular or femoral) veins	≥8 cm	Account for majority of catheter-related bloodstream infections
Pulmonary artery catheters	Inserted through a Teflon® introducer in a central (subclavian, internal jugular or femoral) vein	≥30 cm	Usually heparin-bonded; similar rates of bloodstream infection as central catheters; subclavian site preferred to reduce infection risk
Peripherally inserted central venous catheters (PICC)	Inserted into basilic, cephalic or brachial veins and enter superior vena cava	≥20 cm	Lower rate of infection than non-tunnelled central catheters
Tunnelled central venous catheters	Implanted into subclavian, internal jugular or femoral veins	≥8 cm	Lower rate of infection than non-tunnelled central catheters
Totally implantable	Tunnelled beneath skin; implanted in subclavian or internal jugular vein; have subcutaneous port accessed with needle	≥8 cm	Lowest risk for infection; improved patient self-image; no local catheter-site care required; surgery required for removal
Umbilical catheters	Inserted into either umbilical vein or artery	≤6 cm	Risk of infection similar with catheters placed in umbilical vein or artery

**Fig. 3.9** Intravenous fluid delivery ('drip').

injections to be given simultaneously. Such a vascular catheter can be designated by:

- the type of vessel it occupies (e.g. peripheral venous, central venous, or arterial)
- the intended life span (e.g. temporary or short-term versus permanent or long term)
- the site of insertion (e.g. subclavian, axillary, innominate, femoral, internal jugular veins, or peripherally inserted central catheter [PICC])
- the pathway from skin to blood vessel (e.g. tunnelled versus non-tunnelled)

- the physical length (e.g. long versus short)
- some special characteristic (e.g. presence or absence of a cuff, impregnation with heparin, antibiotics or antiseptics, and the number of lumens).

The more common central lines are:

- *subclavian line* – the simplest central line and a *triple-lumen catheter*. It is easy to place, but is not well protected from infection and therefore should typically be replaced every 5–7 days. Attempts have been made to prolong catheter longevity by coating subclavian lines with chlorhexidine or antibiotics.
- *Hickman® catheter* – also placed in the subclavian vein. This type is softer and the distal end is tunnelled under the skin for 13–25 cm for protection against infection, to appear on the chest close to the nipple. These catheters can stay in place for weeks to months. *Groshong®* and *Broviac®* catheters are similar.
- *pheresis catheters* – larger and sturdier than Hickman® catheters. These are often called 'dialysis catheters', as they can be used for haemodialysis. They can be inserted either with (e.g. *PermCath®*) or without a tunnel (e.g. *Arrow Catheter®*).
- *implantable ports* – inserted in the subclavian vein but completely under the skin, with the distal end formed by a small metal 'drum' or reservoir, which has a membrane on one side for needle access. This drum is surgically placed under the skin, just below the clavicle, with the membrane immediately beneath the skin. Since the entire catheter is under the skin, there is minimal infection risk. Access is with a special needle that is pushed through the skin and the membrane into the reservoir.
- *peripherally inserted central catheter* (PICC line) – inserted into one of the antecubital fossa veins. PICCs can stay in place for several weeks, but typically need replacement earlier than a Hickman® or implantable port.

A central line is usually inserted under LA. A suitable vein is identified with ultrasound, a skin incision made near the clavicle and the tip of the line threaded into a large vein. A chest X-ray confirms that the line is correctly located. Once every week:

- heparin is 'flushed' into the line to prevent it clotting
- caps or bungs are changed

- the exit site is cleaned to reduce the risk of infection and an antibiotic patch is placed around the exit site.

Complications related to central line insertion may include:

- accidental arterial puncture
- air in the line; clamps should always be closed when the line is not in use
- dislodgement
- infection – should be suspected if:
 - ◆ the exit site becomes red, swollen or painful
 - ◆ discoloured fluid discharges
 - ◆ fever develops
- pneumothorax
- thrombosis – should be suspected if there is swelling, redness, tenderness in the ipsilateral arm, chest area or up into the neck, or if there is:
 - ◆ shortness of breath
 - ◆ chest tightness.

ANTIMICROBIAL PROPHYLAXIS

Antimicrobials are used in dentistry to treat an existing infection therapeutically or to prevent an infection prophylactically. To prevent a perioperative infection (primary prophylaxis), prophylactic antibiotics may be administered when a surgical device, such as a prosthetic cardiac valve, is placed. They also may be administered to patients who have an existing medical condition or have received a previously placed device to reduce the risk of infection from a bacteraemia (secondary prophylaxis). Although it is common to prescribe secondary prophylaxis for many dental conditions, there is a general lack of scientific evidence of its effectiveness and accumulating evidence suggests that such prescriptions may be unnecessary. In the past, antibiotic prophylaxis has been used for conditions with no proven benefit. Risks associated with antibiotics include allergic reactions (e.g. anaphylaxis), development of antibiotic-resistant bacteria, development of superinfections, pseudomembranous colitis, cross-reactions with other drugs, and death. The costs involved with the use of antibiotics can be significant as well. This is discussed above and in chapters covering the various organ systems, while Appendix 3.7 summarizes situations where antibiotic prophylaxis has been considered or used in some cases.

Conscious sedation and general anaesthesia

The statement by the General Dental Council (GDC) on both conscious sedation and general anaesthesia is found in the GDC's *Standards for the dental team*. It supports the recommendations and guidance of the Department of Health. Full details are available at <<http://www.gdc-uk.org/dentalprofessionals/standards/Pages/default.aspx>>.
 Department of Health. *A conscious decision: a review of the use of general anaesthesia and conscious sedation in primary dental care*. <http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_4074702>.
 Department of Health, Standing Dental Advisory Committee. *Conscious sedation in the provision of dental care: report of an expert group on sedation for dentistry*. <http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_4069257>.

Consent

The GDC has produced supporting guidance to its standards specifically on consent – *Principles of patient consent*. <[http://www.gdc-uk.org/Newsandpublications/Publications/Publications/PatientConsent\[1\].pdf](http://www.gdc-uk.org/Newsandpublications/Publications/Publications/PatientConsent[1].pdf)>.

APPENDIX 3.1 DRUGS TO BE AVOIDED OR ONLY USED IN LOW DOSAGE IN SPECIFIC CONDITIONS^a

Condition	Drugs that may be contraindicated ^b
Addison disease (hypoadrenocorticism)	Any general anaesthetic
Alcoholism	Antidepressants Any general anaesthetic Aspirin Baclofen Carbamazepine Cefamandole Chlorpropamide Metronidazole Paracetamol (acetaminophen) Salicylate Tinidazole
Allergies	Aspirin Penicillin
Anorexia	Paracetamol (acetaminophen)
Asthma	Aspirin Beta-blockers Non-steroidal anti-inflammatory drugs (NSAIDs) Opioids Radiocontrast media
Bleeding disorders	Aspirin Corticosteroids NSAIDs
Breast-feeding	Aciclovir Alcohol Antidepressants Aspirin Azithromycin Benzodiazepines Buspirone Clarithromycin Corticosteroids Co-trimoxazole Dapsone Dihydrocodeine Famciclovir Indometacin Iodides Itraconazole Ketoconazole Oxcarbazepine Pentazocine Phenytoin Povidone-iodine Sulphonamides Sumatriptan Tetracyclines Voriconazole Warfarin
Burns	Suxamethonium
Carcinoid syndrome	Opioids
Cardiovascular diseases	Adrenaline (epinephrine) Aspirin Chloral hydrate Halothane

(Continued)

Condition	Drugs that may be contraindicated ^b	Condition	Drugs that may be contraindicated ^b
	Itraconazole		Corticosteroids
	NSAIDs		Ketamine
	Pentazocine		NSAIDs
	Rofecoxib		Pentazocine
	Thiopental	Hyperthyroidism	Adrenaline (epinephrine)
	Tricyclics		Atropinics
Cerebrovascular disease	Diazepam ^c	Hypothyroidism	Any general anaesthetic
Children under 16 years	Aspirin		Codeine
	NSAIDs		Diazepam
	Codeine		Dihydrocodeine
	Tetracyclines		Midazolam
Chronic lymphocytic leukaemia	Amoxicillin		Opioids
			Pethidine
	Ampicillin		Thiopental
Constipation	Codeine	Infectious mononucleosis	Amoxicillin
Diabetes mellitus	Aspirin		Ampicillin
	Corticosteroids		Antidepressants
	NSAIDs		Aspirin
	Quinolones		Azithromycin
Diarrhoea	Clindamycin		Carbamazepine
	Mefenamic acid		Carbenoxolone
Drug addiction	Pentazocine		Chloral hydrate
Dystrophia myotonica (myotonic dystrophy)	Suxamethonium		Clarithromycin
			Co-amoxiclav
	Thiopental		Corticosteroids
Elderly	Atropinics		Co-trimoxazole
	Diazepam		Dextropropoxyphene
	Dihydrocodeine		Diazepam
	Ketamine		Erythromycin estolate
	Midazolam		Etretinate
	NSAIDs		Flucloxacillin
	Tricyclics		Flumazenil
Epilepsy	Enflurane		General anaesthetics
	Flumazenil		Halothane
	Fluoxetine		Itraconazole
	Ketamine		Ketoconazole
	Phenothiazines		Lamotrigine
	Quinolones		Metronidazole
	Tricyclics		Miconazole
Glaucoma	Atropinics		Midazolam
	Carbamazepine		Moxifloxacin
	Corticosteroids		NSAIDs
	Diazepam ^c		Opioids or codeine
	Imipramine		Paracetamol (acetaminophen)
	Midazolam		Pentazocine
	Selective serotonin reuptake inhibitors (SSRIs)		Phenothiazines
	Topiramate		Phenytoin
	Tricyclics		Pilocarpine
Glucose-6-phosphate dehydrogenase deficiency	Aspirin		Prednisolone (prednisone)
			Promethazine
	Co-trimoxazole		Propofol
	Sulphonamides		Rifampicin
Gout	Amoxicillin		Sumatriptan
	Ampicillin		Suxamethonium
	Aspirin		Tetracyclines
Head injury	Ketamine		Thiopental
	Opioids		Tricyclics
Hypertension	Adrenaline (epinephrine)		Warfarin
	Aspirin		

(Continued)

Condition	Drugs that may be contraindicated ^b
Malignant hyperpyrexia	Desflurane Enflurane Halothane Ketamine Sevoflurane Suxamethonium
Myasthenia gravis	Aminoglycosides Clindamycin General anaesthetics Lincomycin Quinolones Sulphonamides Tetracyclines
Neuromuscular diseases	Diazepam Midazolam Suxamethonium Tetracyclines Thiopental
Parkinsonism	Benzodiazepines
Peptic ulcer	Aspirin Chloral hydrate Corticosteroids Mefenamic acid NSAIDs
Phaeochromocytoma	Adrenaline (epinephrine) Barbiturates Enflurane
Porphyria	Carbamazepine Co-trimoxazole Dextropropoxyphene Diazepam Erythromycin MAOIs Metronidazole Midazolam Phenytoin Sulphonamides Thiopental
Pregnancy ^d	Care with all drugs Alcohol Aminoglycosides Aspirin Carbamazepine Corticosteroids Co-trimoxazole Dapsone Diazepam Ephedrine Epsilon aminocaproic acid (EACA) Erythromycin Etretinate Fluconazole Flumazenil Gabapentin Itraconazole Ketoconazole Mefenamic acid ^d Methotrexate Metronidazole Midazolam

Condition	Drugs that may be contraindicated ^b
	NSAIDs Opioids Oxcarbazepine Phenytoin Prilocaine Sulphonamides Teicoplanin Tetracyclines Tranexamic acid Vancomycin Voriconazole
Psychiatric disease	Ketamine
Raised intracranial pressure	Ketamine Opioids
Renal disease (systemic)	Aciclovir Aminoglycosides Amoxicillin Any general anaesthetic or CNS depressant or NSAID Aspirin Azathioprine Baclofen Bupivacaine Carbamazepine Cefadroxil Cefalexin Cefixime Chloral hydrate Ciprofloxacin Co-amoxiclav Co-trimoxazole Diazepam Dihydrocodeine Ephedrine Erythromycin Famciclovir Flucloxacillin Fluconazole Gabapentin Itraconazole Lamotrigine Mefenamic acid Metronidazole Midazolam NSAIDs Opioids Paracetamol (acetaminophen) Pentazocine Pilocarpine Prilocaine Sulphonamides Suxamethonium Tetracyclines Valaciclovir Vancomycin Voriconazole Warfarin
Respiratory disease	Any general anaesthetic Dextropropoxyphene Diazepam

(Continued)

Condition	Drugs that may be contraindicated ^b
	Dihydrocodeine
	Midazolam
	Opioids
	Thiopental
Sjögren syndrome	Co-trimoxazole
Suxamethonium sensitivity	Local anaesthetics
	Suxamethonium
Systemic lupus erythematosus	Tetracyclines
Teenagers	Metoclopramide
Thrombotic disease	Epsilon aminocaproic acid (EACA)
	Tranexamic acid
Thyroid disease	Povidone–iodine

Condition	Drugs that may be contraindicated ^b
Tuberculosis	Corticosteroids
Urinary retention (prostatic disease)	Atropinics
	Opioids

^aALWAYS check the *British National Formulary* or an equivalent source, as these lists cannot be complete; nor can their accuracy be guaranteed. Box 27.9 shows drugs whose action may be affected by grapefruit; Box 27.10 shows drugs enhanced by pomegranate. See also Appendices 3.2 and 3.3.

^bContraindications are often relative or of theoretical interest only; other drugs may also be contraindicated.

^cMidazolam may be safer but should still be used with caution.

^dAnd breast-feeding.

APPENDIX 3.2 POSSIBLE CONTRAINDICATIONS TO DRUGS USED IN DENTISTRY^a

Drug	Possible contraindications	Possible reaction
Aciclovir (systemic)	Renal disease	Rise in urea
Adrenaline (epinephrine)	Hypertension (theoretically)	Rise in BP
	Hyperthyroidism (theoretically)	Arrhythmias
	Ischaemic heart disease	Arrhythmias
	Phaeochromocytoma	Hypertension
Ampicillin (or amoxicillin)	Allergy to penicillin	Anaphylaxis
	Chronic lymphocytic leukaemia	Rash
	Gout	Rash
	Infectious mononucleosis	Rash
Antidepressants	Alcoholism	Potentiated
Aspirin	Alcoholism	Gastric bleeding
	Allergy to aspirin including aspirin-induced asthma	Anaphylaxis or asthma
	Bleeding disorders	Gastric bleeding
	Breast-feeding	Reye syndrome
	Cardiac failure	Fluid retention
	Children under 16 years	Reye syndrome
	Diabetes mellitus	Interferes with control
	Glucose-6-phosphate dehydrogenase deficiency	Haemolysis
	Gout	Exacerbation of gout
	Hypertension	Fluid retention
	Liver disease	Bleeding tendency
	Peptic ulcer	Gastric bleeding
	Pregnancy	Haemorrhage
	Renal disease	Fluid retention and gastric bleeding
Atropinics	Elderly	Confusion
	Glaucoma	Exacerbation of glaucoma
	Hyperthyroidism	Tachycardias
	Urinary retention or prostatic hypertrophy	Urine retention
Benzodiazepines (see Midazolam)		
Carbamazepine	Alcoholism	Sedation
	Blood disorders	Dyscrasia
	Elderly	Agitation or confusion
	Glaucoma	Raised intraocular pressure
	Liver disease	Hepatotoxicity
	Porphyria	Acute porphyria
	Pregnancy	Teratogenicity
Carbenoxolone	Liver disease	Toxicity
Cephalosporins	Allergy to cephalosporins	Anaphylaxis
	Allergy to penicillins	Allergy
	Renal disease	Nephrotoxicity

(Continued)

Drug	Possible contraindications	Possible reaction
Chloral hydrate	Cardiovascular disease Gastritis Liver disease Renal disease	Fluid retention Gastric irritation Coma CNS depression
Clindamycin	Diarrhoea Liver disease Renal disease	Aggravation of diarrhoea Increased toxicity Increased toxicity
Codeine	Children Colonic disease Hypothyroidism Liver disease	Potential toxicity Constipation Coma Respiratory depression
Corticosteroids	Diabetes mellitus Glaucoma Hypertension Liver disease Peptic ulcer Tuberculosis	Exacerbation of diabetes Exacerbation of glaucoma Increased hypertension Increased side-effects Perforation Possible dissemination
Co-trimoxazole	Elderly Glucose-6-phosphate-dehydrogenase deficiency Liver disease Porphyria Pregnancy Renal disease Sjögren syndrome	Agranulocytosis Haemolysis Enhanced toxicity Acute porphyria Folate deficiency Increased toxicity Aseptic meningitis
Dextropropoxyphene	Liver disease Porphyria Pregnancy Respiratory disease	Potentiating paralysis Hypertension Fetal depression Respiratory depression
Desflurane	Malignant hyperpyrexia	Pyrexia
Diazepam (see Midazolam)		
Dihydrocodeine	Elderly Hypothyroidism Renal disease Respiratory disease	Increased toxicity Coma Increased toxicity Respiratory depression
Enflurane	Epilepsy Halothane hepatitis Malignant hyperpyrexia Phaeochromocytoma	Epileptogenic Hepatitis Pyrexia Hypertension
Epsilon aminocaproic acid (EACA)	Haematuria Pregnancy Thrombotic disease	Renal tract obstruction Thrombosis Thrombosis
Erythromycin	Breast-feeding Liver disease Porphyria Pregnancy Renal disease	Entry of milk Hepatotoxicity Paralysis ?Teratogenicity Toxicity
Etomidate	Adrenal disease	Adrenal suppression
Etretinate	Liver disease Pregnancy	Hepatotoxicity Teratogenicity
Flucloxacillin	Liver disease	Hepatotoxicity
Fluconazole	Cardiac failure Liver disease Porphyria Pregnancy Renal disease	Cardiac failure Hepatotoxicity Crisis Teratogenicity Toxicity
Flumazenil	Allergy Epilepsy Liver disease Pregnancy	Allergy Epileptogenicity Delayed excretion Teratogenicity

(Continued)

Drug	Possible contraindications	Possible reaction
Fluoxetine	Epilepsy	Epileptogenicity
Halothane	Cardiac arrhythmias	Increased arrhythmias
	Halothane hepatitis	Hepatitis
	Malignant hyperpyrexia	Pyrexia
	Recent anaesthesia with halothane	Hepatitis
Isoflurane	Malignant hyperpyrexia	Pyrexia
Itraconazole (see also Fluconazole)	Heart failure	Heart failure
Ketamine	Elderly	Hallucinations
	Epilepsy	Fits
	Hallucinations	Hallucinations
	Hypertension	Hypertension
	Malignant hyperpyrexia	Pyrexia
	Psychiatric disease	Psychotic reactions
	Raised intracranial pressure	Increased intracranial pressure
	Liver disease	Hepatotoxicity
Ketoconazole (see also Fluconazole)		
Lincomycin (as for Clindamycin)		
Local anaesthetics	Suxamethonium sensitivity	Respiratory depression
Mefenamic acid	Asthma	Bronchospasm
	Diarrhoea	Exacerbation of diarrhoea
	Peptic ulcer	Bleeding
	Pregnancy and lactation	?Teratogenicity
	Renal disease	Renal damage
Metoclopramide	Teenagers	Dystonic reactions
Metronidazole	Alcoholism	Headache
	Blood dyscrasias	Leucopenia
	Breast-feeding	Entry into milk
	CNS disease	Neuropathy
	Epilepsy	Epileptogenicity
	Liver disease	Toxicity
	Porphyria	Acute porphyria
	Pregnancy	?Teratogenicity
	Renal disease	Increased drug effect
Miconazole (see Fluconazole)		
Midazolam	Cerebrovascular disease	Cerebral ischaemia
	Children	Anomalous effects
	Chronic obstructive airways disease	Respiratory depression
	Elderly	Cerebral ischaemia
	Glaucoma	Increased intraocular pressure
	Head injury	Disturbed signs
	Hypothyroidism	Coma
	Neuromuscular disorders	Deterioration of condition
	Porphyria	Acute porphyria
	Pregnancy	Fetal hypoxia/dependence
	Severe kidney disease	Increased midazolam effect
	Severe liver disease	Increased midazolam effect
NSAIDs	Asthma	Bronchospasm
	Bleeding tendency	Bleeding
	Cardiac failure	Cardiac failure
	Children	Toxicity
	Diabetes	Disturbed control
	Elderly	Toxicity
	Hypertension	Disturbed control
	Liver disease	Hepatotoxicity
	Peptic ulcer	Gastric bleeding
	Pregnancy	Patent ductus arteriosus
	Renal disease	Nephrotoxicity

(Continued)

Drug	Possible contraindications	Possible reaction
Opioids	Asthma Carcinoid syndrome Chronic obstructive airways disease Head injury Hypothyroidism Liver disease Pregnancy Renal disease Urinary retention or prostatic enlargement	Bronchospasm Increased toxicity Respiratory depression Confusion of 'eye signs' Coma Increased respiratory depression Fetal depression Increased respiratory depression Urinary retention
Paracetamol (acetaminophen)	Alcoholism Anorexia Liver disease Renal disease	Hepatotoxicity Hepatotoxicity Hepatotoxicity Nephrotoxicity
Penicillins	Allergy to penicillin Renal disease	Anaphylaxis Hyperkalaemia with i.m. benzyl penicillin
Pentazocine	Hypertension Liver disease Myocardial infarct (recent) Narcotic addiction Pregnancy	Hypertension Enhanced activity Cardiac arrest Withdrawal syndrome Fetal depression
Pethidine	Hypothyroidism	Coma
Povidone–iodine	Lactation Pregnancy Thyroid disease	Toxicity Toxicity Toxicity
Promethazine	Liver disease	Coma
Propofol	Children under 17 y	May cause convulsions
Quinolones	Diabetes Epilepsy Myasthenia gravis	Hypoglycaemia Epileptogenicity Muscle weakness
Rifampicin	Liver disease	Hepatotoxicity
Rofecoxib	Cardiac disease	Risk of infarction
Sevoflurane	Malignant hyperpyrexia	Pyrexia
Sulphonamides	Glucose-6-phosphate dehydrogenase deficiency Liver disease Porphyria Pregnancy Renal disease	Haemolysis Toxicity Acute porphyria Fetal haemolysis Crystalluria
Suxamethonium	Burns Dystrophia myotonica Liver disease Malignant hyperpyrexia Myasthenia gravis Renal disease Suxamethonium sensitivity	Arrhythmias Increased muscle weakness Apnoea Pyrexia Increased muscle weakness Apnoea Apnoea
Tetracyclines	After gastrointestinal surgery Children Myasthenia gravis Pregnancy Renal disease Systemic lupus erythematosus	Enterocolitis Tooth staining Increased muscle weakness Tooth staining (fetus) Nephrotoxicity Photosensitivity
Thiopental	Addison disease Barbiturate sensitivity Cardiovascular disease Dystrophia myotonica Hypothyroidism Liver disease Myasthenia gravis Porphyria Postnasal drip Respiratory disease	Coma Anaphylaxis Cardiovascular depression Increased weakness Coma Increased anaesthesia Increased weakness Acute porphyria Laryngeal spasm Respiratory depression

(Continued)

Drug	Possible contraindications	Possible reaction
Tranexamic acid	Haematuria	Renal tract obstruction
	Pregnancy	Thromboses
Triclofos	Thromboembolic disease	Thromboses
Tricyclics	Cardiovascular disease	Postural hypotension, arrhythmias
	Elderly	Hypotension
	Epilepsy	Increased fits
	Glaucoma	Exacerbation of glaucoma
	Liver disease	Increased drug effect
Trimethoprim	Sjögren syndrome	Trimethoprim-induced aseptic meningitis
Voriconazole (see Fluconazole)		

^aALWAYS check the *British National Formulary* or an equivalent source, as these lists cannot be complete; nor can their accuracy be guaranteed. Many of these reactions are likely to be of more theoretical interest than clinical significance, so that reference should also be made to the appropriate chapters for particular diseases. Box 27.9 shows drugs whose action may be affected by grapefruit; Box 27.10 shows drugs enhanced by pomegranate. See also Appendices 3.1 and 3.3.

APPENDIX 3.3 POSSIBLE DRUG INTERACTIONS IN DENTISTRY^a

Drug used in dentistry	Interaction with	Possible effects
Aciclovir	Ciclosporin	Nephrotoxicity
	Tacrolimus	Nephrotoxicity
	Zidovudine	Lethargy
Adrenaline (epinephrine)	Halothane	Arrhythmias
	Propranolol	Hypertension
	Tricyclics	Pressor response in overdose
Amphotericin (i.v.)	Aminoglycosides	Enhanced nephrotoxicity
	Ciclosporin	Enhanced nephrotoxicity
	Corticosteroids	Hypokalaemia
	Diuretics	Hypokalaemia
	Tacrolimus	Nephrotoxicity
Anaesthetics (general)	Antihypertensives	Hypotension
	Monoamine oxidase inhibitors (MAOIs)	Enhanced hypotension; anaesthetics potentiated
Antibiotics	Anticoagulants	Enhanced anticoagulant effect
	Oral contraceptives	Reduced contraceptive effect
	Retinoids	Intracranial hypertension
Aspirin (doses >4g/day)	Angiotensin-converting enzyme inhibitors (ACEIs)	ACEI impaired?
	Alcohol	Increased risk of gastric bleeding
	Antacids	Reduced aspirin absorption
	Anticoagulants	Enhanced anticoagulant effect
	Cilostazol	Toxicity
	Clopidogrel	Increased bleeding
	Corticosteroids	Peptic ulceration
	Digoxin	Digoxin increased
	Iloprost	Increased bleeding
	Lithium	Lithium toxicity
	Methotrexate	Enhanced methotrexate activity
	Metoclopramide	Potential of aspirin absorption
	Mifepristone	Toxicity
	Non-steroidal anti-inflammatory drugs (NSAIDs)	Peptic ulceration
	Oral hypoglycaemics	Enhanced hypoglycaemic effect
	Paracetamol (acetaminophen)	Enhanced hepatotoxicity
	Phenylbutazone	Increased liability of peptic ulceration
	Phenytoin	Phenytoin toxicity
	Probenecid	Uricosuric action reduced
	Sodium valproate	Bleeding tendency
	Selective serotonin reuptake inhibitors (SSRIs)	Bleeding tendency
	Spironolactone	Spironolactone impaired
	Subitramine	Bleeding tendency
	Sulfinpyrazone	Uricosuric action reduced
	Venlafaxine	Bleeding tendency
	Varicella zoster virus (VZV) vaccine	Reye syndrome
	Zafirlukast	Enhanced leukotrienes

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Atropine	Metoclopramide	Antagonism
Azathioprine	Allopurinol	Toxicity
	Clozapine	Blood dyscrasia
	Co-trimoxazole	Blood dyscrasia
	Rifampicin	Transplant rejection
	Trimethoprim	Blood dyscrasia
	Warfarin	Reduced warfarin effect
Azithromycin (see Erythromycin and Clarithromycin)	Antipsychotics	Long QT syndrome (LQTS; Ch. 5)
	Ciclosporin	Increased ciclosporin effect
	Pimozide	Arrhythmias
	Terfenadine	Arrhythmias
	Theophylline	Increased theophylline
Baclofen	ACEIs	Enhanced hypotension
	Alcohol	Sedation
	NSAIDs	Toxicity
Barbiturates	Alcohol	May be increased sedation or resistance
	Anticoagulants	Reduced anticoagulant activity
	Antihistamines	Enhanced sedation
	Antihypertensives	Hypotension
	Corticosteroids	May precipitate hypotensive crises
	Ciclosporin	Reduced effect of ciclosporin
	MAOIs	Enhanced sedation
	Phenothiazines	Tremor
	Phenytoin	Reduced phenytoin effect
	Tricyclics	Cardiac arrest
Carbamazepine	Alcohol	Toxicity
	Antidepressants	Effect increased
	Calcium channel blockers	Carbamazepine toxicity
	Ciclosporin	Reduced effect of ciclosporin
	Cimetidine	Carbamazepine toxicity
	Clarithromycin	Carbamazepine toxicity
	Danazol	Carbamazepine toxicity
	Dextropropoxyphene	Carbamazepine enhanced
	Doxycycline	Reduced doxycycline effect
	Erythromycin	Carbamazepine toxicity
	Fluoxetine	Confusion
	Irinotecan	Irinotecan effect reduced
	Lithium	Lithium toxicity
	MAOIs	Hypertension
	Oral anticoagulants	Reduced anticoagulant effect
	Oral contraceptive	Reduced contraceptive effect
	Paracetamol (acetaminophen)	Liver damage
	Phenytoin	Reduced phenytoin effect
	Protease inhibitors	Interference
	Sodium valproate	Reduced effect of valproate
Cefamandole	Alcohol	Disulfiram-type reaction
	Anticoagulants	Increased anticoagulant activity
Cephalosporins	Antacids	Reduced absorption
	Anticoagulants	Increased anticoagulant activity
	Diuretics	Increased nephrotoxicity
Ciclosporin	ACEIs	Hyperkalaemia
	Aciclovir	Nephrotoxicity
	Allopurinol	Nephrotoxicity
	Aminoglycosides	Nephrotoxicity
	Azoles	Ciclosporin toxicity
	Carbamazepine	Ciclosporin reduced
	Clarithromycin	Ciclosporin toxicity
	Colchicine	Nephrotoxicity and myotoxicity
	Corticosteroids	Both drugs increased
	Diclofenac	Diclofenac enhanced
	Erythromycin	Ciclosporin toxicity
	NSAIDs	Nephrotoxicity

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Clarithromycin	Pimozide	Arrhythmias
	Terfenadine	Arrhythmias
Codeine	MAOIs	Coma
Colchicine	Ciclosporin	Nephrotoxicity and myotoxicity
Corticosteroids	ACEIs	Reduced hypotensive effect
	Aminoglycosides	Reduced steroid effects
	Anticoagulants	Gastric bleeding
	Aspirin/NSAIDs	Increased liability of peptic ulceration
	Oral antidiabetics	Reduced effect
Danazol	Anticoagulants	Potentiated anticoagulation
	Carbamazepine	Carbamazepine toxicity
Dextropropoxyphene	Alcohol	CNS depression
	Anticoagulants	Enhanced anticoagulant effect
	Carbamazepine	Serotonin syndrome
	Orphenadrine	Tremor, anxiety and confusion
	MAOIs	Serotonin syndrome
Doxycycline (see Tetracyclines)		
Ephedrine	MAOIs	Hypertension
	Tricyclics	Hypertension
Erythromycin	Alfentanil	Increased alfentanil effect
	Amiodarone	Arrhythmias
	Amprenavir	Erythromycin toxicity
	Anticoagulants	Increased bleeding
	Antipsychotics	LQTS
	Artemether	Erythromycin toxicity
	Atazanavir	Erythromycin toxicity
	Atomoxetine	Arrhythmias
	Bromocriptine	Erythromycin toxicity
	Buspirone	Buspirone toxicity
	Cabergoline	Erythromycin toxicity
	Carbamazepine	Carbamazepine toxicity
	Ciclosporin	Ciclosporin toxicity
	Cimetidine	Erythromycin toxicity
	Clozapine	Convulsions
	Colchicine	Colchicine toxicity
	Corticosteroids	Metabolism reduced
	Darifenacin	Increased darifenacin level
	Digoxin	Digoxin toxicity
	Efavirenz	Erythromycin toxicity
	Eletriptan	Eletriptan toxicity
	Eplerenone	Increased eplerenone level
	Ergotamine	Ergotism
	Felodipine	Increased felodipine level
	Fluoxetine	LQTS
	Galantamine	Increased galantamine level
	Ivabradine	Arrhythmias
	Loratidine	Loratidine toxicity
	Methysergide	Ergotism
	Midazolam	Midazolam enhanced
	Mizolastine	Mizolastine toxicity
	Moxifloxacin	Arrhythmias
	Oral contraceptive	Reduced effect
	Pentamidine	Arrhythmias
	Phenytoin	Phenytoin toxicity
	Pimozide	Arrhythmias
	Rifabutin	Uveitis
	Ritonavir	Erythromycin toxicity
	Sertindole	Arrhythmias
	Sildenafil	Sildenafil level increased
	Sirolimus	Enhanced drug level
	Statins	Myopathy increased
	Tacrolimus	Tacrolimus toxicity
	Tadalafil	Tadalafil increased

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Fluconazole	Terfenadine	Arrhythmias
	Theophyllines	Toxicity
	Tolterodine	Increased tolterodine level
	Tricyclics	LQTS
	Valproate	Toxicity
	Vardenafil	Increased toxicity
	Venlafaxine	LQTS
	Verapamil	Toxicity
	Zopiclone	Increased zopiclone level
	Anticoagulants	Enhanced anticoagulant effect
	Anticonvulsants	Anticonvulsant enhanced
	Antipsychotics	Antipsychotics enhanced
	Calcium-channel blockers	Cardiac failure
	Carbamazepine	Carbamazepine enhanced
	Celecoxib	Celecoxib enhanced
	Ciclosporin	Ciclosporin enhanced
	Digoxin	Digoxin enhanced
	Midazolam	Midazolam enhanced
	Mizolastine	Mizolastine enhanced
	Oral antidiabetics	Enhanced antidiabetic effect
	Oral contraceptive	May impair contraception
	Parecoxib	Parecoxib enhanced
	Phenytoin	Phenytoin enhanced
	Pimozide	Arrhythmias
	Protease inhibitors (PIs)	PIs enhanced
	Quinidine	Arrhythmias
	Rifampicin	Fluconazole effect reduced
	Sirolimus	Sirolimus enhanced
	Statins	Increased myopathy
	Tacrolimus	Tacrolimus enhanced
Flumazenil	Terfenadine	Arrhythmias
	Vincristine	Vincristine enhanced
	Zidovudine	Myelotoxicity
Fluoxetine	Tricyclics	Sedation
	Alcohol	Enhanced alcohol effect
	Antiepileptics	Antagonism
Ganciclovir	Carbamazepine	Confusion
	MAOIs	CNS effects
	Warfarin	Enhanced anticoagulant effect
Gentamicin	Zidovudine	Marrow suppression
	Furosemide	Toxicity and nephrotoxicity
	Aminophylline	Arrhythmias
Halothane	Anticonvulsants	Phenytoin toxicity
	Antihypertensives	Hypotension
	Diazepam	Enhanced activity of halothane
Indometacin	Fenfluramine	Arrhythmias
	Isoprenaline	Arrhythmias
	L-dopa	Arrhythmias
Itraconazole (as for Fluconazole)	Lithium	Arrhythmias
	Opioids	Respiratory depression
	Phenothiazines	Respiratory depression; hypotension
Ketamine	Haloperidol	Drowsiness
	CNS depressants	Increased sedation
	Ciclosporin	Nephrotoxicity
Ketoconazole (see Fluconazole)	Simvastatin	Risk of myopathy
	Terfenadine	Cardiotoxicity
	Anticoagulants	Enhanced anticoagulant effect
Mefenamic acid	Oral hypoglycaemics	Enhanced hypoglycaemia

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Metronidazole	Alcohol Anticoagulants Anticonvulsants BCNU (bis-chloroethylnitrosourea) Busulfan Ciclosporin Cimetidine Cyclophosphamide Fluorouracil Lithium	Headache and hypotension Increased bleeding tendency Phenytoin toxicity BCNU toxicity Busulfan toxicity Ciclosporin toxicity Metronidazole toxicity Cyclophosphamide toxicity Fluorouracil toxicity Lithium toxicity
Miconazole (as for Fluconazole)		
Midazolam and other sedatives	Alcohol Anticoagulants Anticonvulsants Antidepressants Antihistamines Antipsychotics Azoles Baclofen Benzodiazepines Calcium-channel blockers Cimetidine Clarithromycin Disulfiram Esomeprazole Erythromycin Fluvoxamine General anaesthetics L-dopa Lithium Macrolides Omeprazole Opioids Pentazocine Phenytoin PIs Quinupristin Rifampicin Suxamethonium Telithromycin Tizanidine Tricyclics	Enhanced sedation Increased bleeding Midazolam potentiated Enhanced sedation Enhanced sedation Enhanced sedation Midazolam potentiated Midazolam potentiated Enhanced sedation Midazolam potentiated Enhanced sedation Midazolam potentiated Midazolam potentiated? Midazolam potentiated? Midazolam potentiated Midazolam potentiated Anaesthesia enhanced Antagonism Hypothermia Midazolam potentiated Midazolam potentiated? Respiratory depression Respiratory depression Phenytoin toxicity Midazolam potentiated Midazolam potentiated Midazolam effect reduced Activity of suxamethonium reduced Midazolam potentiated Enhanced sedation Enhanced sedation
Monoamine oxidase inhibitors (MAOIs)	Anticoagulants Antihypertensives Codeine General anaesthetics L-dopa Opioids Oral hypoglycaemics Pethidine Propranolol Tricyclics Tyramine-containing foods	Enhanced anticoagulant effect Reduced or increased hypotensive effect Hypertension Hypertension Hypertensive crisis Respiratory depression Enhanced hypoglycaemia Hypertensive crisis Hypertensive crisis Hypertensive crisis Excitation and other interactions Hypertensive crisis
Non-steroidal anti-inflammatory drugs (NSAIDs; >4g/day)	Alcohol Anticoagulants Anticonvulsants Antihypertensives Baclofen Ciclosporin Corticosteroids Cytotoxics	Gastric irritation Increased bleeding tendency Phenytoin toxicity Hypotension, hyperkalaemia Toxicity Nephrotoxicity Gastric irritation Toxicity

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Noradrenaline (norepinephrine) Opioids	Diuretics	Nephrotoxicity
	Lithium	Lithium toxicity
	Moclobemide	NSAID enhanced
	Oral antidiabetics	Enhanced antidiabetic activity
	Paracetamol (acetaminophen)	Hepatotoxicity
	Pentoxifylline	Increased bleeding
	Quinolones	Convulsions
	SSRIs	Bleeding
	Tacrolimus	Nephrotoxicity
	Warfarin	Increased bleeding
	Zidovudine	Blood dyscrasia
	Tricyclics	Hypertension
	Diazepam	Respiratory depression
	Halothane	Respiratory depression
Paracetamol (acetaminophen)	MAOIs	Respiratory depression or coma
	Thiopental	Respiratory depression
	Alcohol	Hepatotoxicity
	Anticoagulants	Increased bleeding tendency
	Anticonvulsants	Hepatotoxicity
	Busulfan	Toxicity
	Carbamazepine	Hepatotoxicity
	Colestyramine	Reduced absorption of paracetamol (acetaminophen)
	Domperidone	Increased absorption of paracetamol (acetaminophen)
	Isonicotinic acid hydrazide (INAH)	Enhanced INAH hepatotoxicity
	Metoclopramide	Increased absorption of paracetamol (acetaminophen)
	Zidovudine	Increased myelosuppression
	Diazepam	Respiratory depression
	Antidepressants	Serotonin syndrome
Pentazocine Pethidine	MAOIs	Hypertensive crisis
	Phenothiazines	Respiratory depression
	Alcohol	May be increased sedation
	Anticoagulants	Enhanced anticoagulant effect
	Antihistamines	Enhanced sedation
	Antihypertensives	Hypotension
	Barbiturates	Tremor
	Diazepam	Respiratory depression
	Opioids	Respiratory depression
	Pethidine	Respiratory depression
	Tricyclics	Convulsions
	Aspirin	Increased liability to peptic ulceration
	Aspirin	Phenytoin toxicity
	Azoles	Phenytoin toxicity
Phenylbutazone Phenytoin	Baclofen	Phenytoin toxicity
	Carbamazepine	Reduced carbamazepine effect
	Cimetidine	Phenytoin toxicity
	Clarithromycin	Phenytoin toxicity
	Disulfiram	Disulfiram potentiated
	INAH	INAH potentiated
	Midazolam	Phenytoin toxicity
	NSAIDs	Phenytoin toxicity
	Phenylbutazone	Phenylbutazone potentiated
	Thiopental	Respiratory depression
	Antacids	Reduced absorption
	Anticoagulants	Bleeding increased
	Antidiabetics	Antidiabetic enhanced
	Anticonvulsants	Phenytoin enhanced
Promethazine Quinolones	Artemether	Toxicity
	Ciclosporin	Nephrotoxicity
	Iron	Reduced absorption
	Theophylline	Convulsions
	Zolmitriptan	Increased effect of zolmitriptan

(Continued)

Drug used in dentistry	Interaction with	Possible effects
Rifampicin	Antacids	Reduced rifampicin absorption
	Anticoagulants	Reduced bleeding tendency
	Antifungals	Increased metabolism of antifungals
	Ciclosporin	Reduced effect of ciclosporin
	Oral contraceptive	Reduced contraceptive effect
Selective serotonin reuptake inhibitors (SSRIs)	Anticoagulants	Bleeding
	Lithium	Serotonin syndrome
	NSAIDs	Bleeding
	Tramadol	Serotonin syndrome
Sulphonamides	Anticoagulants	Enhanced anticoagulant effect
	Methotrexate	Increased methotrexate toxicity
	Oral hypoglycaemics	Enhanced hypoglycaemia
	Phenytoin	Phenytoin toxicity
Suxamethonium	Cytotoxic drugs	Prolonged muscle paralysis
	Diazepam	Activity of suxamethonium reduced
	Diethylstilbestrol	Prolonged muscle paralysis
	Digitalis	Digitalis toxicity enhanced
	Ecothiopate	Prolonged muscle paralysis
	Lithium	Onset of suxamethonium delayed; action prolonged
	Spironolactone	Plasma potassium rises; potential arrhythmias
Tetracyclines	ACEIs	Reduced serum levels of tetracyclines
	Antacids	Lower serum levels of tetracyclines
	Anticoagulants	Bleeding tendency
	Barbiturates	Reduced doxycycline blood levels
	Cimetidine	Reduced serum tetracycline levels
	Iron	Reduced serum tetracycline levels
	Lithium	Lithium toxicity
	Methoxyflurane	Renal damage
	Milk	Reduced tetracycline absorption
	Oral contraceptive	Reduced contraceptive effect
	Retinoids	Benign intracranial hypertension
Thiopental	Alcohol	Increased sedation
	Antihypertensives	Hypotension
	MAOIs	Coma
	Opioids	Respiratory depression
	Phenothiazines	Respiratory depression
	Sulphonamides	Barbiturate potentiated
Tramadol	Antidepressants	Serotonin syndrome
Tricyclics	Adrenaline (epinephrine)	Hypertensive response in overdose
	Alcohol	Enhanced CNS effects
	Anticoagulants	Enhanced anticoagulant effect
	Antihypertensives	Impaired blood pressure control
	Atropinics	Enhanced atropinic effect
	Carbamazepine	Confusion
	Cimetidine	Tricyclic enhanced
	Contraceptive pill	Tricyclic effect reduced
	Diazepam	Enhanced sedation
	General anaesthetics	Cardiac arrest
	MAOIs	Excitation and other interactions
	Phenothiazines	Convulsions
Valproate	Anticoagulants	Bleeding
	Erythromycin	Valproate enhanced
Voriconazole (see Fluconazole)		

^aALWAYS check the *British National Formulary* or an equivalent source, as these lists cannot be complete; nor can their accuracy be guaranteed. Many of these drug interactions are of little more than theoretical importance in dentistry, or are the result of overdose of one or both agents. However, there can be a wide range of individual variations in response to drugs, especially sedating agents. Box 27.9 shows drugs whose action may be affected by grapefruit; Box 27.10 shows drugs enhanced by pomegranate. See also Appendices 3.1 and 3.2.

APPENDIX 3.4 GENERAL ANAESTHESIA, SEDATION AND RESUSCITATION

RECOMMENDATIONS FROM THE POSWILLO REPORT (DEPARTMENT OF HEALTH)

- The use of general anaesthesia should be avoided wherever possible.
- The same general standards in respect of personnel, premises and equipment must apply irrespective of where the general anaesthetic is administered. (Para 3.8)
- Dental anaesthesia must be regarded as a postgraduate subject. (Para 3.11)
- All anaesthetics should be administered by accredited anaesthetists who must recognize their responsibility for providing dental anaesthetic services. (Para 3.13)
- Anaesthetic training should include specific experience in dental anaesthesia. (Para 3.14)
- Health authorities should review the provision of consultant dental anaesthetic sessions to ensure that they are sufficient to meet local needs. (Para 3.14)
- Doctors and dentists with knowledge, experience and competence sufficient to satisfy the College of Anaesthetists and the Faculty of Dental Surgery are to be under no detriment. (Para 3.16)
- The no detriment arrangements must have been implemented within 2 years of the publication of this report. (Para 3.17)
- The administration of general anaesthesia in dental surgeries and clinics equipped to the recommended standards of monitoring necessary for patient safety shall continue. (Para 3.17)
- An electrocardiogram, a pulse oximeter and a non-invasive blood pressure device are essential for the non-invasive monitoring of a patient under general anaesthesia. (Paras 3.16 and 3.19)
- A capnograph is to be used where tracheal anaesthesia is practised. (Para 3.20)
- A defibrillator must be available. (Para 3.21)
- Equipment conforming to recognized standards should be purchased and installed, regularly serviced and maintained in accordance with the manufacturer's instructions. (Para 3.21)
- Intravenous agents should be administered via an indwelling needle or cannula, which should not be moved until the patient has fully recovered. (Para 3.22)
- Appropriate training must be provided for those assisting the anaesthetist and dentist. (Paras 3.25 and 4.15)
- At no time should the recovering patient be left unattended. (Para 3.26)
- Adequate recovery facilities should be available. (Para 3.26)
- Good contemporaneous records of all treatments and procedures should be kept. (Para 3.26)
- Written consent should be obtained on each occasion prior to the administration of a general anaesthetic. (Para 3.30)
- Consideration should be given to developing a national general anaesthetic/sedation consent form for general dental practitioners. (Para 3.31)
- Patients should be provided with comprehensive pre- and post-treatment instructions and advice. (Para 3.31)

APPENDIX 3.5 CLASSIFICATION OF OPERATIONS AND ADMISSIONS

CLASSIFICATION OF OPERATIONS

Emergency

Immediate life-saving operation, resuscitation simultaneous with surgical treatment (e.g. trauma, ruptured aortic aneurysm). Operation usually within 1 h.

Urgent

Operation as soon as possible after resuscitation (e.g. irreducible hernia, intussusception, oesophageal atresia, intestinal obstruction, major fractures). Operation within 24 h.

Scheduled

An early operation but not immediately life-saving (e.g. malignancy). Operation usually within 3 weeks.

Elective

Operation at a time to suit both patient and surgeon (e.g. cholecystectomy, joint replacement).

Day case

A patient who is admitted for investigation or operation on a planned non-resident basis (i.e. no overnight stay).

CLASSIFICATION OF ADMISSIONS

Elective

At a time agreed between the patient and the surgical service.

Urgent

Within 48 h of referral/consultation.

Emergency

Immediately following referral/consultation, when admission is unpredictable and at short notice because of the clinical need.

APPENDIX 3.6 INSTRUCTIONS TO PATIENTS AFTER TOOTH EXTRACTION

These should preferably be given to the patient in writing.

After a tooth has been extracted, the socket will usually bleed for a short time. This bleeding stops because a healthy blood clot forms in the tooth socket. These clots are easily disturbed, and if this happens, bleeding will recur. To avoid disturbance of the clot, please follow these instructions:

1. After leaving the hospital or dental surgery, do not rinse out your mouth for 24 h, unless you have been told otherwise by the dentist.

2. Do not disturb the clot in the socket with your tongue or fingers.
3. For the rest of the day, take only soft foods.
4. Try not to chew on the affected side for at least 3 days.
5. Avoid unnecessary talking, excitement or exercise for the rest of the day.
6. Do not take alcoholic or very hot drinks for the rest of the day.
7. If the tooth socket continues to bleed after you have left the surgery, do not be alarmed – much of the liquid that appears to be blood is actually saliva. If bleeding persists, make a small pad from a clean handkerchief or cotton wool, place over the socket and close the teeth firmly on it. Keep up the pressure for 15–30 min. If the bleeding still does not stop, seek dental or medical advice.

APPENDIX 3.7 ANTIMICROBIAL PROPHYLAXIS

ANTIBIOTIC PROPHYLAXIS CONSIDERED IN SOME CASES

- Prosthetic heart valves
- Heart murmurs, e.g. mitral valve prolapse (with incompetence) and history of rheumatic fever, rheumatic heart disease
- Patients with congenital heart disease
- Dialysis patients – those with arteriovenous shunts and those on continuous ambulatory peritoneal dialysis (CAPD)
- Organ transplant patients, pre- and post-transplant – depends on ‘counts’
- Chemotherapy patients, including bone marrow transplant – depends on ‘counts’
- Artificial joint patients
- Poorly controlled diabetic patients
- Radiation therapy patients, depending on procedure
- Down syndrome patients (many have cardiac defects)
- Immunosuppressed patients, depending on treatment).

ENDOCARDITIS PROPHYLAXIS RECOMMENDED

High-risk category

- Prosthetic cardiac valves, including bioprosthetic and homograft valves
- Previous bacterial endocarditis
- Complex cyanotic congenital heart disease (e.g. single ventricle states, transposition of the great arteries, tetralogy of Fallot)
- Surgically constructed systemic–pulmonary shunts or conduits.

Moderate-risk category

- Most other congenital cardiac malformations (other than above and below)
- Acquired valvular dysfunction (e.g. rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvular regurgitation and/or thickened leaflets.

ENDOCARDITIS PROPHYLAXIS NOT RECOMMENDED

Negligible-risk category (no greater risk than general population)

- Isolated secundum atrial septal defect
- Surgical repair of atrial septal defect, ventricular septal defect or patent ductus arteriosus (without residual beyond 6 months)
- Previous coronary artery bypass graft surgery
- Mitral valve prolapse without valvular regurgitation
- Physiological, functional or innocent heart murmurs
- Previous Kawasaki disease without valvular dysfunction
- Previous rheumatic fever without valvular dysfunction
- Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators.

Prophylaxis is recommended for high-risk patients and optional for medium-risk patients.

Prophylaxis is optional for high-risk patients.

PROPHYLAXIS MAY BE CONSIDERED

- Immunocompromised/immunosuppressed patients
- Inflammatory arthropathies: rheumatoid arthritis, systemic lupus erythematosus
- Disease-, drug- or radiation-induced immunosuppression
- Other patients:
 - ◆ Type 1 (insulin-dependent) diabetes
 - ◆ First 2 years following joint placement
 - ◆ Previous prosthetic joint infections
 - ◆ Malnourishment
 - ◆ Haemophilia.

HIGHER-INCIDENCE BACTERAEMIC DENTAL PROCEDURES

- Dental extractions
- Periodontal procedures, including surgery, subgingival placement of antibiotic fibres/strips, scaling and root planing, probing, recall maintenance
- Dental implant placement and reimplantation of avulsed teeth
- Endodontic (root canal) instrumentation or surgery only beyond the apex
- Initial placement of orthodontic bands but not brackets
- Intraligamentary LA injections
- Prophylactic cleaning of teeth or implants where bleeding is anticipated.

LOWER-INCIDENCE BACTERAEMIC DENTAL PROCEDURES

- Restorative dentistry (operative and prosthodontic) with/without retraction cord
- LA injections (non-intraligamentary)
- Intracanal endodontic treatment; post-placement and build-up
- Placement of rubber dam
- Postoperative suture removal
- Placement of removable prosthodontic/orthodontic appliances
- Taking of oral impressions

- Fluoride treatments
- Taking of oral radiographs
- Orthodontic appliance adjustment.

KEY POINTS

- Listen
- Look

This chapter alphabetically summarizes a range of the more important medical conditions.

ABDOMINAL PAIN

Abdominal pain is common and often due to gastroenteritis. Acute and severe pain may be a symptom of more serious intra-abdominal disease, from inflammatory bowel disease to various ‘surgical emergencies’ (‘acute abdomen’); this includes appendicitis, intestinal obstruction, perforated peptic ulcer, perforated diverticulitis, ectopic pregnancy, twisted ovarian cyst, dissecting abdominal aneurysm, mesenteric embolism or thrombosis, biliary tract disease, pancreatitis and renal stone. A leaking abdominal aneurysm is an emergency.

Gangrene and intestinal perforation can follow as little as 6 hours after interruption of the intestinal blood supply from appendicitis, a strangulating obstruction or arterial embolism – and can lead to potentially fatal peritonitis.

ALOPECIA

Alopecia (hair loss) may be temporary and caused, for example, by radiotherapy, cytotoxic chemotherapy, other drugs (e.g. anticoagulants, retinoids, beta-blockers and oral contraceptives) or tinea capitis (ringworm). More permanent alopecia may be:

- *involutional alopecia* – the gradual progressive normal thinning of the hair seen in ageing in both sexes
- *androgenic alopecia* – a genetically predisposed condition that affects both sexes, earlier in men than women, with the hairline receding and hair from the crown gradually and permanently disappearing (male-pattern baldness)
- *alopecia areata* – patchy hair loss in children and young adults of uncertain cause, often sudden in onset and sometimes causing complete baldness, though the hair regrows within a few years in 90%
- *alopecia universalis* – loss of all body hair of uncertain cause, with a low chance of regrowth, especially when in children.

Autoimmune diseases, particularly lupus erythematosus, may also cause hair loss, as may factitious (self-induced) hair-pulling.

AMENORRHOEA

Amenorrhoea – absence of menstruation (menses) – is pathological, except before puberty, during pregnancy or early lactation, and after the menopause. Amenorrhoea may be caused by anatomical abnormalities, endocrine dysfunction (hypothalamic, pituitary, adrenal,

thyroid, anorexia nervosa or other), cirrhosis, chemo- or radio-therapy, ovarian failure or genetic defects.

Amenorrhoea is either primary (menarche has not occurred by age 16) or secondary (menses have not occurred for 3 or more months in women who have had menses).

ANAEMIA

Anaemia is a reduction in the haemoglobin level for an individual’s age and sex. Anaemia may be normocytic, microcytic or macrocytic, according to the cause (Ch. 8).

ANGINA PECTORIS

See ‘Chest pain’ and Chapter 5.

ANOREXIA

Anorexia, or loss of appetite, is a non-specific symptom seen in many conditions, but notably in malignant disease (Ch. 22), chronic infections and eating disorders (Ch. 27).

ANOSMIA

Anosmia (loss of the sense of smell) is usually due to nasal occlusion from the common cold, rhinitis, hay fever or nasal polyps. Some loss of smell may be normal with ageing but medications may change or impair the ability to detect odours. Anosmia can also arise from damage to olfactory nerves after head injury, radiotherapy or viral infections. Systemic causes include cerebrovascular events, Alzheimer dementia, tabes (syphilis), brain tumours, and many endocrine, nutritional and nervous disorders.

ANXIETY

Anxiety is common, and may be normal or part of a psychiatric disorder (Ch. 10), but it may also be caused by stimulant drugs such as amphetamines, caffeine, cocaine, ecstasy and many others – or by their withdrawal; neurological disorders (brain trauma, infections, inner ear disorders); cardiovascular disorders (cardiac failure, arrhythmias); endocrine diseases (adrenal or thyroid hyperfunction, hypoglycaemia, pheochromocytoma); or respiratory diseases (asthma, chronic obstructive pulmonary disease).

APHASIA

Aphasia is a language disorder that impairs both expression and understanding of language, as well as reading and writing. Aphasia results from damage to the left cerebral hemisphere, often as the result

Fig. 4.1 Corneal arcus.

of a stroke, injury or tumour. Speech disorders such as dysarthria or apraxia of speech, which also result from brain damage, may be associated.

ARCUS (CORNEAL ARCUS)

Corneal arcus (arcus senilis) is a white or grey ring in the eyes due to cholesterol deposits in the cornea (Fig. 4.1); it is seen mainly in older age groups. These rings cause no visual problems but can indicate a problem with cholesterol metabolism – and an increased risk of ischaemic heart disease. Corneal arcus not only is associated with high cholesterol levels, but also can be seen in people with diabetes or hypertension, or those who smoke tobacco.

ARRHYTHMIAS

See Chapter 5.

ASCITES

Ascites is the accumulation of fluid in the peritoneal cavity, either from peritoneal sources (bacterial, fungal or parasitic disease; cancer [malignant ascites]; endometriosis or starch peritonitis) or from extraperitoneal sources (cirrhosis, congestive heart failure, hypoalbuminaemia, myxoedema or ovarian disease, e.g. Meig syndrome).

ATAXIA

Ataxia is incoordination or clumsiness of movement that has a cerebellar, vestibular or sensory (proprioceptive) origin rather than being the result of muscle weakness. In ataxia, movement is uncoordinated – defined as an inability to coordinate movements finely. Causes include: drugs (e.g. alcohol, aminoglutethimide, anticholinergics, phenytoin, carbamazepine, phenobarbital and tricyclic antidepressants); stroke or transient ischaemic attack (TIA); multiple sclerosis; head trauma; poisoning; and hereditary conditions (congenital cerebellar ataxia, Friedreich ataxia, ataxia telangiectasia). Ataxia may also follow infection (typically chickenpox or encephalitis).

Cerebellar ataxia is produced by lesions of the cerebellum or its afferent or efferent connections in cerebellar peduncles, pons or red nucleus.

Vestibular ataxia is produced by lesions anywhere along the eighth nerve pathway from labyrinth to brainstem or in the vestibular nuclei. Viral labyrinthitis is a typical cause. Nystagmus is frequently present, typically unilateral, and most pronounced on gaze away from the side of vestibular involvement. Vestibular ataxia is also gravity-dependent – incoordination of limb movements cannot be demonstrated when the patient is examined lying down but only when the patient attempts to stand or walk.

Sensory ataxia can result from abnormalities anywhere along the afferent pathway from peripheral nerve to the parietal cortex. Clinical findings include defective joint position and vibration sense in the leg and sometimes the arms, unstable stance with Romberg sign (sways with eyes shut), and a gait of slapping quality.

BACK PAIN

Back pain is a very common complaint; nearly four out of five people experience it at some time. Most cases do not have a definable cause but sedentary jobs and lifestyles predispose, as can obesity, or strenuous sports such as football and gymnastics. Women who have been pregnant, smokers, and workers who repetitively lift heavy objects are all at greater risk of back pain.

Back pain can develop from:

- spinal causes – muscular disorders or strain, back overuse or injury, pressure on a nerve root or ruptured intervertebral/vertebral disc ('slipped disc'), spinal arthritis, fractures or metastases
- non-spinal causes – menstruation or premenstrual syndrome (PMS), endometriosis or ovarian cysts.

BLEEDING TENDENCIES

Prolonged bleeding usually has a local cause such as excessive operative trauma (Ch. 5). Other causes include: haemorrhagic disease; anticoagulants; uncontrolled hypertension; and aspirin or other drugs that interfere with platelet function.

BLINDNESS

See 'Visual impairment'.

BRADYCARDIA

Bradycardia (slow pulse rate) may have intrinsic or extrinsic causes (Ch. 5).

Intrinsic causes include: myocardial infarction, ischaemia or idiopathic degeneration; infiltrative diseases (sarcoidosis, amyloidosis or haemochromatosis); collagen diseases; myotonic muscular dystrophy; surgical trauma; and endocarditis.

Extrinsic causes include: autonomically mediated syndromes (vomiting, coughing, micturition, defecation, etc.); carotid-sinus hypersensitivity from vagal hypertonicity; drugs (beta-adrenergic blockers, calcium-channel blockers, clonidine, digoxin, antiarrhythmic agents); hypothyroidism; hypothermia; neurological disorders (affecting the autonomic nervous system); and electrolyte imbalances (hypokalaemia, hyperkalaemia).

Table 4.1 *Main causes of acute chest pain*

Cause of pain	Features	Predisposing factors
Myocardial infarction	Severe persistent crushing retrosternal pain, possibly radiating to left arm. Unrelieved by glyceryl trinitrate. May be accompanied by nausea or vomiting	Coronary heart disease Hypertension
Angina pectoris	Retrosternal pain, possibly radiating to left arm. Often previously experienced. Relieved in 3 min by glyceryl trinitrate	Coronary heart disease Hypertension
Acute abdominal pain	Pain location is of particular importance. Depending on cause, there may be concomitant symptoms such as gastro-oesophageal reflux, nausea, vomiting, diarrhoea, constipation, jaundice, melaena, haematuria, haematemesis, weight loss, and mucus or blood in stool	Serious causes: ruptured abdominal aortic aneurysm, perforated viscus, mesenteric ischaemia, ruptured ectopic pregnancy, intestinal obstruction, appendicitis, pancreatitis
Dissecting aneurysm	Sudden severe chest or upper back pain, often described as tearing, ripping or shearing sensation that radiates down back, loss of consciousness, shortness of breath	Men between 40 and 70 y
Oesophagitis	Low retrosternal pain on lying down or stooping. Improved by antacids	Hiatus hernia
Anxiety (hyperventilation)	Anxious patients with precordial pain. Overbreathing, panic and precordial pain	Stress
Trauma	Obvious history	–
Lung infection or tumour	Pain on inspiration. May be accompanied by dyspnoea or cough	Pneumonia Pleurisy Bronchogenic carcinoma

Table 4.2 *Causes of finger clubbing*

Hereditary	Respiratory	Cardiovascular	Gastrointestinal	Metabolic
	Lung cancer	Endocarditis	Ulcerative colitis	Thyrotoxicosis
	Bronchiolitis	Cyanotic congenital heart disease	Crohn disease	Acromegaly
	Fibrosing alveolitis		Coeliac disease	
	Asbestosis		Liver disease	
	HIV, fungal and mycoplasmal infections			
	Mesothelioma			

CERVICAL LYMPH NODE ENLARGEMENT

See ‘Lymphadenopathy’.

CHEST PAIN

Angina and myocardial infarction (acute coronary syndromes) are the main causes of acute chest pain (Table 4.1; Ch. 5).

CLUBBING OF FINGERS

Finger-clubbing is enlargement of the end of the digits. The cause is uncertain but might be hypoxia and circulating hormones such as erythropoietin. Clubbing can be hereditary but is usually acquired (Table 4.2).

COMA

A coma is profound unconsciousness in which the person is alive but unable to react or respond to stimuli. Coma results from central nervous system (CNS) diseases and conditions that affect CNS function, especially brain trauma, stroke, tumour, epilepsy, infection (e.g. meningitis), metabolic abnormalities (diabetic coma, ketoacidosis or electrolyte abnormality – hypernatraemia, hypercalcaemia), intoxication (e.g. alcohol, drugs of abuse, analgesics, anticonvulsants, antihistamines,

benzodiazepines, digoxin, heavy metals, hydrocarbons, barbiturates, insulin, lithium, organophosphates, phencyclidine, phenothiazines, salicylates or tricyclic antidepressants), shock, hypoxia or hypotension (arrhythmia, heart failure).

Persistent coma is termed the vegetative state. Level of consciousness is assessed by the Glasgow Coma Scale (Ch. 24).

CONFUSION

The confused patient has fluctuating consciousness and impaired orientation and short-term memory, and is usually more confused at night. Causes are multiple and include old age, dementia and most of the causes of coma. See also “delirium”. Delusions or hallucinations can cause severe agitation. The confused patient should receive immediate medical attention since brain damage may result from many of the causes (see ‘Coma’). Confusional states need to be differentiated from dementia, in which there are similar disturbances of orientation and memory, with unimpaired consciousness.

CONSTIPATION

Constipation is the passage of small amounts of hard, dry faeces, usually fewer than three times a week. If they do not have a bowel movement every day, some people believe they are constipated or irregular – but

there are no criteria for 'normal'. Constipation is the most common gastrointestinal complaint.

Common causes include: lifestyle habits; inadequate dietary fibre, liquids or exercise; changes in life or routine, such as pregnancy, older age and travel; abuse of laxatives; or ignoring the urge to have a bowel movement. Codeine, opioids, antacids that contain aluminium, antispasmodics, antidepressants, iron supplements, diuretics and anticonvulsants may be implicated. More important but less common causes include colorectal disease (obstruction, scar tissue [adhesions]), diverticulosis, tumours, strictures, irritable bowel syndrome and Hirschsprung disease. Constipation may also be caused by systemic disease, such as neurological disorders (multiple sclerosis, Parkinson disease, chronic idiopathic intestinal pseudo-obstruction, stroke, spinal cord injuries), metabolic and endocrine conditions (diabetes, thyroid dysfunction, uraemia), or immunological disorders (amyloidosis, lupus, scleroderma).

COUGH

A cough is a sudden, voluntary or involuntary, explosive expiratory manoeuvre that intends to clear material (sputum) from the airways. Transient cough may simply be a mechanism to expel mucus or an inhaled foreign body. Cough is typical of respiratory, and sometimes of cardiac, disorders. Angiotensin-converting enzyme inhibitors (ACEIs) may also produce a cough.

A morning cough persisting until sputum is expectorated typifies chronic bronchitis. A cough that is provoked by exposure to cold air or during exercise may suggest asthma. Cough associated with rhinitis or wheezing or that is seasonal may be allergic. Cough induced by postural change may suggest chronic lung abscess, tuberculosis, bronchiectasis or a tumour. Cough associated with eating suggests a swallowing disturbance, or possibly pharyngeal pouch or tracheo-oesophageal fistula. A persistent cough should be taken seriously and tumours and infections excluded. See also "haemoptysis"

CYANOSIS

Cyanosis is a bluish or purplish tinge to the skin due to very low oxygen saturation (SaO_2) and thus excess reduced (deoxygenated) haemoglobin. Approximately 5 g/dL of reduced haemoglobin has to be present in the capillaries to generate the dark blue colour of cyanosis. For this reason, patients who are anaemic may be hypoxaemic without showing any cyanosis.

Peripheral cyanosis is a dusky or bluish tinge to the fingers and toes. When unaccompanied by hypoxaemia, it is caused by peripheral vasoconstriction as in the cold, especially in Raynaud disease.

Central cyanosis (where the colour is also seen in the lips or the mouth) is more serious and is usually an indication of hypoxaemia because of cardiac failure or respiratory disease, or both in cor pulmonale. Many factors, from natural skin pigment to room lighting, can affect detection of cyanosis and, if hypoxaemia is suspected, measurement of the oxygen level is necessary (arterial blood gas determination, pulse oximetry). Central cyanosis is an indication of gross hypoxia; such patients needing conscious sedation must be dealt with in hospital.

DELIRIUM

Delirium is a state of mental confusion, caused by a disturbance in normal brain functioning, which develops quickly and usually fluctuates in intensity. More frequent in older people, delirium affects 1 in 10 hospitalized patients and is common in many terminal illnesses.

In contrast to dementia, delirium appears quickly, in hours or days, with a fluctuating level of consciousness. There may be limited awareness of the environment; confusion or disorientation (especially of time); memory impairment, especially of recent events; hallucinations, illusions and misinterpreted stimuli; mood disturbance, possibly including anxiety, euphoria or depression; and language or speech impairment. There are many possible causes of delirium, including:

- metabolic encephalopathy – hepatic or renal failure, diabetes, hyperthyroidism or hypothyroidism, vitamin deficiencies, fluid and electrolytes imbalance or severe dehydration
- drug intoxication – alcohol, anticholinergics (including atropine, hyoscine [scopolamine], chlorpromazine and diphenhydramine), sedatives (including barbiturates and benzodiazepines), antidepressants (including lithium, anticonvulsant drugs, corticosteroids), anticancer drugs (including methotrexate, procarbazine, cimetidine) and street drugs (e.g. marijuana, lysergic acid diethylamide [LSD], amphetamines, cocaine, opioids, phenylcyclidine, inhalants, legal highs)
- poisons – e.g. carbon monoxide, heavy metals, insecticides (e.g. parathion and carbaryl), mushrooms (such as *Amanita* spp.) and plants (jimsonweed [*Datura*] and morning glory [*Ipomoea* spp.])
- fever, cerebral disorders (infection, head trauma, epilepsy, cerebrovascular events, brain tumour), blood gas changes (hypoxaemia, hypercapnia) or following surgery.

DEMENTIA

Dementia is a progressive loss of mental ability, including the ability to remember, think and reason (Ch. 10). The most common features include changes in memory, behaviour, mood and personality, and difficulty in communicating or understanding. Alzheimer disease is the most common form and responsible for about 50% of cases. Vascular dementia is the second leading cause and is a result of several TIAs. Other causes include parkinsonism, Huntington disease, human immunodeficiency virus (HIV) infection and Creutzfeldt–Jakob disease. Dementia may be reversible if caused by brain diseases or conditions such as tumours, depression or alcoholism.

DIARRHOEA

Diarrhoea is defined as loose, watery stools passed more than three times in a day. Diarrhoea may be temporary, such as from an infection; this is common, usually lasts a day or two and resolves spontaneously. Prolonged diarrhoea can be a sign of other disorders, particularly intestinal disease such as infections: bacterial infections or toxins, such as preformed staphylococcal enterotoxin (from *S. aureus*) in contaminated food or water; viral infections; parasites; food intolerances (e.g. to lactose); drug reactions (such as to antibiotics like clindamycin, and antacids containing magnesium); intestinal diseases (inflammatory bowel disease, coeliac disease or irritable bowel syndrome); or after surgery (e.g. gastric surgery or cholecystectomy).

Where food hygiene is poor, diarrhoea can be life-threatening, especially if due to infections such as shigellosis (bacillary dysentery), *Escherichia coli* or cholera. The passing of blood in the stools is typical of severe diarrhoea – termed dysentery.

DIPLOPIA

Double vision (diplopia) is the simultaneous perception of two images of a single object displaced horizontally, vertically or diagonally (i.e. both

Table 4.3 *Causes of diplopia*

Structure involved	Site	Causes	Features that may be associated
Extraocular muscles	Orbit	Trauma Exophthalmos Myasthenia gravis	Middle-third facial fracture Thyrotoxicosis Myopathy
Cranial nerves III, IV and VI	Orbit	Trauma, tumour, sarcoid	Middle-third facial fracture
	Superior orbital fissure	Trauma, tumour, sarcoid	Often several muscles paralysed. Involvement of ophthalmic division of trigeminal. Pupil often normal
	Cavernous sinus	Aneurysms, infection, fistula, trauma	Similar to superior orbital fissure syndrome
Cranial nerve nuclei	Skull base	Aneurysms, tumours, meningitis, fractures	May be involvement of single nerves; may be pupil dilatation
	Brainstem	Vascular lesions, tumours, multiple sclerosis	May be involvement of trigeminal or facial nerves or complex neurological disorders

vertically and horizontally) in relation to each other. Diplopia is caused by misalignment of the eyes due to visual functional defects, mainly stemming from eye muscle or neurological disorders; by a structural defect in the eye's optical system; or by drugs (e.g. alcohol, phenytoin, carbamazepine or lamotrigine). Diplopia may be an occasional transient complication of dental LA injections, presumably because anaesthetic tracks to the inferior orbital fissure, where it can block orbital nerves. Diplopia is not uncommon after maxillofacial or head trauma (from assault, accident and/or alcohol or drugs) but usually resolves spontaneously within a few days or weeks. Persistent diplopia after trauma can be caused by blow-out fractures of the floor of the orbit, entrapment of (or damage to) the orbital muscles or damage to the suspensory ligament to the frontal process or the zygomatic bone. Later fibrous adhesions between the orbital periosteum and coverings of the eye may cause permanent limitation of movement, as may injury to cranial nerves III, IV and VI (Table 4.3). Paralytic strabismus is characterized by variable deviation of the ocular axes according to the position of gaze and is the usual type of strabismus that follows maxillofacial injuries.

DIZZINESS

Dizziness (vertigo) is a sensation of feeling unsteady or giddy, sometimes with a sensation of movement, spinning or floating. It is often due to disorders of the labyrinth. Movement of fluid in the semicircular canals signals the direction and speed of rotation of the head. Dizziness can also be due to central vestibular disorders (a problem in the brain or its connecting nerves); Ménière disease – an inner-ear fluid balance disorder that also causes fluctuating hearing loss and tinnitus (ringing in the ears); or perilymph fistula – a leakage of inner ear fluid to the middle ear. Dizziness can follow head injury or physical exertion; rarely, it has no known cause. Benign paroxysmal positional vertigo (a brief intense sensation of vertigo caused by a specific positional change of the head), labyrinthitis (inner ear infection) and vestibular neuronitis (a viral infection of the vestibular nerve) are other causes. Systemic disorders (vascular disorders) may occasionally be implicated.

DROOLING

See 'Sialorrhoea'.

DRY MOUTH

Important causes of dry mouth (hyposalivation) are drugs, irradiation of major salivary glands, Sjögren syndrome and infections (Box 4.1).

Box 4.1 Causes of dry mouth

Iatrogenic

- Drugs (antimuscarinics, sympathomimetics)
- Cancer therapy (irradiation of salivary glands, radioactive iodine, cytotoxic drugs)
- Graft-versus-host disease

Salivary gland disease

- Aplasia
- Sjögren syndrome
- Sarcoidosis
- Infection with HIV, human T-lymphotropic virus 1 (HTLV-1), hepatitis C or other viruses
- Infiltrates (amyloidosis; haemochromatosis)
- Cystic fibrosis
- Others

Dehydration

- Diabetes mellitus
- Diabetes insipidus
- Renal failure
- Haemorrhage
- Other causes of fluid loss or deprivation

If dry mouth occurs when salivary flow is normal, it may be psychogenic. Smoking and alcohol use aggravate the complaint of dry mouth – xerostomia.

DUPUYTREN CONTRACTURE

Dupuytren contracture affects the hands and fingers, cause one or more finger, on one or both hands, to bend into the palm (Fig. 4.2). Apart from familial cases, diabetes, epilepsy, heavy smoking and heavy alcohol consumption have also been linked to the contracture.

DYSPHAGIA

Swallowing is a process by which food and liquid move from the mouth, through the pharynx and then the oesophagus, and into the stomach. Each individual swallows 500–2000 times per day and swallowing also occurs during sleep. It is divided into three phases:

- Oral – food is reduced to a bolus, chewed, mixed with saliva and then transported from the anterior to the posterior oral cavity.

Fig. 4.2 Dupuytren contracture affecting both hands.

- **Pharyngeal** – the velopharyngeal opening completely closes, the hyoid and larynx ascend and the epiglottis folds down. The tongue base makes contact with the pharyngeal wall to form a seal and the pharyngeal muscles start to contract. The laryngeal inlet closes and the vocal cords adduct. The cricopharyngeus then relaxes, the upper oesophageal inlet opens and apnoea prevents food from entering the airway.
- **Oesophageal** – the upper oesophageal sphincter opens and peristalsis carries the bolus through the oesophagus to the stomach. This phase may take 10–12 seconds.

Cranial nerves IX to XII, and the pharyngeal muscles in particular, are essential to swallowing (Box 4.2). Dysphagia is ‘difficulty in swallowing’ (from the Greek *dys* meaning difficulty or disordered, and *phagia* ‘to eat’) and has many causes; older people in particular may develop swallowing dysfunction. This is due mainly to conditions such as cerebrovascular events or Parkinson’s disease. People with mental impairment often have cognitive and physiological impairments that may result in dysphagia.

Dysphagia may be secondary to defects in any stage of the swallowing process:

- **Neurological causes** – may be fixed or progressive (Table 4.4)
- **Mechanical and obstructive causes:**
 - ◆ Infections, e.g. tonsillitis, dental abscess, tuberculosis
 - ◆ Traumatic injuries to the face/neck
 - ◆ Reduced muscle compliance
 - ◆ Zenker diverticulum (pharyngeal pouch)
 - ◆ Thyromegaly
 - ◆ Oesophageal strictures
 - ◆ Oesophageal malignancies
 - ◆ Lung malignancies/lymphomas
 - ◆ Head/neck malignancies
 - ◆ Cervical osteophytes.
- **Drug-induced, caused by:**
 - ◆ medications affecting the oesophageal muscles, e.g. oxybutynin, tolterodine
 - ◆ combinations of medications that produce a dry mouth, e.g. diuretics, calcium-channel blockers, antihistamines; antipsychotic/neuroleptic drugs may cause a dry mouth and, additionally, some can cause movement disorders that may affect the muscles of the face and tongue used in swallowing (e.g. haloperidol, risperidone, clozapine)
 - ◆ local anaesthetics used for dental treatment, which may cause a temporary loss of sensation and ability to swallow

Box 4.2 Causes of dysphagia

Psychogenic

- Globus hystericus

Organic

Mouth

- Dry mouth
- Inflammatory or neoplastic lesions

Pharynx

- Inflammatory or neoplastic lesions
- Foreign bodies
- Sideropenic dysphagia (Paterson–Brown-Kelly syndrome)
- Pouch

Oesophagus

- Benign stricture
- Inflammatory or neoplastic lesions
- Scleroderma
- External pressure from mediastinal lymph nodes

Neurological and neuromuscular causes

- Achalasia
- Cerebellar disease
- Cerebral palsy
- Cerebrovascular accidents
- Cerebrovascular disease (pseudobulbar palsy)
- Dermatomyositis
- Diphtheria
- Guillain–Barré syndrome
- Motor neuron disease
- Muscular dystrophies
- Myasthenia gravis
- Myopathies
- Parkinsonism
- Poliomyelitis
- Syringobulbia

Table 4.4 Neurological causes of dysphagia

Non-progressive	Progressive
Cerebral palsy	Amyotrophic lateral sclerosis
Cerebrovascular events	Cerebrovascular events
Post-surgery	Dementia
Traumatic brain injury	Head and neck malignancies
	Huntington disease
	Multiple sclerosis
	Muscular/myotonic dystrophy
	Myasthenia gravis
	Parkinson disease
	Supranuclear palsy

- ◆ drugs affecting the CNS and swallowing (antiepileptic medication, benzodiazepines, narcotics and smooth muscle relaxants).

Swallowing may be assessed by watching for signs of leakage from the mouth, facial weakness, poor muscular coordination, delayed pharyngeal/laryngeal elevation, choking, breathlessness and changes in voice quality after swallowing. The ‘gold standard’ is videofluoroscopy

(VFS; modified barium swallow), in which radio-opaque barium liquid is swallowed by the patient and moving images of swallowing are captured. Fiberoptic endoscopic evaluation of swallowing (FEES) with nasoendoscopy has an advantage over VFS in that it is a bedside procedure with no radiation exposure.

Swallowing problems may lead to inhalation of either oropharyngeal or gastric contents into the airway. Aspiration may lead to chest infections, which are the leading cause of death in such people. The main risk of dysphagia is choking if the passage of air to the lungs is blocked by a foreign body; this is a precursor to asphyxiation. Signs of choking include coughing, gagging, inability to speak, breathe or cry, loss of consciousness and cyanosis. If the obstruction is not successfully removed, the patient is at risk from asphyxiation and ultimately death.

The major dental concern when treating patients with dysphagia is the risk of aspiration during treatment, which may lead to choking or aspiration pneumonia.

DYSPNOEA

Dyspnoea is difficulty in breathing. Functional causes include anxiety, panic disorders and hyperventilation. Organic causes include cardiac and respiratory disorders and anaemia. Dyspnoea is typically exacerbated by exercise, but may occur at rest and persist or worsen when lying down (orthopnoea). Paroxysmal nocturnal dyspnoea (cardiac asthma) is a sudden attack of severe dyspnoea due to pulmonary oedema that wakes the patient from sleep with a terrifying sensation of suffocation.

DYSRHYTHMIAS

See Chapter 5.

DYSURIA

Dysuria is the sensation of pain or burning on urination. It is more common in women than in men, and then bacterial cystitis (usually after intercourse) is the commonest cause. In men too, dysuria is usually a result of urinary tract infection – in younger patients most often caused by a sexually transmitted organism such as *Chlamydia trachomatis*. In those over 35 years, coliform bacteria predominate and infection typically results from urinary stasis secondary to prostatic hyperplasia.

Dysuria in either sex may occasionally be caused by renal calculus, genitourinary malignancy, spondyloarthropathy and medications.

EARACHE

As aircraft descend, pressure rises even in the normal middle ear, and this can cause excruciating pain. Earache (otalgia) is commonly due to middle ear infection (otitis media) and is especially common in children, often following a sore throat or cold. There is severe pain and often a temporary loss of hearing; with severe infections, the ear drum may perforate, causing a leakage of pus from the ear. Tumours in the middle ear are uncommon but include cholesteatoma. Pain may be referred to the ear from elsewhere, such as tongue cancer, the antra, dental abscesses and temporomandibular disorders.

ENCOPRESIS

Encopresis is the soiling of underwear with stool by children who are past the age of toilet training, but it is not considered a medical condition unless the child is at least 4 years old. A large amount of hard stool is in the intestine, and stool leaks around this mass and out through the anus. The best way to prevent encopresis is to avoid constipation by eating a varied diet with plenty of fruits and vegetables and wholegrain bread and cereals.

EPILEPSY

See Chapter 13.

EPISTAXIS (NOSEBLEEDS)

Most nosebleeds are caused by nose-picking, minor nose injuries, the common cold, or vigorous nose-blowing or sneezing. Rarely, they may be caused by a foreign body lodged in the nose, barotrauma, chemical irritants, drugs (e.g. anticoagulants, anti-platelet agents, non-steroidal anti-inflammatory drugs [NSAIDs] or vitamin E), maxillofacial or nasal surgery, hereditary telangiectasia or thrombocytopenia.

EROSION OF TEETH

Tooth erosion can result from exposure to dietary acidic sources (carbonated drinks, citrus fruits and juices, pickles, vinegar, wine) or some drugs (e.g. chewable vitamin C); regurgitated gastric contents (anorexia nervosa, bulimia, gastro-oesophageal reflux or alcoholism); industrial sources (various acids); or, rarely, other sources (e.g. swimming-pool water).

EXOPHTHALMOS

See 'Proptosis'.

FAINTING (VASOVAGAL SYNCOPE)

Syncope, commonly called fainting or 'passing out', is a temporary loss of consciousness due to a sudden decline of brain blood flow. Syncope can occur in otherwise healthy people and affects all age groups, but does so more often in older people. Vasovagal syncope is a reflex mediated by autonomic nerves in which there is splanchnic and skeletal muscle vasodilatation, bradycardia and thus diminished cerebral blood flow, leading to loss of consciousness. Fainting can be precipitated by psychological factors (e.g. pain, or fear at the sight of a needle or blood); postural changes; hypoxia; or carotid sinus syndrome. The latter is usually seen in older patients in whom mild pressure on the neck causes a vagal reaction, leading to syncope with bradycardia or cardiac arrest. Vasovagal syncope is treated by having the patient lie down with their legs raised (Ch. 1).

Recurrent syncope with complex associated symptoms in so-called neurally mediated syncope (NMS) is associated with any of the following: preceding or succeeding sleepiness, preceding visual disturbance ('spots before the eyes'), sweating and light-headedness. Other types of syncope include:

- *carotid sinus* – happens because of carotid artery constriction after turning the head, while shaving, or when wearing a tight collar

- *vertebrobasilar* – occurs when arterial disease in the upper spinal cord or lower brain causes syncope if there is a reduction in blood supply, which may occur with extending the neck
- *cardiogenic* – is more common in older patients, and includes arrhythmic, obstructive, ischaemic, drug or cardiomyopathic causes
- *orthostatic (postural)* – is as common as vasovagal syncope but caused by a change in body posture, most often associated with movement from lying or sitting to a standing position; it does not necessarily signal any serious underlying disease. The most susceptible individuals are older frail people, or persons dehydrated from hot environments or inadequate fluid intake
- *neuropathic* – may be seen in neurological disorders such as parkinsonism, postural orthostatic tachycardia syndrome (POTS), and diabetic or other types of neuropathy
- *drug-related* – is caused by diuretics, beta-blockers, calcium antagonists, ACEI, nitrates, antipsychotics, antihistamines, L-dopa, narcotics and alcohol.

FACIAL PARALYSIS

See Chapter 13.

FACIAL SENSORY LOSS

See Chapter 13.

FEVER (PYREXIA)

Normal body temperature (37°C) has a diurnal rhythm, lower in the morning before dawn and higher in the afternoon. Temperature control activities balance heat loss and production. An abnormal rise in body temperature is caused by either hyperthermia or fever. In fever, the body temperature controls are functioning correctly, but the hypothalamic set point is raised by exogenous or endogenous pyrogens; temperature rises as the body responds to cytokines such as interleukin-1, produced by microorganisms or immunocytes.

The main causes of fever include: infections, tumours, drugs (e.g. chemotherapy drugs, biological response modifiers, and antibiotics such as vancomycin and amphotericin), neuroleptic malignant syndrome, blood transfusion reactions, connective tissue disorders, cerebrovascular events and or graft-versus-host disease.

Fever may, in children under 6 years, be complicated by seizures (febrile convulsions) and, in older persons when the hypothalamus temperature-regulating centres may function poorly, by arrhythmias, heart failure, cerebral hypoxia and confusion.

GASTROINTESTINAL BLEEDING

Bleeding in the digestive tract can be the result of many different conditions, some of which are life-threatening. Bleeding can sometimes be unnoticed (occult or hidden bleeding), but the faecal occult blood test (FOBT) checks stool samples for traces of blood, detecting bleeding from almost anywhere in the digestive tract. Causes of gastrointestinal bleeding, apart from drugs such as NSAIDs, include lesions in: the oesophagus (oesophagitis [hiatus hernia], varices, tears [Mallory–Weiss syndrome, after severe vomiting], cancer); the stomach (ulcers,

gastritis, cancer); the small intestine (duodenal ulcer, inflammatory bowel disease); and the large intestine and rectum (haemorrhoids, infections, ulcerative colitis, diverticular disease, polyps or cancer).

The appearance of blood in the faeces depends upon the site and severity of bleeding. Bleeding from the oesophagus, stomach or duodenum can cause black or tarry stools (melaena). The stool may be mixed with darker blood if the bleeding is higher in the colon. Blood originating from the rectum or lower colon is bright red.

Vomited blood may be bright red or have the appearance of coffee grounds.

Endoscopy permits examination of the oesophagus, stomach, duodenum (oesophagoduodenoscopy), colon (colonoscopy) and rectum (sigmoidoscopy), and facilitates biopsies. Magnetic resonance imaging (MRI), computed tomography (CT), barium radiography, angiography, radionuclide scans and ultrasound can also be used to locate sources of chronic occult gastrointestinal bleeding.

GINGIVAL SWELLING

Gingival swelling may be localized or generalized. It is usually drug-induced gingival overgrowth (DIGO), but occasionally is due to a systemic disease (Box 4.3).

HAEMATEMESIS

Haematemesis (blood in the vomit) typically results from blood regurgitation from the gastrointestinal tract (mouth, pharynx, oesophagus, stomach and small intestine). Conditions that cause haematemesis include bleeding ulcer(s), neoplasms, angiomas or varices in the stomach, duodenum or oesophagus; prolonged and vigorous retching, which may tear small blood vessels of the throat or oesophagus; drugs; and ingested blood (e.g. swallowed after a nosebleed) or gastroenteritis. It may be difficult to distinguish haematemesis from coughing up blood from the lung (haemoptysis) or a nosebleed (bloody postnasal drainage), but it can also cause blood in the stool.

HAEMATURIA

Haematuria, blood in the urine, typically originates in the urinary tract (urethra, bladder or ureter) but, in women, vaginal/uterine blood may appear in the urine and, in men, a bloody ejaculate is usually due to a prostate disorder. Causes of haematuria include: haematological disorders (e.g. coagulopathies, sickle cell disease, renal vein thrombosis or thrombocytopenias); renal and urinary tract diseases (calculi, benign familial haematuria, infection, tumours, renal vein thrombosis, systemic lupus erythematosus, haemolytic–uraemic syndrome, anaphylactoid (Henoch–Schönlein) purpura, polycystic kidney disease, glomerulonephritis, congenital anomalies); prostatitis; hypercalciuria (increased calcium in urine); urethral ulceration or meatal stenosis; trauma (fractured pelvis, renal trauma, urethral trauma, surgical procedures, including catheterization, circumcision, surgery and biopsy); or drugs (anticoagulants, cyclophosphamide, metirosine, oxyphenbutazone, phenylbutazone or tiabendazole).

HAEMOPTYSIS

Haemoptysis is the coughing or expectoration or spitting up of blood or bloody mucus from the lungs. It may be confused with bleeding

Box 4.3 Causes of gingival enlargement**Generalized****Congenital**

- Aspartylglycosaminuria
- Fucosidosis
- Hereditary gingival fibromatosis and related disorders
- Hypoplasminogenaemia
- Infantile systemic hyalinosis
- Leprechaunism (Donohue syndrome)
- Mucopolysaccharidosis I-H
- Pfeiffer syndrome
- Primary amyloidosis

Acquired**Haematological**

- Acute myeloid leukaemia
- Pre-leukaemic leukaemia(s)
- Aplastic anaemia
- Vitamin C deficiency

Drugs

- Phenytoin
- Ciclosporin
- Calcium-channel blockers

Localized**Congenital**

- Fabry syndrome (angiokeratoma corporis diffusum universale)
- Cowden syndrome (multiple hamartoma and neoplasia syndrome)
- Tuberous sclerosis
- Sturge-Weber angiomas
- Congenital gingival granular cell tumour

Acquired**Epulides**

- Pregnancy epulis
- Fibrous epulis
- Giant-cell epulis (e.g. secondary to primary hyperparathyroidism)

Granulomatous conditions

- Pyogenic granuloma
- Sarcoidosis
- Crohn disease
- Orofacial granulomatosis
- Wegener granulomatosis

Infections with human papillomavirus (HPV)

- Papilloma
- Condyloma
- Warts
- Heck disease

Tumours

- Squamous cell carcinoma
- Lymphomas
- Langerhans cell tumours
- Multiple myeloma
- Kaposi sarcoma
- Plasmacytomas
- Other primary and secondary neoplasms

from the mouth, nose, throat or gastrointestinal tract. Apart from a simple recent nosebleed and irritation of the throat from violent coughing, causes may include diagnostic tests (bronchoscopy, laryngoscopy, biopsy, mediastinoscopy or spirometry), pulmonary infection,

bronchitis, bronchiectasis, cancer, embolus, oedema, cystic fibrosis and systemic lupus erythematosus.

HALITOSIS (ORAL MALODOUR)

Volatile sulphur compounds (VSC) of microbial origin are at least partly responsible for oral malodour (bad breath). Oral malodour is common on awakening (morning breath), and then transient and rarely of any special significance, probably resulting from increased microbial metabolic activity during sleep, aggravated by a physiological reduction in salivary flow, lack of nocturnal physiological oral cleansing (e.g. movement of the facial and oral muscles) and variable oral hygiene procedures prior to sleep. Starvation can lead to a similar malodour.

Malodour at other times may be due to ingestion of certain food and drinks, such as spices, garlic, onion, durian, cabbage, cauliflower and radish, or of habits such as smoking tobacco or drinking alcohol, and is usually transient. It is considered to arise from both intraoral (food debris) and extraoral (respiratory) origins. Halitosis is most frequently due to oral infection (such as the tongue flora or periodontal disease), and rarely stems from systemic causes (Table 4.5).

HEADACHE

See Chapter 13.

HEARING IMPAIRMENT

Hearing loss is categorized on which part of the auditory system is damaged. There are three basic types of hearing loss: conductive, sensorineural and mixed.

Conductive hearing loss is due to middle or external ear disorders – when sounds that should be carried from the tympanic membrane to the inner ear are blocked by, for example, foreign bodies, wax, fluid, infection or abnormal bone growth.

Sensorineural hearing loss is due to defects of the cochlear nerve or its central connections – as in damage to the inner ear or auditory nerve (e.g. in birth defects, head injury, surgery, tumours, certain drugs, hypertension or stroke). Hearing can be lost by exposure to very loud noises, (pop music, explosions, loud machinery, etc.), particularly for long periods.

Deafness is common and, in 30% of cases, is hereditary. It may occasionally be associated with congenital malformations, such as first arch syndromes. Age-related changes include especially *presbycusis* – the most common hearing problem in older people and linked to inner ear changes.

Hearing aids are available to help. Differing in design, size, amount of amplification, ease of handling, volume control and special features, all have similar components that include a microphone to detect sound, an amplifier to make the sound louder, and a receiver (miniature loudspeaker) to deliver the sound into the ear. Bone-anchored hearing aids are implantable devices that act by directly stimulating the inner ear through the bone. Hearing assistive devices are available for use with or without hearing aids. Electromagnetic interference can be an issue with these aids (Ch. 5).

People with a severe-to-profound hearing loss who cannot be helped with hearing aids may find cochlear implants of benefit. Cochlear implants stimulate the auditory nerve directly, helping sensorineural

Table 4.5 Main causes of halitosis

Causes	Examples
Plaque-related gingival and periodontal disease	Gingivitis Periodontitis Necrotizing ulcerative gingivitis Pericoronitis Abscesses
Oral ulceration	Systemic disease (inflammatory/infectious disorders, cutaneous, gastrointestinal and haematological disease) Malignancy Local causes Aphthae Drugs
Hyposalivation	Drugs Sjögren syndrome Radiotherapy Chemotherapy
Tongue coating	Poor hygiene
Wearing dental appliances	Poor hygiene
Dental conditions	Food packing
Bone diseases	Jaw dry sockets Osteomyelitis Osteonecrosis Malignancy
Respiratory system	Sinusitis Antral malignancy Cleft palate Foreign bodies in the nose Nasal malignancy Tonsilloliths Tonsillitis Pharyngeal malignancy Lung infections Bronchitis Bronchiectasis Lung malignancy
Gastrointestinal tract	Oesophageal diverticulum Gastro-oesophageal reflux disease Malignancy
Metabolic disorders (blood-borne)	Acetone-like smell in uncontrolled diabetes Uraemic breath in renal failure Foetor hepaticus in liver disease Trimethylaminuria (fish odour syndrome) Hypermethioninaemia Cystinosis
Drugs (blood-borne)	Amphetamines Chloral hydrate Cytotoxic agents Dimethyl sulfoxide (DMSO) Disulfiram Nitrates and nitrites Phenothiazines Solvent abuse
Psychogenic causes	

hearing loss. They have external parts behind the ear (receiver) and internal (surgically implanted) electrodes. People with cochlear implants are more likely to contract bacterial meningitis than those without. In addition, some children who are candidates for cochlear implants have inner ear anatomical abnormalities that may increase their risk for meningitis. The Centers for Disease Control (CDC) recommend that these children receive pneumococcal vaccination.

Precautions are needed for electrosurgery in patients with cochlear implants; use bipolar where possible. If monopolar diathermy is necessary, ensure that the distance between the active electrode and the return electrode is as short as possible by using a return electrode mat. It is always important when communicating with people with hearing impairment to face them, without a face mask, and to speak clearly, in the absence of extraneous noise. The sign language (‘deaf’) alphabet helps (Fig. 4.3).

HEART FAILURE

Heart failure is usually the result of cardiac disease, but an otherwise normal heart can fail as a consequence of overload (e.g. severe anaemia). The common causes are ischaemic heart disease, hypertension, valve disease and chronic obstructive pulmonary disease. Failure can affect either the left or the right side of the heart predominantly, but left-sided heart failure is more common. Failure of one side of the heart usually leads to failure of the other. Right-sided failure often follows left-sided failure, particularly when there is mitral stenosis, and causes congestive cardiac failure (CCF). See also Chapter 5.

HEPATOMEGALY

Hepatomegaly is enlargement of the liver beyond its normal size. The lower edge of the liver normally comes just to the lower edge of the ribs (costal margin) on the right side and it cannot be palpated. The diagnosis must be confirmed by imaging.

Causes include infections (viral, bacterial or parasitic, e.g. viral hepatitis, infectious mononucleosis); malignancy (leukaemias, tumour metastases, neuroblastoma, hepatocellular carcinoma); anaemias; storage diseases (Niemann–Pick disease, hereditary fructose intolerance, glycogen storage disease); heart failure; congenital heart disease; toxins (e.g. alcohol); primary biliary cirrhosis; sarcoidosis; sclerosing cholangitis; haemolytic–uraemic syndrome; or Reye syndrome.

HIRSUTISM (HYPERTRICHOSIS)

Hirsutism is the excessive growth of dark, coarse body hair in women (and children), and typically appears in a male distribution pattern. Excessive facial hair is usually the most troublesome aspect. Signs of masculinization, such as voice deepening, increased muscle mass, decreased breast size, increased genital size and menstrual irregularities, may be associated.

Common causes of hirsutism include: genetic factors, endocrine abnormalities (polycystic ovarian syndrome, Cushing syndrome, adrenocortical carcinoma, congenital adrenal hyperplasia, precocious puberty, pregnancy, menopause, ovarian tumour or cancer, ovarian overproduction of androgens) or drugs (androgens, aminoglutethimide, calcium-channel blockers, ciclosporin, finasteride, phenytoin, glucocorticoids, metoclopramide and minoxidil).

Fig. 4.3 Manual alphabet.

HOARSENESS

Hoarseness is usually due to acute laryngitis, secondary to excessive talking/singing/shouting, or caused by a viral upper respiratory infection such as a cold, and is self-limiting. Chronic laryngitis is the commonest cause of persistent hoarseness; predisposing factors are usually smoking and voice abuse. However, any patient with hoarseness persisting for over 1 month should be investigated for trauma to the vocal cords (from persistent shouting or singing – singer’s nodules); thyroid cancer; laryngeal cancer; surgical damage to the vagus or recurrent laryngeal nerve during thyroid or cardiovascular surgery; and psychological problems.

HOSTILITY

Hostile (acutely disturbed) patients can totally disrupt their environment and harm those with whom they come into contact. Frequently, the cause is drug/alcohol intoxication or an acute psychosis. Otherwise, the disorder may be due to infection or withdrawal of drugs (alcohol or other drugs of abuse). If the patient appears unresponsive to

reason, no treatment should be attempted, but the physician or psychiatrist should be contacted. No attempt should be made to sedate the patient; benzodiazepines usually worsen violently psychotic behaviour and adequate doses of phenothiazines, such as chlorpromazine, can cause severe hypotension. If the patient becomes violent, the police have to be called to restrain them; ambulance personnel cannot usually manage such cases. The usual treatment, once the patient has been forcibly restrained, is to give haloperidol by injection.

HYPERPIGMENTATION

Most pigmentation is racial in origin. Local pigmentations, such as a tattoo, are common. Systemic causes of hyperpigmentation, apart from suntan, are rare (Box 4.4).

HYPERTHERMIA

Hyperthermia is an unusual rise in body temperature above normal, caused by disordered body temperature control. A group of inherited

Box 4.4 Causes of hyperpigmentation**Congenital**

- Racial (even in some Caucasians)
- Naevi
- Syndromes
 - Peutz–Jeghers syndrome: oral and perioral hyperpigmentation with small intestine polyps
 - Carney complex: lentiginosis due to adrenal disease, and multiple neoplasia such as myxomas of skin, heart and breast, schwannomas, pituitary adenomas, testicular and thyroid tumours
 - Laugier–Hunziker syndrome: oral and perioral hyperpigmentation with nail pigmentation
 - NAME syndrome (naevi, atrial myxoma, myxoid neurofibromas and ephelides)
 - LAMB syndrome (lentigines, atrial myxoma, mucocutaneous myxoma, blue naevi)
 - LEOPARD syndrome: lentigines with hypertrophic cardiomyopathy, or arterial dissections

Acquired**Endocrine or metabolic**

- Addison disease
- Adrenocorticotrophic hormone (ACTH) therapy
- ACTH-producing tumours (lung cancer)
- Haemochromatosis
- Nelson syndrome

Neoplastic

- Melanoma
- Kaposi sarcoma

Foreign bodies**Drugs**

- Smoking
- Antimalarials
- Cytotoxics (particularly busulfan)
- Oral contraceptives
- Phenothiazines
- Minocycline
- Zidovudine
- Clofazimine

Others

- Human immunodeficiency syndrome (HIV) infection and acquired immunodeficiency syndrome (AIDS)

muscle problems, characterized by muscle breakdown following certain stimuli, is termed malignant hyperthermia. Attacks can be precipitated by anaesthesia, extreme exercise, fever or certain drugs (Ch. 23).

HYPERVENTILATION

See 'Tachypnoea'.

HYPODONTIA

Most missing teeth are caused by tooth extraction. Hypodontia is the developmental absence of teeth and affects about 5% of the population. The teeth most commonly missing, apart from third molars, are the mandibular second premolars, maxillary lateral incisors and maxillary second premolars. Severe hypodontia is the absence of six or more teeth and can be a feature of ectodermal dysplasia, Down syndrome, hemifacial microsomia and van der Woude syndrome.

HYPOGLYCAEMIA

Hypoglycaemia (low blood sugar) is when blood glucose levels drop, causing the patient to feel weak, drowsy, confused, hungry, aggressive and dizzy. Pallor, headache, irritability, trembling, sweating, rapid pulse and a cold, clammy feeling are other signs and, in severe cases, unconsciousness or coma can result.

Hypoglycaemia is caused by diabetes (insulin or drug overdose, missing or delaying a meal, eating too little food for the amount of insulin taken); exercising too strenuously, particularly when associated with beta-blocker medication; prolonged fasting; certain foods and drinks (alcohol, aspirin [in some children], unripe Jamaican ackee fruit); liver disease; hormonal states (early pregnancy, insulinomas, growth hormone deficiency, breast cancer and adrenal cancer); or hereditary enzyme deficiencies (hereditary fructose intolerance [attacks of hypoglycaemia, marked by seizures, vomiting and unconsciousness] or galactosaemia [also causes vomiting, weight loss and cataracts]).

HYPOTENSION

See 'Low blood pressure'.

HYPOTHERMIA

Cold exposure is the main cause of hypothermia (low body temperature). Conditions that may predispose include drugs (alcohol, anxiolytics, antidepressants, antiemetics and some over-the-counter cold remedies); illnesses that restrict activity (stroke or other causes of paralysis, severe arthritis, Parkinson disease, Alzheimer disease); or hypothyroidism.

IMPOTENCE

Impotence is the term used particularly for erectile dysfunction (ED), lack of sexual desire and ejaculation or orgasm problems. ED is the repeated inability to achieve or maintain an erection adequate for intercourse. Causes of impotence are psychological factors, including stress, anxiety, guilt, depression, low self-esteem and fear of sexual failure; smoking; drugs (antihypertensives, antihistamines, antidepressants, finasteride, tranquilizers, appetite suppressants and cimetidine); various diseases (diabetes, renal disease, alcoholism, multiple sclerosis, atherosclerosis, neurological disease); hormonal abnormalities (inadequate testosterone); and injuries to the nerves or conditions that impair penile blood flow. These include trauma in particular (to penis, spinal cord, prostate, bladder or pelvis), including that from surgery (especially radical prostate surgery). Sildenafil citrate (Viagra) is effective treatment.

INSOMNIA

See Chapter 13.

JAUNDICE

Jaundice (icterus) is the accumulation of, and colouring of the skin and mucous membranes by, bilirubin, if it appears in excessive

amounts or is not conjugated or excreted. Jaundice can be a manifestation of haemolytic anaemias, liver disease, biliary disease or pancreatic disorders (Ch. 9).

LOW BLOOD PRESSURE (HYPOTENSION)

The main causes of hypotension are described here.

Drugs causes include:

- alcohol
- analgesics
- antidepressants
- anxiolytics
- diuretics.

Orthostatic hypotension, including postprandial orthostatic hypotension, is brought on by a sudden change in body position, most often when shifting from lying down to standing. This type of hypotension usually lasts only a few seconds or minutes. It most commonly affects older adults, those with high blood pressure, and persons with parkinsonism, excessive use of diuretics, vasodilators or other drugs, dehydration, Addison disease, atherosclerosis or dysautonomias, such as in diabetes.

Neurally mediated hypotension (NMH) occurs when a person has been standing for a long time and most often affects young adults and children.

Disease causes of low blood pressure include:

- anaphylaxis
- arrhythmias
- dehydration
- diabetes
- fainting
- heart failure
- infection
- myocardial infarction
- sudden blood loss.

Symptoms of hypotension may include:

- blurred vision
- confusion
- dizziness
- fainting
- light-headedness
- sleepiness
- weakness.

LYMPHADENOPATHY

Many diseases can cause lesions in the neck, but most commonly they involve swellings and/or pain in the cervical lymph nodes. About one-third of all lymph nodes are in the neck and the dental surgeon can often detect serious disease by examination of the neck.

A limited number of lymph nodes swell, usually because of infection in the area of drainage. The nodes are then often firm, discrete and tender but mobile (lymphadenitis), and the focus of inflammation can usually be found in the drainage area, which is anywhere on the face, scalp, nasal cavity, sinuses, ears, pharynx and oral cavity.

Lymphadenopathy in the anterior triangle of the neck alone is often due to local disease, especially if the nodes are enlarged on one side only. Infection and malignancy in the drainage area are important

causes. Metastatic infiltration causes the node to feel distinctly hard, and it may become bound down to adjacent tissues ('fixed') and, in advanced cases, may ulcerate through the skin.

Lymph nodes may also swell in systemic infections or disorders involving the immune system, and then there is usually involvement of more than one node, and often several in different sites. Most children or young people may have small palpable cervical, axillary and/or inguinal nodes. Most of these are caused by viral infections.

Lymph node enlargement may have several disparate causes including infections; lymphadenitis (inflammation of lymph nodes) is the most common cause of lymphadenopathy. The location of the affected nodes is usually related to the site of the underlying infection ([Box 4.5](#)).

MALABSORPTION

Malabsorption is difficulty with the digestion or absorption of nutrients from food, such as failure to absorb specific sugars, fats, proteins or other nutrients (such as vitamins). Diarrhoea, bloating or cramping, weakness, failure to thrive, frequent bulky stools that are difficult to flush, muscle-wasting and a distended abdomen may result; in children, malabsorption can affect growth and development.

Causes of malabsorption include: intestinal, biliary or pancreatic disease (cystic fibrosis, biliary atresia, Whipple disease, Shwachman–Bodian–Diamond syndrome); food allergies or intolerances (coeliac disease, lactose intolerance, bovine lactalbumin intolerance [cow's milk protein], soy milk protein intolerance); vitamin B₁₂ malabsorption (pernicious anaemia, ileal disease, *Diphyllobothrium latum* [fish tapeworm] infestation); other parasites (*Giardia lamblia*, *Strongyloides stercoralis* [threadworm], *Necator americanus* [hookworm]); or, rarely, acrodermatitis enteropathica or abetalipoproteinaemia.

MALAISE

Malaise is a generalized feeling of discomfort, illness, uneasiness, fatigue or lack of well-being, often associated with a disease state. However, it is a very non-specific symptom and can be due to almost any infection, cancer and metabolic, endocrine, psychiatric or neurological disorders, and may develop slowly or rapidly, depending on the nature of the disease.

MELAENA

Melaena is the passage of black, tarry and foul-smelling stools, and usually indicates bleeding from the upper gastrointestinal tract. Other substances, such as blackberries, iron or liquorice, can cause black stools (false melaena), so that black stools should be formally tested for blood. [Table 4.6](#) shows the causes of stools of various colours.

MENORRHAGIA

Menorrhagia is heavy regular bleeding over consecutive menstrual cycles ('periods'). The definition of heavy periods is the loss of 80 mL or more of blood, but passage of clots and overuse of sanitary towels or tampons may be suggestive. It may cause anaemia.

Common causes of menorrhagia are dysfunctional uterine bleeding (DUB) and uterine fibroids. Other causes are endometriosis, clotting disorders and anticoagulants.

Box 4.5 Causes of cervical lymphadenopathy**Bacterial**

- Dental, face or scalp infections
- Tuberculosis
- Syphilis
- Cat scratch disease
- Brucellosis

Viral

- Herpetic stomatitis
- Infectious mononucleosis
- Adenovirus infections
- HIV
- Cytomegalovirus

Parasitic

- Toxoplasmosis

Connective tissue disorders

- Rheumatoid arthritis
- Systemic lupus erythematosus

Lymphoid or reticuloendothelial disease

- Leukaemias
- Hodgkin disease
- Non-Hodgkin lymphomas

Neoplasms

- Metastases from any tumour in the drainage area
- Nasopharyngeal carcinoma
- Neuroblastoma
- Thyroid carcinoma, chronic lymphocytic thyroiditis
- Kaposi sarcoma
- Langerhans histiocytosis

Immunodeficiency syndromes and phagocytic dysfunction

- Chronic granulomatous disease
- Hyperimmunoglobulin E (Job) syndrome
- HIV/AIDS

Metabolic and storage diseases

- Gaucher disease
- Niemann–Pick disease
- Cystinosis

Haemopoietic diseases

- Sickle cell anaemia
- Thalassaemia
- Congenital haemolytic anaemia
- Autoimmune haemolytic anaemia

Drug-induced hypersensitivity syndrome

- Phenytoin
- Others (such as cephalosporins, penicillins or sulphonamides)

Immunological disorders

- Serum sickness
- Chronic graft-versus-host disease
- Benign sinus histiocytosis
- Angioimmunoblastic or immunoblastic lymphadenopathy
- Chronic pseudolymphomatous lymphadenopathy (chronic benign lymphadenopathy)
- Sarcoidosis, Crohn disease and orofacial granulomatosis
- Kawasaki disease (mucocutaneous lymph node syndrome)
- Angiolymphoid hyperplasia with eosinophilia, haemangioma, with eosinophilic infiltration and lymphoid hyperplasia
- Castleman disease (angiofollicular lymphoid hyperplasia or benign giant lymph node hyperplasia).
- Kikuchi syndrome (Ch. 37)

Table 4.6 Causes of coloured stools (apart from foods/drinks/drugs)

Black	Maroon	Red
Bleeding gastric ulcer	All the causes of black-coloured stool	All the causes of black- or maroon-coloured stool
Gastritis	Bleeding diverticula	Haemorrhoids
Oesophageal varices	Bleeding vascular malformation	Anal fissures
Mallory–Weiss tear	Intestinal infection (e.g. bacterial enterocolitis)	
Bleeding disorder	Inflammatory bowel disease	
	Colonic polyps	
	Colonic cancer	

MOUTH ULCERS

Oral ulcers are common; most are traumatic or recurrent aphthae, but more serious causes must always be excluded. Particular care must be taken to exclude drugs, cancer, blood dyscrasias, infections, and gastrointestinal or mucocutaneous disease (Box 4.6 and Ch. 11).

MURMURS

Heart murmurs are caused by turbulence of blood flow through valves or ventricular outflow tracts. The prevalence of cardiac murmurs in the general population is very high, and some indicate cardiac disease. Functional (high-flow – also called physiological) murmurs are innocent murmurs that are heard in the absence of cardiac valvular disease. An example is an aortic systolic ejection murmur caused by a high cardiac output state, as in athletes and anaemia. Another example is pregnancy, where the rise in cardiac output, especially when coupled with anaemia, can result in physiological ejection murmurs.

NAUSEA AND VOMITING

Nausea is the sensation leading to the urge to vomit; vomiting is the forced ejection of stomach contents through the oesophagus and out of the mouth. Causes of nausea and vomiting are varied, but may include unusual motion (e.g. travel/motion sickness); gastroenterological causes (infections, food poisoning, food allergies, gastroenteritis, pyloric stenosis); neuropsychiatric factors (bulimia, cyclic vomiting syndrome, emotional stress, labyrinthitis, migraine); morning sickness during pregnancy; and many drugs (especially alcohol, chemotherapy, erythromycin, general anaesthetics). Complications of vomiting include dehydration, loss of electrolytes, peptic oesophagitis, haematemesis, aspiration, Mallory–Weiss tear, and tooth erosion if vomiting is chronic. Apart from treating underlying causes, antiemetic drugs may help.

NECK LUMPS

The lumps in the neck of most significance are enlarged cervical lymph nodes, but lumps may also be due to other pathology (Box 4.7).

Box 4.6 Causes of oral ulceration
Systemic causes
Blood diseases (Ch. 8)

- Leukopenias, including HIV disease
- Leukaemias and myelodysplastic syndrome
- Deficiency states or anaemia
- Hypereosinophilic syndrome

Infections

Viral, mainly (Ch. 21)

- Herpes viruses
- Coxsackie viruses
- ECHO viruses

Bacterial

- Acute necrotizing gingivitis
- Syphilis
- Tuberculosis

Fungal

- Cryptococcosis
- Histoplasmosis
- Paracoccidioidomycosis
- Blastomycosis
- Zygomycosis
- Aspergillosis

Protozoal

- Leishmaniasis

Gastrointestinal disease (Ch. 7)

- Coeliac disease
- Crohn disease
- Ulcerative colitis

Mucocutaneous diseases (Ch. 11)

- Lichen planus
- Chronic ulcerative stomatitis
- Pemphigus
- Pemphigoid
- Localized oral purpura
- Erythema multiforme
- Epidermolysis bullosa
- Dermatitis herpetiformis
- Linear immunoglobulin A (IgA) disease
- Behçet and Sweet syndromes

Connective tissue and other diseases (Ch. 16)

- Lupus erythematosus
- Reiter syndrome
- Vasculitides
- Giant cell arteritis
- Wegener granulomatosis
- Periarthritis nodosa

Malignant neoplasms (Ch. 22)

- Squamous cell carcinoma
- Others

Local causes

- Trauma
- Chemical irritation
- Burns
- Irradiation

Aphthae and aphthous-like ulcers

Drugs (Ch. 29)

Box 4.7 Causes of neck lumps other than lymphadenopathy
Infections

- Abscess
- Actinomycosis

Cysts

- Thyroglossal
- Branchial
- Cystic hygroma
- Sebaceous cyst
- Dermoid cyst

Hamartomas

- Haemangioma/lymphangioma

Thyroid

- Goitre
- Nodules (and carcinoma)

Carotid

- Aneurysm
- Body tumour

Skin

- Lipoma
- Seroma
- Carcinoma
- Pharyngeal pouch

NECK STIFFNESS

Neck pain and stiffness may originate from any neck structure or from the shoulders and arms, ranging from the cervical vertebrae to blood vessels, muscles and lymphatic tissue. Causes mainly include strain and spasm of neck muscles; trauma (road traffic accidents); or arthritis. Neck stiffness can have serious significance since it can also originate from meningeal irritation in meningitis (there may also be fever, an aversion to light, vomiting, and severe headache) and meningism – a non-infective syndrome with similar features, caused by meningeal irritation by, for example, an intracranial haemorrhage or tumour.

NOCTURIA

Nocturia is the passing of too much urine at night. Young people tend to excrete their daily urine output mostly in the day; older people commonly also pass urine once or twice at night. Causes of nocturia include, in particular, drinks such as coffee or tea too close to bedtime; insomnia or other sleep-related difficulties; urinary or prostatic disorders (e.g. benign prostate disease or cystitis); chronic kidney disease; diabetes; or cardiac failure.

NYSTAGMUS

A few irregular eye jerks are normal in some individuals when the eyes are deviated far to one side. Nystagmus is involuntary rapid, back-and-forth, repetitive eye movements, caused by abnormalities of function in the areas of the brain that control eye movements. It may be congenital (the most common cause), when it is usually mild, unchanging in severity, and not associated with any other disorder. Causes include cataract, glaucoma, retinal disease, Down syndrome and albinism.

Nystagmus may be acquired and caused by disease or injury later in life, most commonly by head injury or, in older people, by stroke, but any brain diseases, such as multiple sclerosis or tumours, inner ear problems or drugs, can be responsible.

The most common form of nystagmus is rhythmic (jerk), which is usually horizontal but can be vertical or rotary. It results from drug intoxication (barbiturates, phenytoin toxicity and alcohol intoxication); inner ear disease (Ménière disease); cerebellar disease; or brain-stem disease.

OBESEITY

See Chapter 27.

OEDEMA

Oedema is the accumulation of fluid in the tissues. Slight oedema of the legs is common in healthy persons, especially in the warm summer months, after prolonged standing and/or on long flights or car journeys. Injury or trauma, insect bite or sting, burns, allergic reactions or angioedema can cause oedema. It may also stem from more serious conditions. When venous pressure rises in cardiac failure, subcutaneous oedema gravitates to dependent parts; ankle oedema is seen in ambulant patients and sacral oedema in those in bed. Oedema may be pitting (when a finger is pressed against a swollen area for 10 seconds and then quickly removed, an indentation is left that fills slowly) or non-pitting (no indentation is left). In pregnancy (pre-eclampsia – hypertension with albuminuria), oedema can appear between the 20th week of pregnancy and the end of the first week postpartum. Other causes include loss of plasma proteins from renal factors or malnutrition (causing the nephrotic syndrome) and medical treatments (body fluid overload, infiltration of an intravenous site, diagnostic tests, e.g. venogram), including drugs (corticosteroids, androgenic and anabolic steroids, oestrogens, antihypertensives, NSAIDs).

PALMAR ERYTHEMA

Redness of the palms of the hands may be seen in cirrhosis, pregnancy, rheumatoid arthritis, systemic lupus erythematosus and hyperthyroidism.

PALPITATIONS

Palpitations are the consciousness of rapid heart action (Ch. 5). Cardiac activity is controlled by the autonomic nervous system and is commonly sensed only by persons with abnormally heightened awareness of their body functions, as in anxiety states, or following exercise – when heart stroke volume or rate rises. Palpitations are most commonly caused by arrhythmias but may also stem from disorders such as anaemia, aortic regurgitation or thyrotoxicosis. Palpitations accompanied by myocardial ischaemia-type chest pain probably indicate coronary artery disease. Enquiry into the rate and the rhythm of palpitations helps differentiate pathological from physiological, since palpitations due to an arrhythmia may be accompanied by weakness, dyspnoea or light-headedness.

Atrial or ventricular extrasystoles are often described as skipped beats, and atrial fibrillation as total irregularity, while supraventricular

or ventricular tachycardia is most often perceived as being rapid and regular, and of sudden onset and termination.

PAPILLOEDEMA

Papilloedema is a swelling of the optic nerve seen on ophthalmoscopy. The optic nerve anatomy makes it sensitive to slight rises in cerebrospinal fluid (CSF) pressure, and when the optic nerve is exposed to such pressure or when it becomes inflamed, it can bulge (papilloedema). Causes of raised CSF pressure and papilloedema are brain disease, raised intracranial pressure (e.g. haemorrhage, tumours, infections – brain abscess, meningitis or encephalitis) and pseudotumour cerebri or benign intracranial hypertension (results from CSF overproduction). This is more common in women who are obese and of childbearing age, and seems to be triggered at times of hormone change, such as pregnancy, the start of contraceptive pill use, tetracycline use, the first menstrual period or menopause. Papilloedema can also arise from local inflammation (optic neuritis); multiple sclerosis is the most common cause.

Symptoms related to papilloedema are mainly caused by raised intracranial pressure and include headache and nausea with vomiting. About 25% of patients with advanced papilloedema also develop some visual symptoms, such as recurring brief episodes in which the vision turns grey or ‘blacks out’, as if a veil has fallen over the eyes. Ophthalmoscopy shows an elevated optic disc with a blurred margin, and there is a wider blind spot and narrowing of peripheral vision.

PARAESTHESIA

Paraesthesia is a burning or prickling sensation, most common when there is sustained pressure on a nerve and experienced as temporary paraesthesia – ‘pins and needles’ – when individuals have sat with their legs crossed for too long or fallen asleep with an arm crooked under their head; the feeling abates once the pressure is relieved. Nerve entrapment syndromes, such as carpal tunnel syndrome, can cause paraesthesia sometimes accompanied by pain but are usually very peripheral and obvious. Chronic paraesthesia may be a feature of traumatic nerve damage or an underlying neurological disease, such as cerebrovascular issues (stroke and TIAs), multiple sclerosis, connective tissue diseases, sarcoidosis, transverse myelitis, brain or spinal cord tumour or vascular lesion, encephalitis and some drugs. Some LA agents can be neurotoxic (Ch. 3).

POLYDIPSIA

Polydipsia is an abnormal feeling of constant thirst. The most common cause is the excessive intake of salty foods but the desire to drink excessively beyond a certain limit may reflect underlying disease, either physical or emotional. Causes include excessive loss of water and salt (as with water deprivation, profuse sweating, diarrhoea or vomiting, severe infections or widespread burns); fluid loss during exercise; bleeding sufficient to cause a significant fall in blood volume; drugs (including anticholinergics, demeclocycline, diuretics, lithium, phenothiazines); endocrine disorders (diabetes mellitus, Conn disease, Cushing disease, hyperthyroidism, diabetes insipidus); and cardiac, hepatic or renal failure. Psychogenic causes are most commonly seen in women over age 30.

POLYURIA

Polyuria – the passing of abnormally large amounts of urine (for an adult, at least 2.5 L per day) – is fairly common and often first noticed

at night. Polyuria is to be expected with excessive intake of fluids, particularly ones containing caffeine or alcohol, or too much salt or glucose (especially if diabetic); the use of diuretics can also lead to polyuria. Other causes include diabetes mellitus or insipidus; psychogenic polydipsia; renal failure; sickle cell anaemia; and radiography using contrast media.

PRESSURE ULCERS (BED SORES)

Pressure sores or ulcers are injuries to skin and underlying tissues from prolonged pressure on skin that covers bony areas of the body, such as the heel, ankles, hips or buttocks. People most at risk are those with medical conditions that limit their ability to change position, requires them to use a wheelchair or confines them to bed for long periods. Sores develop through a series of stages:

- **Stage I**
The skin is intact and red in people with lighter skin colour, failing to blanch when touched.
The site may be painful, firm, soft, warmer or cooler compared with surrounding skin.
- **Stage II**
A pressure ulcer may appear – as a shallow, pinkish-red ulcer. It may also appear as an intact or ruptured fluid-filled blister.
- **Stage III**
There is a deep wound, usually with fat exposed.
The bottom of the wound may have some slough.
Damage may extend beyond the primary wound below layers of healthy skin.
- **Stage IV**
The wound may expose muscle, bone and tendons.
The wound base contains slough or eschar.
Damage often extends beyond the primary wound below layers of healthy skin.

Risk factors, apart from continued pressure, include:

- age
- lack of sensory perception; spinal cord injuries, neurological disorders and other conditions can result in a loss of sensation
- weight loss
- poor nutrition and hydration
- urinary or faecal incontinence
- excess moisture or dryness
- diabetes and vascular disease, affecting the circulation
- smoking
- decreased mental awareness
- muscle spasms.

Complications of pressure ulcers include:

- sepsis
- cellulitis
- bone and joint infections
- cancer (Marjolin ulcer).

Treatment consists of the following measures:

- Relief of pressure by repositioning. Special cushions, pads, mattresses and beds may be used.
- Removal of damaged tissue by surgical mechanical, enzymatic or autolytic debridement.
- Cleaning and dressing of wounds.

- Pain management. Interventions may include the use of NSAIDs, such as ibuprofen and naproxen, particularly before and after repositioning, debridement procedures and dressing changes. Topical pain medications, such as a combination of lidocaine and prilocaine, also may be used during debridement and dressing changes.
- Antibiotics.
- Healthy diet.
- Muscle spasm relief. Relaxants such as diazepam, tizanidine, dantrolene and baclofen may inhibit spasms.
- Surgical repair.

PROPTOSIS

Proptosis is the anterior displacement of one or both eye globes within the bony orbit. The term exophthalmos is sometimes used, particularly when the proptosis is related to thyroid dysfunction. The normal amount of ocular protrusion as measured (with an exophthalmometer) from the lateral orbital rim to the corneal apex is 14–21 mm in adults; protrusion greater than 21 mm or a 2-mm change is abnormal. On scans, proptosis is defined as globe protrusion greater than 21 mm anterior to the interzygomatic line on axial scans at the level of the lens.

Proptosis without displacement (axial) is due to intraconal, most commonly dysthyroid, eye disease. In this case, the protrusion is caused by inflammatory swelling of the small eye-moving muscles behind the globe. Thyroid exophthalmos may appear months or years after the onset of a thyroid disorder but may occasionally precede it. Tumours (such as glioma and meningioma of the optic nerve and cavernous haemangioma) may also be responsible.

Proptosis with displacement (non-axial) is due to extraconal disease, most commonly lacrimal tumours or a mucocoele.

Pseudoproptosis is either the simulation of abnormal eye prominence, or a true asymmetry that is not the result of increased orbital contents. Causes include enlarged eye globe (high myopia, buphthalmos); extraocular muscle weakness or paralysis; contralateral enophthalmos; asymmetrical orbital size (congenital, post-irradiation, post-surgical); and asymmetrical palpebral fissures (e.g. caused by ipsilateral eyelid retraction, scarring, facial nerve paralysis or contralateral ptosis).

PRURITUS (ITCHING)

Pruritus is a peculiar tingling or uneasy irritation of the skin, which leads to a desire to scratch the affected area. Causes include skin irritation from insect bites, stings and chemicals; environmental causes (drying, sunburn); or urticaria. Parasites (e.g. lice) or skin conditions (e.g. lichen planus, dermatitis herpetiformis) are other causes. Less commonly, pruritus is due to infectious diseases (chickenpox), pregnancy, allergic reactions, biliary obstruction, chronic kidney disease, lymphomas, drugs (penicillin, sulphonamides, gold, griseofulvin, isoniazid, opiates, phenothiazines or vitamin A) or contact irritants (such as soaps, chemicals or wool).

Pruritus ani is a common and troublesome complaint that can result from such causes as haemorrhoids or irritable bowel syndrome; fistulas or fissures; mucocutaneous diseases such as lichen planus; or infections such as candidosis or worms.

PTOSIS

Ptosis is drooping eyelids, caused by weakness of the muscle responsible for raising the eyelid (levator palpebrae superioris), as in

Fig. 4.4 Mydriasis.

myasthenia gravis, damage to the extraocular nerves, or skin laxity in the upper eyelids.

Congenital ptosis is most commonly due to a defect in the levator palpebrae superioris or rare myopathies (e.g. myotonia congenita). Marcus Gunn ‘jaw-winking’ syndrome is ptosis usually in one eye only; it is due to the lid partially opening as the jaw opens because of an abnormal nerve connection.

Acquired ptosis can be through age-related defects of the eyelid muscles and nerves, or by damage to the sympathetic nerve supply or the oculomotor nerve. A mechanical defect caused by anything that increases the weight of the eyelid, such as a cyst, may also cause ptosis.

PUPIL ANOMALIES

The pupils normally are equal in size, and they constrict on exposure to bright light and on accommodation for near objects. Light shone in one eye causes pupillary constriction in that eye (direct light reflex) and also in the unexposed eye (indirect or consensual reflex).

Pupil size is determined by dilator fibres (the sympathetic nerve supply from the superior cervical ganglion runs along the internal carotid artery and joins the ophthalmic division of the trigeminal nerve and the long ciliary nerves) and the sympathetic nerve supply is also partially responsible for contraction of the levator palpebrae superioris muscle (raising the upper eyelid). Pupil size is also determined by constrictor fibres (the parasympathetic supply runs with the oculomotor nerve). Pupil constriction (miosis) can be caused by a lesion of the sympathetic supply, and dilatation (mydriasis) by a third nerve lesion (Fig. 4.4). The most important cause of an abnormally dilated pupil is a rise in intracranial pressure, when the pupil also becomes non-reactive owing to pressure on the oculomotor nerve (Table 4.7).

PURPURA

Purpura is abnormal bruising (Fig. 4.5) with small bleeds into the skin (petechiae) or larger bleeds (ecchymoses), and bleeding from mucosae (epistaxes – nosebleeds – and gingival bleeding). Causes of purpura include:

- *purpura simplex* (easy bruising) – the most common vascular bleeding disorder, due to excessive vascular fragility and usually seen in women in whom the platelet count and tests of platelet function, blood coagulation and fibrinolysis are normal. Bruises develop without known trauma on the thighs, buttocks and upper arms, and are typically small.
- *senile purpura* – a common disorder affecting older patients, mainly on the extensor surfaces of the hands and forearms, particularly in those who have had excessive sun exposure. Lesions appear often without known trauma as dark purple

Table 4.7 Causes of pupillary abnormalities

Pupils	Other signs	Significance
Constricted bilaterally	±Signs of drug abuse	Opiate use
Constricted bilaterally, unequal, react to accommodation but not light	–	Argyll Robertson pupils – neurosyphilis, multiple sclerosis, diabetes mellitus, sarcoid, brain tumour, amyloid, trauma, Lyme disease
Constricted unilaterally	Ptosis, absence of facial sweating, enophthalmos sometimes	Horner syndrome – damage to sympathetic fibres, usually in neck (e.g. by trauma or bronchial carcinoma)
Dilated unilaterally	Ptosis	Third nerve lesion
Dilated unilaterally and react slowly to light or convergence	Possible absence of ankle or knee jerks	Usually benign Adie (Holmes–Adie) pupil
Dilated bilaterally and reactive	±Signs of drug abuse	Cocaine or other drug use
Dilated bilaterally and unreactive	±Headaches	Raised intracranial pressure

Fig. 4.5 Purpura.

ecchymoses and slowly resolve over several days, leaving a brownish discolouration caused by deposits of haemosiderin. The condition has no serious consequences. Angina bullosa haemorrhagica may be a localized form of purpura seen in the mouth or throat.

- *thrombocytopenia* – the most important systemic cause of purpura (Ch. 8).

RAISED INTRACRANIAL PRESSURE

Normal intracranial pressure (ICP) for an adult at rest is 7–15mmHg supine, becoming negative (–10mmHg) in the vertical position. Changes in ICP are attributed to volume changes in one or more of the constituents contained in the cranium; any expansion of cranial contents causes a rise of ICP, which tends to impede the venous return from the brain and to increase the pressure further. Cerebral blood flow is thus diminished, even though the raised CSF pressure causes a reflex rise in systemic blood pressure in an attempt to improve cerebral blood flow.

Table 4.8 *Types of glaucoma*

Type	Features	Treatment
Open-angle	Most common. The angle that allows fluid to drain out of the anterior chamber is <i>open</i> . However, the fluid passes too slowly through the meshwork drain. Optic nerve damage and narrowed side vision develop. Risk groups include people of African heritage over the age of 40, anyone over age 60 and a family history of glaucoma	Drugs or laser trabeculoplasty
Low-tension or normal-tension	Optic nerve damage and narrowed side vision develop unexpectedly in people with normal eye pressure	Drugs or laser trabeculoplasty
Closed-angle	The fluid at the front of the eye cannot reach the angle and leave it because the angle is blocked by part of the iris. Without treatment, the eye can become blind within 48h	A medical emergency. Immediate laser treatment
Congenital	Involves defects in the angle of the eye that slow the normal drainage of fluid	Surgery
Secondary	Develops as a complication of other medical conditions, cataracts, uveitis, eye surgery, injuries or tumours	Various

Causes of raised ICP include hydrocephalus, intracranial haemorrhage (after head injury), space-occupying lesions (abscess, tumour or haematoma), oedema (trauma, malignant hypertension, vascular lesions or tumours of the brain), or obstruction to the flow of CSF (blockage of the aqueduct of Sylvius, or subarachnoid adhesions due to meningitis).

Idiopathic intracranial hypertension, sometimes called benign intracranial hypertension or pseudotumour cerebri, occurs in the absence of a tumour or other disease affecting the brain or meninges.

Characteristic symptoms of raised ICP are headache, transient visual changes or loss in one or both eyes usually lasting seconds, pulse-synchronous tinnitus (a 'whooshing noise'), diplopia (double vision) and visual loss. Signs of raised ICP include papilloedema (bulging of the optic disc with engorgement of its vessels seen by ophthalmoscopy); restlessness (in the unconscious patient); vomiting; decreasing consciousness; rising blood pressure and slowing of the pulse; dilatation of the pupil on the side of the lesion with diminished reaction to light, and loss of visual acuity and fields. Diplopia, if present, may be due to abducens palsy.

Raised ICP can be fatal, as the pressure can cause herniation of the brain (displacement of part of the brain from one dural compartment to another) and pressure is exerted on the brainstem and medullary respiratory and cardiac control centres (this is called 'coning'). *Lumbar puncture is contraindicated*, as it can precipitate brain herniation and death by coning. The possibility of herniation is suggested by signs of raised ICP, particularly pupil dilatation and reduced reactivity to light caused by stretching of the oculomotor nerves.

RAISED INTRAOCULAR PRESSURE

Normal intraocular pressure is between 12 and 21 mmHg. Glaucoma is a group of diseases of raised intraocular pressure that can lead to damage to the eye's optic nerve and result in impaired vision (Table 4.8). Glaucoma often affects both eyes, usually in varying degrees but one eye may develop glaucoma quicker than the other. Glaucoma occurs when the eye drainage tubes (trabecular meshwork) become slightly blocked, impeding eye fluid (aqueous humour) drainage. When the fluid cannot drain properly, intraocular pressure (IOP) increases and can damage the optic nerve and the retina. The main types of glaucoma are:

- *chronic open-angle glaucoma* – the most common type; develops slowly
- *primary angle-closure glaucoma* – rare; can develop slowly, or rapidly with a sudden, painful build-up of pressure

**Fig. 4.6** Red eye.

- *secondary glaucoma* – the result of an eye injury or another eye condition, such as uveitis
- *developmental (congenital) glaucoma* – rare but serious; usually presents at birth or develops shortly after.

Early diagnosis is important because any damage cannot be reversed. Treatment aims to control the condition and minimize future damage with eye medication drops (prostaglandin inhibitors, sympathomimetics, beta-blockers or carbonic anhydrase inhibitors), laser trabeculoplasty, cyclodiode therapy or surgery (trabeculectomy).

Drug-induced elevation of intraocular pressure is more common by an open-angle mechanism; some antidepressants, atropine, corticosteroids, diazepam, glycopyrrolate, hyoscine (scopolamine) and topiramate are implicated and therefore contraindicated. Most drugs that have glaucoma as a contraindication or adverse effect, however, are concerned with inducing acute angle-closure glaucoma and include topical anticholinergic or sympathomimetic dilating drops; antidepressants (tricyclic antidepressants, monoamine oxidase inhibitors [MAOIs]); antihistamines; antiparkinsonians; antipsychotics; antispasmodics; and benzodiazepines.

Overviews of drug-induced glaucoma can be found at <http://emedicine.medscape.com/article/1205298-overview> and http://www.fmshk.org/database/articles/03mb6_5.pdf (accessed 25 May 2013).

RED EYE

There are many causes of red eye (Fig. 4.6), ranging from trauma or simple superficial inflammation (conjunctivitis) to more serious corneal ulceration, uveitis (inflammation of iris, ciliary body and choroids) and acute glaucoma – a medical emergency.

Box 4.8 Causes of salivary gland swelling**Inflammatory**

- Mumps
- Bacterial ascending sialadenitis
- Obstructive sialadenitis
- Allergic sialadenitis (e.g. to iodides or chlorhexidine)
- Sjögren syndrome and IgG4 syndrome
- Sarcoidosis
- HIV infection
- Tuberculosis and non-tuberculous mycobacteriosis
- Actinomycosis
- Toxoplasmosis

Neoplastic

- Pleomorphic adenoma and many others

Endocrine and metabolic

- Alcoholic and other types of cirrhosis
- Diabetes mellitus
- Acromegaly
- Malnutrition or bulimia
- Cystic fibrosis
- Chronic renal failure
- Amyloidosis
- Haemochromatosis

Drugs (rarely)

- Antiretroviral drugs (lipomatosis)
- Chlorhexidine
- Iodides
- Isoprenaline
- Phenylbutazone

**Fig. 4.7** Unilateral parotid swelling.**Fig. 4.8** Prolapsed intervertebral disc ('slipped disc').**RED LESIONS IN THE MOUTH**

Many oral mucosal red lesions are due to infections or are inflammatory with no identified infectious agent (sarcoidosis, Crohn disease); vascular anomalies (e.g. telangiectasias); or mucosal atrophy (erythema migrans [geographic tongue], desquamative gingivitis, erythroplasia or deficiency state). Lichen planus, lupus erythematosus and candidosis may cause red or white lesions (Ch. 11). Red lesions are sometimes due to Kaposi sarcoma or Wegener granulomatosis.

SALIVARY SWELLING

The most common cause of salivary swelling is mumps (Ch. 21), which usually affects children and typically causes bilateral painful swellings, but there are many other causes (Box 4.8). Salivary obstruction, as by a calculus (stone), is the common cause of a unilateral swelling. Neoplasms (usually pleomorphic adenoma) must be considered, particularly when there is a persistent unilateral swelling in older patients (Fig. 4.7). Painless bilateral salivary swelling in an adult is usually due to sialadenosis (sialosis) and to autonomic dysfunction; it is thus a rare feature of alcoholic cirrhosis, diabetes mellitus, acromegaly, starvation or bulimia, or may be idiopathic. Sjögren syndrome and immunoglobulin G4 (IgG4) disease may also cause salivary gland swelling (see Box 4.8).

SCIATICA

Sciatica is pain down the leg, caused by irritation of the sciatic nerve, the main nerve to the leg. The pain travels below the knee and may involve the foot, and there may be numbness and weakness of the lower leg muscles. The most common cause is a 'slipped disc' (a prolapsed intervertebral disc or herniated nucleus pulposus). Pressures within intervertebral discs can be high on bending or twisting, even without carrying a load. If part of the fibrous outer ring of the disc is weak, the softer nucleus pulposus centre may push its way through, and if it presses against a nerve it causes symptoms. Sciatica occurs when the herniated disc presses against the sciatic nerve (Fig. 4.8).

CT or MRI scans determine whether an operation will help cure the sciatica. Simple analgesics, such as paracetamol or ibuprofen, help. Activities likely to put unnecessary strain on the back should be avoided. In the minority of cases in which sciatica does not settle or complications arise, surgery is needed.

SELF-HARM

See Chapter 10.

SIALORRHOEA (HYPERALIVATION)

Normally, any excess of saliva is swallowed and causes no symptoms. However, in normal infants, and in patients who have learning impairment, poor neuromuscular coordination or pharyngeal or oesophageal obstruction, drooling is common without any true overproduction of saliva (hypersalivation).

Causes of decreased saliva clearance include:

- infections such as tonsillitis, retropharyngeal and peritonsillar abscesses, epiglottitis and mumps
- jaw problems, e.g. fracture or dislocation
- neurological disorders such as myasthenia gravis, Parkinson disease, rabies, bulbar paralysis, bilateral facial nerve palsy and hypoglossal nerve palsy
- radiation therapy.

Causes of saliva overproduction include:

- excessive starch intake
- foreign bodies (e.g. new mouth appliances)
- gastro-oesophageal reflux disease, in such cases specifically called water brash, and characterized by a sour fluid or almost tasteless saliva
- liver disease
- oral infections or ulcers
- pancreatitis
- pregnancy
- rabies
- serotonin syndrome.

Drugs that can cause saliva overproduction include:

- clozapine
- ketamine
- pilocarpine
- potassium chlorate
- rabeprazole sodium
- risperidone.

Toxins that can cause hypersalivation include:

- arsenic
- copper
- mercury
- organophosphates (insecticide).

However, there is often no objective evidence for hypersalivation – when it may have a psychogenic basis.

Hypersalivation or drooling may be controllable with anticholinergic drugs (benzatropine, glycopyrronium and trihexyphenidyl hydrochloride) or antimuscarinic agents such as sublingual atropine or propantheline bromide. Botulinum toxin injections can be effective in certain circumstances. If hypersalivation is very severe, surgical relocation of the parotid duct, such that it discharges into the pharynx, may be effective, and the submandibular duct can also be moved.

SNEEZING (STERNUTATION)

Sneezing is a sudden, forceful, involuntary burst of air through the nose and mouth, almost invariably caused by irritation to the mucous membranes of the nose or throat. Rarely a sign of serious disease, sneezing typically is caused by allergy or hay fever, upper respiratory tract infections, opioid withdrawal or corticosteroid inhalation.

SNORING

Snoring is caused by obstructed breathing; the sound is usually made by the palate vibrating when the muscles relax, narrowing the airway. Snoring is usually normal, of unknown cause and not an indication of any underlying disorder. Excess alcohol or sedation can contribute. However, snoring can also be a sign of the *sleep apnoea syndrome*, with chronic nasal congestion or obstruction by enlarged tonsils and adenoids – or more serious pathology. It often causes nocturnal xerostomia. Snoring may often be reduced by not taking too much alcohol or sedation at bedtime, by avoiding sleeping flat on the back, and by weight loss (Ch. 14).

SORE THROAT

A sore throat is discomfort, pain or scratchiness in the throat, often associated with pain on swallowing. Sore throats are common, especially in children between the ages of 5 and 10, most often caused by upper respiratory viruses (Ch. 14). Streptococcal throat is the most common bacterial cause and can occasionally lead to rheumatic fever, so antibiotics are indicated. Other causes of sore throat include trauma (a fish or chicken bone or other foreign substance stuck in the throat, endotracheal intubation, or local surgery, such as tonsillectomy and adenoidectomy). Occasionally, more serious pathology underlies the complaint.

SPLENOMEGALY

Splenomegaly is enlargement of the spleen beyond its normal size. The spleen is involved in the production and maintenance of erythrocytes and the production of certain immunocytes; it may be affected and enlarged by many conditions involving the blood or lymph system, and by infection, liver disease, haemolytic anaemias, malignancies and parasites. Causes of splenomegaly can include those listed in [Box 4.9](#).

Rupture of the enlarged spleen is possible and usually due to trauma.

STROKE (CEREBROVASCULAR EVENT OR ACCIDENT; CVA)

See Chapter 13.

STUTTERING

Stuttering (stammering) is a speech disorder in which the normal flow of speech is disrupted by frequent repetitions or prolongations of speech sounds, syllables or words, or by an individual's inability to start a word. Stuttering usually has a genetic basis but other causes can be neurogenic – following a stroke or other brain injury, or psychogenic – particularly anxiety. Stuttering may be accompanied by rapid eye blinks, lip and/or jaw tremors or other movements. Certain situations, such as lecturing, talking on the telephone or being interviewed, tend to aggravate stuttering, whereas others, such as singing or speaking alone, often improve it.

SWEATING

Sweating is a heat-regulatory mechanism, mediated by the hypothalamus, when in a warm environment or exercising. The evaporation of

Box 4.9 Causes of splenomegaly**Infections**

- Malaria (worldwide the most common cause)
- Infectious mononucleosis
- Cytomegalovirus infection
- Other viral infections
- Parasitic infections
- Cat scratch disease
- Bacterial infections

Liver diseases

- Cirrhosis (portal vein obstruction, portal hypertension)
- Sclerosing cholangitis
- Wilson disease
- Biliary atresia
- Cystic fibrosis

Haemolytic anaemias

- Thalassaemia
- Haemoglobinopathies
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Idiopathic autoimmune haemolytic anaemia
- Immune haemolytic anaemia

Malignant disease

- Leukaemia
- Lymphoma
- Hodgkin disease

Other causes

- Sarcoidosis
- Sickle cell splenic crisis
- Banti syndrome
- Felty syndrome

sweat, produced by sweat glands in the skin, leads to heat loss. Other causes of sweating are shown in [Box 4.10](#).

SYNCOPE

Syncope is a feeling of faintness, dizziness or light-headedness (presyncope), or loss of consciousness (syncope), due to a sudden decline in blood flow to the brain. Syncope can affect otherwise healthy people but may also be caused by an irregular cardiac rate or rhythm, or by changes of blood volume or distribution. The main causes include: vasovagal attack (fainting, Ch. 1); respiratory factors (severe coughing causing vagal stimulation); cardiac disease (arrhythmias, heart block, aortic stenosis); paralytic factors – in the elderly, especially those taking drugs such as phenothiazines, L-dopa, hypotensive agents, tricyclics or benzodiazepines; brainstem factors – owing to migraine or vertebrobasilar disease, usually in the elderly; and carotid sinus syndrome – an exaggerated baroreceptor response resulting in periods of inappropriately high vagal tone and sympathetic suppression. The diagnosis is frequently made in men over 50 and in patients with atherosclerosis and hypertension. Syncope may also be caused by turning or pressing on the neck.

TACHYCARDIA

See Chapter 5.

Box 4.10 Causes of sweating

- Exercise
- Infections
- Menopause
- Malignant disease
 - Breast cancer
 - Prostate cancer
 - Hodgkin disease
 - Phaeochromocytoma
 - CNS tumours
 - Endocrine tumours
- Drugs
 - Tamoxifen
 - Opioids
 - Antidepressants
 - Steroids
 - Recreational drugs
- Hypothalamic disease
- Sweating disorders (hyperhidrosis)

Box 4.11 Causes of tachypnoea

- Psychological states
 - Anxiety
 - Stress
 - Situations in which there is a psychological advantage in having a sudden dramatic illness
- Drug use
 - Stimulant use
 - Drugs (e.g. aspirin overdose)
- Respiratory disorders
 - Asthma
 - Chronic obstructive pulmonary disease
 - Pneumonia
 - Pulmonary fibrosis
 - Pleurisy
 - Pulmonary embolism
- Cardiac disease
 - Congestive heart failure
 - Coronary artery disease
 - Valvular disease
- Severe pain
- Ketoacidosis and similar medical conditions

TACHYPNOEA

Tachypnoea or hyperventilation is excessive, rapid and deep breathing, resulting in a fall in the carbon dioxide level in the blood. Hyperventilation is not uncommon in young adults, especially in women, usually when they are nervous and tense. It can also be a symptom of other disorders. Causes of tachypnoea include those shown in [Box 4.11](#).

TASTE DISORDERS

See Chapter 13.

Box 4.12 Causes of tiredness

- Excessive physical exertion
- Poor nutrition
- Infections (e.g. tuberculosis, bacterial endocarditis, HIV, hepatitis, influenza and mononucleosis)
- Chronic fatigue syndrome
- Psychological disorders
 - Anxiety and depression
 - Chronic boredom
 - Grief
 - Sleep disorders, such as insomnia
 - Stress
- Anaemia
- Endocrinopathies (e.g. diabetes, hypothyroidism, Addison disease, acromegaly)
- Drugs (e.g. antihistamines, antihypertensives, sedatives or diuretics)
- Chronic disease (e.g. cancer, rheumatoid arthritis, systemic lupus erythematosus)
- Most types of surgery
- Cardiac failure

TEETHING

Restlessness, irritability, finger-sucking, gum-rubbing and drooling may be associated with the eruption of deciduous teeth. Teething is traditionally blamed for a variety of other signs and symptoms in infancy, but is not responsible for diarrhoea, fever, convulsions or other systemic disorders. These have systemic causes, usually infections – often herpetic stomatitis.

TINNITUS

Tinnitus is a ringing, roaring or other sound inside the ears. It may be caused by ear problems (wax, infection, Ménière disease); neurological causes; or aspirin or certain antibiotics (aminoglycosides mainly). However, the reason for the tinnitus often cannot be found. Tinnitus can fluctuate or can resolve spontaneously, but is frequently untreatable.

TIREDNESS

Tiredness is a feeling of lack of energy, fatigue or weariness. Fatigue represents a normal response to physical exertion, emotional stress or lack of sleep, but can also be a non-specific symptom of a psychological or physiological disorder. In many cases, fatigue is related to boredom, unhappiness, disappointment, lack of sleep or hard work. Because it is such a common complaint and is often caused by psychological problems, its potential seriousness is often overlooked.

Pathological (illness-related) fatigue is not relieved by rest, adequate sleep or removal of stressful factors. An example is the so-called *chronic fatigue syndrome*.

The pattern of fatigue may help delineate its underlying cause: individuals who arise in the morning rested but, with activity, rapidly fatigue may have a disease, while individuals who awaken fatigued and the level of fatigue remains constant throughout the day may be suffering from depression. Other causes are shown in [Box 4.12](#).

Table 4.9 Causes of discolouration of teeth

Extrinsic	Intrinsic
Most teeth affected Smoking, beverages, e.g. tea Drugs, e.g. iron, chlorhexidine, minocycline Poor oral hygiene, betel chewing	Tetracycline, fluorosis, amelogenesis imperfecta, dentinogenesis imperfecta, kernicterus, biliary atresia, porphyria
One or a few teeth affected As above	Trauma, caries, resorption

Table 4.10 Different types of tremor

Type	Causes
Contraction tremors (e.g. making a tight fist while the arm is resting and supported)	Essential tremor, cerebellar disease, hyperthyroidism, drugs such as caffeine and anticholinergic agents
Intention (action or kinetic) tremors (e.g. finger-to-nose test)	Cerebellar disorders and alcohol
Posture tremors (e.g. with the arms raised against gravity)	Essential tremor, physiological tremor, tremor with basal ganglia disease (as in parkinsonism), cerebellar disease, peripheral neuropathy, post-traumatic and alcoholic
Resting tremors (e.g. when the hands are lying on the lap)	Parkinsonism, antipsychotic drugs, essential tremor

TOOTH DISCOLOURATION

Most causes of discolouration of several teeth are extrinsic stains. Discolouration of isolated teeth is commonly related to caries or trauma. Fluorosis, tetracyclines or congenital defects of enamel or dentine may cause brown or white intrinsic discolouration of most or all teeth; biliary atresia may cause green teeth, and erythropoietic porphyria may cause red teeth ([Table 4.9](#)).

TREMOR

Tremor is an unintentional, somewhat rhythmic, involuntary muscle movement involving to-and-fro movements (oscillations) of one or more parts of the body, most commonly affecting the hands. Tremor may also affect the arms, head, face, vocal cords, trunk and legs ([Table 4.10](#)). Caffeine (e.g. in coffee and carbonated beverages) and other stimulants should be avoided because they commonly worsen a tremor, as may emotion, stress, fever or physical exercise.

The most common form of tremor occurs in otherwise healthy people; this is essential tremor (no known cause). Tremor may also be caused by drugs (e.g. alcohol, amphetamines, caffeine, corticosteroids, ciclosporin, lithium, major tranquillizers and valproate); poisoning (e.g. mercury); neurological disorders (e.g. parkinsonism, multiple sclerosis, cerebellar disease); psychogenic reactions; or metabolic disorders (hypoglycaemia, hyperthyroidism, liver failure).

Fig. 4.9 Trismus.

TRISMUS

40–50mm from incisal edge to incisal edge is considered normal mouth opening but 3 fingers is usually a rough guide. Limited oral opening (Fig. 4.9) can arise from temporomandibular joint disorders or from extra-articular causes such as infection, submucous fibrosis or scarring, or even tetanus.

Intra-articular causes may include:

- ankylosis
 - ◆ bony ankylosis: after trauma, infections and prolonged immobilization
 - ◆ fibrous ankylosis: due to trauma and infection
- arthritis
- synovitis.

Extra-articular causes may include:

- infection
 - ◆ odontogenic
 - ◆ non-odontogenic: peritonsillar abscess, tetanus, meningitis, brain abscess, parotid abscess.

URINARY INCONTINENCE

Urinary incontinence is an inability to hold urine until a lavatory is reached. It results from an underlying medical condition and is often only temporary. Women, particularly older women, experience incontinence twice as often as men because of problems associated with pregnancy and childbirth, and the menopause. Both women and men can become incontinent from neurological injury, birth defects, strokes, multiple sclerosis and physical problems associated with ageing.

Stress incontinence results from physical changes from pregnancy, childbirth and the menopause, and causes incontinence when coughing, laughing, sneezing or other movements that put pressure on the bladder.

Urge incontinence is caused by inappropriate bladder contractions, which result from overactive nervous control of the bladder. Urine is lost for no apparent reason while suddenly feeling the need or urge to urinate. Urge incontinence can mean that the bladder empties during sleep, after drinking a small amount of water, or when touching water or hearing it running (as when washing dishes or hearing someone else taking a shower). Involuntary actions of bladder muscles can occur due to damage to the nerves of the bladder, to the nervous system (spinal cord and brain), or to the muscles themselves as in multiple sclerosis, Parkinson disease, Alzheimer disease, stroke and injury.

Functional incontinence appears in people who have problems thinking, moving or communicating that prevent them from reaching a lavatory fast enough, as in Alzheimer disease. A person in a wheelchair may be blocked from getting to a lavatory in time.

Overflow incontinence is seen when the bladder is always full because of weak bladder muscles or a blocked urethra (e.g. prostatic disease), so that it leaks urine frequently. Nerve damage from diabetes or other diseases can lead to weak bladder muscles; tumours and urinary stones can block the urethra.

VERTIGO

See 'Dizziness'.

VISUAL IMPAIRMENT

Visual impairment may be suspected if a patient has overcautious driving habits; finds lighting either too bright or too dim; has frequent spectacle prescription changes; holds books or reading material close to the face or at arm's length; squints or tilts the head to see; has difficulty in recognizing people; changes leisure-time activities, personal appearance or table etiquette; moves about cautiously or bumps into objects; or acts confusedly or is disoriented.

Visual impairment can have a range of causes, from disease of the lens such as cataract, to albinism, glaucoma, retinitis pigmentosa, retinal detachment or nerve lesions. Blindness or defects of visual fields can be caused by ocular, optic nerve or cortical damage, but the type of defect varies according to the site and extent of the lesion. A complete lesion of one optic nerve causes that eye to be totally blind. There is no direct reaction of the pupil to light (loss of constriction) and, if a light is shone into the affected eye, the pupil of the unaffected eye also fails to respond (loss of the consensual reflex). However, the nerves to the affected eye that are responsible for pupil constriction run in the third cranial nerve and should be intact. If, therefore, a light is shone into the *unaffected eye*, the pupil of the affected eye also constricts, even though that eye is sightless.

Lesions of the optic tract, chiasma, radiation or optic cortex cause various visual field defects involving both visual fields but without total field loss on either side.

Visual field examination (perimetry) tests the total area where objects can be seen in the peripheral vision while the eye is focused on a central point. Confrontation visual field examination is a quick and basic evaluation of the visual field done by an examiner sitting directly in front of the patient, who is asked to look at the examiner's eye and say when they can see the examiner's hand. Tangent screen examination involves the patient looking at a central target and telling the examiner when an object brought into the peripheral vision can be seen.

Automated perimetry is when the patient sits in front of a computer-driven program that flashes small lights at different locations, and presses a button whenever the lights in the peripheral vision are seen. An ophthalmological opinion should always be obtained if there is any suggestion of a visual field defect.

Vision is tested by visual acuity testing using the Snellen eye chart or another standard eye chart. This displays a series of letters or letters and numbers, with the largest at the top. As the person being tested reads down the chart, the letters gradually become smaller. When visual acuity is being checked, one eye is covered at a time and the vision of each eye is recorded separately, as well as both eyes together. Normal vision is 20/20, which means that the eye being tested can read

Fig. 4.10 Complete blindness: an opaque eye.

a letter of a certain size when it is 20 feet away. If a person sees 20/40, then at 20 feet from the chart that person can read letters that a person with 20/20 vision could read from 40 feet away. The 20/40 letters are twice the size of 20/20 letters; however, if 20/20 is considered 100% visual efficiency, 20/40 visual acuity is 85% efficient. For people who have worse than 20/400 vision, a different eye chart can be used. It is common to record vision worse than 20/400 as count fingers (CF at a certain number of feet), hand motion (HM at a certain number of feet), light perception (LP) or no light perception (NLP). As for legal blindness, in the UK the statutory definition of 'blind' is 'so blind as to be unable to perform any work for which eyesight is essential' (the Blind Persons Act 1920). There is no statutory definition of 'partial sight', although the guideline is 'substantially and permanently handicapped by defective vision caused by congenital defect, illness, or injury' (the National Assistance Act 1948).

After the pupils have been dilated, direct *ophthalmoscopy/funduscopy* provides a wider magnified view of the retina. *Tonometry* measures pressure inside the eye and is one of several tests necessary to detect glaucoma. *Slit-lamp examination* allows examination of the front of the eye. *Phoroptery* detects refractive errors.

Visual impairment can vary from limitations in sight for distance, colour, size or shape to full blindness (Fig. 4.10). It is an important disability that invariably restricts activity to some degree. Most visual impairment is caused by disease or malnutrition. The main causes include:

- cataracts
- glaucoma
- uveitis
- age-related macular degeneration (ARMD)
- trachoma
- corneal opacity
- diabetic retinopathy.

Cataracts, the most common cause of visual impairment in older people, are lens opacities that are more common in diabetes or after excess exposure to sunlight, ionizing irradiation or corticosteroids.

Visual defects are also among the most common genetic disorders, and congenital blindness may be associated with other handicaps such as epilepsy.

Clearly, communication is best verbally, though, for the partially sighted, writing matter can sometimes be used but must be in large, bold, black type on a white background.

Adaptive technology that may help includes adaptations around the home, as well as large-print books, books on tape and in Braille, and low-vision and blindness-related products.

Fig. 4.11 Vitiligo (see also Fig. 2.25).

Fig. 4.12 Xanthelasma.

VITILIGO

Vitiligo is loss of skin pigmentation (Fig. 4.11), which can be dramatically unaesthetic. It is usually an autoimmune disorder.

WEIGHT LOSS

Involuntary weight loss is a non-specific finding but is of concern. Causes, apart from malnutrition, are diabetes, hyperthyroidism, eating disorders, cancer (e.g. lung, gastrointestinal), infections (e.g. HIV disease, tuberculosis), depression and drugs.

WHITE LESIONS IN THE MOUTH

Most white oral lesions are due to local causes, such as keratoses caused by irritation, or idiopathic leukoplakia. Rare congenital causes include white sponge naevus (can involve the vagina and anus), dyskeratosis congenita and pachyonychia congenita.

Candidosis may cause white or red lesions (Ch. 21). Lichen planus and lupus erythematosus are discussed in Chapter 11. Cancer may present as a white lesion.

XANTHELASMA

These are flat yellow plaques over the upper or lower eyelids, most often near the inner canthus (Fig. 4.12). They are areas of lipid-containing

macrophages; the presence of xanthelasma and corneal arcus indicates a higher risk of developing ischaemic heart disease and, though xanthelasma also have other causes, patients should have fasting lipid levels checked and those with hyperlipidaemia should have a formal cardiac assessment.

KEY POINTS

- Ischaemic heart disease is common and potentially fatal
- Stress and anxiety can precipitate cardiac events

The heart is vital to life, as its essential function is pumping oxygenated blood to the brain and vital organs. Blood is oxygenated in the lungs and travels in the pulmonary vein to the heart at the left atrium, from where it flows to the left ventricle through the mitral valve. Blood leaves the left ventricle through the aortic valve to the aorta (the body's main artery) and is distributed via arteries throughout the body. Thus the left ventricle is the most powerful chamber, as it has to move blood all around the body. Oxygen is transported on the red blood-cell (erythrocyte) pigment haemoglobin, which colours the blood red. Arteries branch to arterioles and then to capillaries to transport oxygen to the tissues (Fig. 5.1) and collect waste carbon dioxide. A vast venous network collects deoxygenated blood from all the tissues and returns it to the superior vena cava and inferior vena cava and thence to the right atrium of the heart (Fig. 5.2). This blood flows through the tricuspid valve to the right ventricle and then leaves the right ventricle

through the pulmonary valve to the pulmonary artery and thence to the lungs, where it takes up oxygen. The heart thus consists of four chambers: two ventricles and two atria. It is centrally located in the chest (thorax) but, because the left ventricle is larger, the heart beat (apex beat) is found to the left side (Fig. 5.3).

The heart rate and force of contraction are controlled by nerves (mainly vagus and sympathetic) and hormones (especially adrenaline [epinephrine], which increases both rate and force). Anxiety and exercise can increase the pulse rate and force of the heart beat.

Heart disease is a major killer; in the USA, possibly one person dies from heart disease every 30 seconds. It also causes significant morbidity and disability in many aspects of life, including effects on entitlement to drive a motor vehicle. There is a wide range of disorders that can affect the heart (Box 5.1).

CONGENITAL HEART DISEASE (CHD)

General aspects

Congenital heart defects are the most common type of heart problem in children, present in about 1% of live births. Lesions may involve the

Fig. 5.1 Major arteries.

Fig. 5.2 Major veins.

Fig. 5.3 Cardiac anatomy.

Box 5.1 Causes of cardiovascular disease

Organic heart disease

- Myocardial
 - Overload secondary to hypertension or valve disease^a
 - Coronary (ischaemic) heart disease^a
 - Cardiomyopathies
- Endocardial
 - Rheumatic heart disease
 - Congenital anomalies^a
 - Infective endocarditis
- Pericardial
 - Pericarditis
 - Pericardial effusion

Functional disorders

- Due to hypertension^a
- Due to abnormalities in heart rate
 - Tachycardias
 - Bradycardias
 - Other arrhythmias
- Changes in circulatory volume
 - Hypervolaemia (shock syndrome)
 - Hypervolaemia (circulatory overload)
 - Others

^aCommon causes of heart failure.

heart or adjacent great vessels, in isolation or in a variety of combinations, and include a wide variety of structural defects that can lead to malfunction such as arrhythmias or flow problems. Vessel or valve stenosis or obstruction and septal defects strain the myocardium.

The types of CHD are summarized in Table 5.1. CHD may be: cyanotic (‘blue babies’), where there is right-to-left shunting – in general these are more severe defects; or acyanotic. Cyanosis and hypoxia can lead to neurological deficits, polycythaemia (with hypercoagulability and thromboses) and systemic infections (e.g. brain abscess). Approximately 20% of patients with CHD also have other congenital anomalies.

The cause of CHD is often unidentified but some causes are genetic (e.g. Down syndrome; see Ch. 28). There are many other causes (Table 5.2;

Table 5.1 Types of congenital heart disease^a

Cyanotic	Acyanotic	
	With no shunt	With left-to-right shunt
Eisenmenger syndrome	Aortic stenosis (AS)	Atrial septal defect (ASD)
Fallot tetralogy	Bicuspid aortic valve	Patent ductus arteriosus (PDA)
Pulmonary atresia (PA)	Coarctation of the aorta	Ventricular septal defect (VSD)
Pulmonary valve stenosis	Dextrocardia	
Total anomalous venous drainage (TAVD)	Mitral valve prolapse	
Transposition of the great vessels		
Tricuspid atresia (TA)		

^aSee also Table 5.2.

Appendices 5.1 and 5.2) and syndromes (e.g. oesophageal atresia and heart disease, and forearm/digit abnormalities and atrial septal defect [ASD]). The main acquired causes of CHD are maternal infections such as TORCH – congenital *toxoplasmosis*, *rubella*, *cytomegalovirus* or *herpes* infection – which can lead to patent ductus arteriosus (PDA), pulmonary stenosis, ventricular septal defect (VSD) and coarctation of the aorta; maternal drug use (e.g. alcohol, anticonvulsants, lithium, recreational drugs, thalidomide and warfarin); or maternal systemic disease (systemic lupus erythematosus and Sjögren syndrome [both can cause heart block], and diabetes [which is associated with an increased incidence of VSD, coarctation and transposition of the great arteries and/or a characteristic hypertrophic cardiomyopathy]); and, rarely, maternal irradiation.

Clinical features

Cyanotic CHD is, in general, a much more severe defect than acyanotic (Fig. 5.4), which can lead to cardiac failure or be life-threatening or fatal without surgical intervention. In the absence of treatment, 40% of children with cyanotic CHD die within the first 5 years. Cyanosis (caused by >5 g of reduced haemoglobin per decilitre of blood) results from shunting deoxygenated blood from the right ventricle into the left side of the heart and the systemic circulation (*right-to-left shunt*), and leads to chronic hypoxaemia (Fig. 5.5). Patients may crouch in an effort to improve venous return but eventually polycythaemia develops – with consequent haemorrhagic or thrombotic tendencies. Finger- and toe-clubbing are associated with cyanotic CHD, but appear after about 3 months of age (Fig. 5.6). Patients with CHD are liable to a range of complications (Box 5.2).

Pulmonary hypertension and, eventually, right ventricular hypertrophy may be seen where the shunt is *left-to-right* and some of the output of the left ventricle is recirculated through the lungs. The shunt may eventually reverse and then cyanosis develops.

General management

An obstetric ultrasound scan is often used to screen pregnant women at around 20 weeks for signs of CHD in their unborn babies. Most defects, however, are well tolerated *in utero* and it is only after birth that the impact of the anatomical and subsequently haemodynamic abnormality becomes evident. In young children, chest radiography may show cardiomegaly. Electrocardiography (ECG) may

Table 5.2 Main features of congenital heart disease (CHD)

CHD	Main pathology/location	Main features
Aortic stenosis	Narrowing of the aortic valve	Angina, dyspnoea and syncope. Balloon valvuloplasty or surgery may be indicated
Atrial septal defect (ASD)	Usually near foramen ovale and termed a secundum defect. Associated in 10–20% with mitral valve prolapse	Initially acyanotic, with survival into middle age in most cases, and therefore is the most common CHD presenting in adults. In the absence of surgical correction, right ventricular failure eventually develops. Usually repaired by primary closure or by pericardial or Dacron patch
Bicuspid aortic valve	Valve is bicuspid instead of tricuspid. Often associated with other left-sided lesions (e.g. coarctation of the aorta or interrupted aortic arch)	Usually asymptomatic, even in athletes, but there is a high risk of infective endocarditis
Coarctation of the aorta	In the aorta beyond the origin of the subclavian arteries	Normal blood supply to the head, neck and upper body but restricted to the lower body. Surgery is indicated
Dextrocardia	Right-sided heart	Usually asymptomatic but may be part of situs inversus (all organs transposed) with bronchiectasis and sinusitis (Kartagener syndrome)
Ebstein anomaly	Congenital abnormality of the tricuspid valve, usually associated with ASD	Ebstein anomaly is mild in most and surgery is needed only if the tricuspid valve leaks severely enough to result in heart failure or cyanosis
Eisenmenger syndrome or reaction	The process in which a left-to-right shunt in the heart causes increased flow through the pulmonary vasculature (and pulmonary hypertension) which, in turn, causes increased pressures in the right heart and reversal into a right-to-left shunt	Ventricular or atrial septal defects, patent ductus arteriosus and more complex types of acyanotic heart disease can underlie this. Initially there is pulmonary hypertension, polycythaemia and a hyperviscosity syndrome with haemorrhagic and thrombotic tendencies. Later there is right ventricular hypertrophy and cyanosis. Anticoagulants and pulmonary vasodilators (e.g. bosentan) may be indicated
Fallot tetralogy	Ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy and an aorta that overrides both ventricles. Fluconazole use in pregnancy may predispose	Cyanosis progressive from birth. Chronic hypoxia causes decreased neurological function. Episodes of acute hypoxia from infundibular spasm are life-threatening. Polycythaemia causes hypercoagulability and thrombosis. Right-to-left shunting is associated with a higher incidence of systemic infection such as a brain abscess. Surgery is indicated
Mitral valve prolapse (floppy mitral valve; Barlow syndrome)	The most common CHD, affecting 5–10% of the population. Seen mainly in women. Strong hereditary tendency. Seen especially in Marfan, Ehlers–Danlos and Down syndromes. May be associated with polycystic kidney disease and panic disorder	May cause no symptoms but, if there is mitral regurgitation, some patients develop pain, irregular or racing pulse, or fatigue and heart failure
Patent ductus arteriosus (PDA)	A persistent opening (normally closed by the third month of life) between aorta and pulmonary artery, common in prematurity and maternal rubella	Shunt is left to right, initially acyanotic, and a typical complication is right ventricular failure. Closure can be promoted in early infancy by giving intravenous indometacin, a prostaglandin inhibitor
Patent foramen ovale	Communication between atria	Often symptomless
Pulmonary atresia	No pulmonary valve exists, so blood cannot flow from the right ventricle into the pulmonary artery and to the lungs. The right ventricle is not well developed. The tricuspid valve is often poorly developed. An ASD allows blood to exit the right atrium, so the baby is cyanotic. The only source of lung blood flow is the PDA	Early treatment often includes using a drug to keep the PDA from closing, and surgery to create a shunt between the aorta and the pulmonary artery
Pulmonary stenosis	Narrowing of the pulmonary valve	Symptoms are breathlessness and right ventricular failure. Balloon valvuloplasty or surgery may be indicated
Total anomalous pulmonary venous return (TAPVR)	Blood returns from the lungs to the right rather than left atrium	Survivors also have ASD or patent foramen ovale
Transposition of the great vessels	Reversal of pulmonary artery and aorta origins	Cyanosis and breathlessness from birth, with early congestive cardiac failure and death in infancy unless there are associated defects providing sufficient collateral circulation (such as a patent interventricular septum or PDA)
Tricuspid atresia	Absence of the tricuspid valve means no blood can flow from the right atrium to the right ventricle. Thus the right ventricle is small. Survival depends on there being an ASD and usually a ventricular septal defect	A surgical shunting procedure is often needed to increase the lung blood flow and reduce cyanosis. Some children may need pulmonary artery banding to reduce blood flow to the lungs. Others may need a more functional repair (Fontan procedure)
Ventricular septal defect (VSD)	One of the most common CHDs. Ranges from a pinhole compatible with survival at least into middle age, to a large defect causing death in infancy if untreated. Some 90% of children with VSD have an additional cardiac defect	Initially left-to-right shunt but, with right ventricular hypertrophy, shunt may eventually reverse with late-onset cyanosis. Right ventricular failure may develop. Usually repaired by primary closure or by a pericardial or Dacron patch

Fig. 5.4 Central cyanosis in a child with a congenital heart defect, showing purple lips and gingivae.

Fig. 5.5 Chest radiograph of a child with congenital heart disease showing gross cardiac enlargement. (The heart normally occupies less than half the width of the chest).

Fig. 5.6 Finger-clubbing in a patient with Fallot tetralogy. Finger-clubbing can be found in several different disorders, particularly cyanotic heart disease, chronic respiratory disease, lung cancer, Crohn disease, etc., but is sometimes benign and hereditary.

Box 5.2 Possible complications in congenital heart disease

- Bleeding tendency
- Cardiac failure
- Cyanosis
- Fatigue
- Growth retardation
- Infections (e.g. brain abscess, endocarditis)
- Polycythaemia
- Pulmonary oedema

demonstrate an abnormal cardiac axis, ventricular hypertrophy and strain, depending on the lesion present. CHD is more commonly diagnosed through echocardiography, which has superseded intracardiac catheter studies, and confirmed by cardiac magnetic resonance imaging (MRI).

Early correction of the congenital defect, often by transvenous catheter techniques, is the treatment of choice. More complex defects may require an operation. Medical treatment may be needed for the management of pulmonary oedema, heart failure, polycythaemia, infection or emotional disturbances. Modern surgical and medical care helps children survive into adult life and patients are then often said to have adult or 'grown-up' CHD. Nevertheless, complications observed in adults who were previously thought to have had successful repair of CHD include arrhythmias, valve disorders and cardiac failure, and residual defects can still predispose to complications such as infective endocarditis.

Dental aspects

All dental health-care professionals (HCPs) should be certified in basic cardiopulmonary resuscitation (CPR), and the entire team should rehearse emergency protocol procedures regularly (Ch. 1).

Patients with heart disease should take their medications as usual on the day of the dental procedure, and should bring all their medications to the dental surgery for review at the time of the first appointment. The most important aspect for dentists to consider is how well the patient's heart condition is compensated. Patients with stable heart disease receiving atraumatic treatment under local anaesthesia (LA) can receive treatment in the dental surgery. Since cardiac events are most likely to occur in the early morning, patients with cardiac disease should be treated in the late morning or early afternoon. The dental team should provide dental care with a stress-reduction protocol and with good analgesia, limiting the dosage of adrenaline (epinephrine). An aspirating syringe should be used to give an LA, since adrenaline in the anaesthetic entering a vessel may theoretically raise the BP or precipitate arrhythmias. Gingival retraction cords containing adrenaline should be avoided. Conscious sedation, preferably with nitrous oxide, can be given with the approval of the physician. General anaesthesia (GA) is a matter for expert anaesthetists in hospital.

Congestive cardiac failure may complicate management. In cyanotic CHD there may also be polycythaemia-related bleeding tendencies caused by thrombocytopenia, platelet dysfunction, coagulation defects (from liver hypoxia – causing reduced vitamin K-dependent factors) and excessive fibrinolytic activity. Thus platelets may be reduced, and the haematocrit, prothrombin time (PT [and International Normal Ratio, INR]; Ch. 8) and activated partial thromboplastin time (APTT) increased. Occasionally, there is a thrombotic tendency. A special hazard in some CHD is the development of cerebral abscess, sometimes

due to oral bacteria. Leukopenia may be a factor in some right-to-left shunts. There may be susceptibility to infective endocarditis. Oral abnormalities can be associated with cyanotic CHD and may include:

- delayed eruption of both dentitions
- positional anomalies
- enamel hypoplasia – the teeth often have a bluish-white, ‘skimmed milk’ appearance and there is gross vasodilatation in the pulps
- greater caries and periodontal disease activity, probably because of poor oral hygiene and lack of dental attention
- after cardiectomy, the possible appearance of transient small, white, non-ulcerated mucosal lesions of unknown aetiology.

CONGENITAL HEART DISEASE IN OTHER SYNDROMES

Down syndrome

See Chapter 28.

Noonan syndrome

Noonan syndrome, usually an autosomal dominant trait, is characterized by CHD (the commonest cardiac lesions are pulmonary stenosis, septal defects and hypertrophic cardiomyopathy), short stature, unusual facies, chest deformity, learning disability, and cryptorchidism in males. Facial features may include an elongated mid-face, hypertelorism, retrognathia, a lower nasal bridge and nasal root, a wider mouth, a more prominent upper lip and low-set ears. Abnormal vision and hearing are common. Other associations include hepatosplenomegaly and an abnormal bleeding tendency associated with low levels of clotting factors (particularly XI and XII), and with cherubism, jaw giant-cell lesions and neurofibromatosis.

Hypercalcaemia–supravalvular aortic stenosis syndrome (Williams syndrome)

Williams syndrome comprises, in its rare complete form, infantile hypercalcaemia, elfin facies, learning disability and CHD. Most cases appear to be sporadic. These children may be sociable and talkative (‘cocktail party manner’). Hypercalcaemia typically remits in infancy but leaves growth deficiency, osteosclerosis and cranio-stenosis. Cardiovascular lesions include supravalvular subaortic stenosis or other abnormalities, and may contraindicate GA. Also, masseter spasm has been reported during GA with halothane and suxamethonium, but it is not malignant hyperthermia. Dental defects may include hypodontia, microdontia and hypoplastic, bud-shaped teeth. The upper dental arch may be disproportionately wide and overlap the lower.

ACQUIRED HEART DISEASE

General aspects

Most acquired heart disease is ischaemic heart disease (IHD; coronary artery disease, CAD) – the most important cardiac disease, which can lead to heart failure and is the major killer in the high-income world. Functional disorders, where there is no organic disease of the heart itself, can also cause circulatory failure, as in shock. A variety of common extracardiac diseases can aggravate heart disease, particularly if there is impaired oxygenation, as in severe anaemia.

Clinical features

Serious heart disease is not always symptomatic and patients can die suddenly from myocardial infarction (MI), despite having experienced neither chest pain nor any other symptom (‘silent infarction’). Also, many patients with manifest cardiac disease can have signs and symptoms effectively controlled so that they may superficially appear well and, often, only the drug history gives a clue to the nature of any cardiac illness. Common clinical features of cardiac disease include breathlessness, chest pain, palpitations and cyanosis, while signs may be seen on the hands (clubbing, cyanosis) or deduced from measuring the BP, palpating the pulse or listening to the heart (auscultation).

General management

The heart rate, force of contraction and rhythm can be assessed from palpation of the pulse; disturbances of rhythm may signify cardiac disease.

The BP is measured by sphygmomanometry. The finding of either normal levels (pressures of 120 mmHg systolic and 80 mmHg diastolic) or grossly raised levels (>160/90 mmHg for a male of 45 years or over) is informative. However, these must be checked on further occasions, as the BP frequently increases in anxiety. In an injured patient, a falling BP is also a danger sign that must not be ignored, since it implies a serious complication such as haemorrhage or shock.

Experienced cardiologists can identify by auscultation the vast majority of innocent functional murmurs and can differentiate these from the serious murmurs of aortic stenosis, mitral regurgitation, tricuspid regurgitation, pulmonary stenosis, VSD and hypertrophic cardiomyopathy.

Other investigations include blood assays of cardiac enzymes (troponin, troponin T (cTnT), creatine kinase), which are raised after cardiac damage such as an MI. Chest radiography (CXR) helps detect heart enlargement (e.g. in cardiac failure or hypertension). ECG, invaluable for the diagnosis of arrhythmias and of IHD, is a graphic tracing of the variations in electrical potential caused by the excitation of the atria (Fig. 5.7). The QRS deflections are due to excitation (depolarization) of the ventricles. The T wave is due to recovery of the ventricles (repolarization). Doppler echocardiography (cardiac ultrasonography done trans-thoracically or trans-oesophageally) is a valuable non-invasive imaging tool for the heart; it is helpful in establishing a specific diagnosis and estimating the severity of various diseases by evaluating cardiac chamber size, wall thickness, wall motion, valve configuration

Fig. 5.7 Normal ECG tracing.

Table 5.3 Predictors of high cardiovascular risk

Very high risk	Medium risk	Low risk
MI in previous month	Mild angina	Old age
Unstable or severe angina	Myocardial infarction (MI) more than 1 month previously	ECG abnormalities only
Atrioventricular block		Atrial fibrillation
Ventricular arrhythmias	Compensated heart failure	Stroke
Severe cardiac valvular disease		Uncontrolled hypertension
Advanced heart failure		Mild heart failure

and motion, and the proximal great vessels. This technique also provides a sensitive method for detecting pericardial and pleural fluid accumulation, and can allow identification of mass lesions within and adjacent to the heart. Cardiac MRI, scans using gadolinium, thallium-201 or technetium-99, and positron emission tomography (PET) using 18F-deoxyglucose (FDG) are also extremely useful.

Medical treatments are available to control many cardiac disorders, but surgery may be required, especially for IHD.

Dental aspects

Management implications in oral health care depend mainly on the type of intervention and the degree of cardiovascular risk (Table 5.3 and see below). Both the anxiety and the pain that may be associated with dental care can cause enhanced sympathetic activity and adrenaline (epinephrine) release, which increases the load on the heart and the risk of angina or arrhythmias. Therefore, patients with unstable angina (pain pattern changing in occurrence, frequency, intensity or duration; pain at rest) and those with MI <3 months previously should have dental treatment in a hospital environment. Patients with stable angina and those who are at least 3 months post-MI may be treated in primary care. However, appointments should be made for the late morning, with the patient's glyceryl trinitrate (GTN) available and used preoperatively, and the use of pulse oximetry and prophylactic sedatives considered. Nitrate drugs, which include glyceryl trinitrate (GTN), isosorbide dinitrate and isosorbide mononitrate are vasodilators and act by reducing load on the heart. GTN is available for sublingual use as a tablet or a spray, or as a skin patch. Tables have a limited shelf life of about 8 weeks. Oral use works within a minute or so and lasts 30 mins but the patch takes about an hour to work and is often left on for 12 hours. The most common adverse effects of nitrates are a throbbing headache, flushing, and dizziness, and they interfere with sildenafil. Pain control is crucial to minimize endogenous adrenaline release. LA must be given with aspiration and it may be prudent to avoid adrenaline-containing LA. If a patient is taking a non-selective beta-blocker (e.g. propranolol), no more than two carpules of LA with adrenaline 1:80 000 should be administered. The combination of aspirin with other antiplatelet drugs increases the chances of significant postoperative bleeding. Furthermore, drugs such as erythromycin and clarithromycin should be avoided in long QT syndrome and in patients also taking statins (antihyperlipidaemics). In the case of intraoperative chest pain, medical assistance should be summoned and emergency management commenced, including the use of GTN aspirin and oxygen. Cardiac monitoring is desirable in many instances (Figs 5.8 and 5.9).

Fig. 5.8 Cardiac monitoring – chest leads.

Fig. 5.9 Cardiac monitoring – arm lead.

Effective painless LA is essential. An aspirating syringe should be used since adrenaline in the anaesthetic may get into the blood and may (theoretically) raise the BP and precipitate arrhythmias. BP tends to rise during oral surgery under LA, and adrenaline theoretically can contribute, but this is usually of little practical importance. However, adrenaline-containing LA should not be given in excessive doses to patients taking beta-blockers, as this may induce hypertension and cardiovascular complications. *Note:* A woman on beta-blockers, who was (inexcusably) given 16 dental cartridges of LA, died from lidocaine overdose, *not* from accelerated hypertension. Gingival retraction cords containing adrenaline should be avoided wherever possible. General anaesthesia for dental care in cardiac patients should be avoided unless essential.

A range of cardiovascular drugs can influence oral health care (Table 5.4), while drugs used in dentistry can interact with cardiac drugs. Aspirin may cause sodium and fluid retention, which may be contraindicated in severe hypertension or cardiac failure. Indometacin may interfere with antihypertensive agents. Macrolides and azoles may cause statins to produce increased muscle damage.

An association between periodontal disease and cardiovascular disease has been suggested but several evidence-based reviews question this association.

Table 5.4 Cardiovascular drugs: potential effects on oral health care

Group	Oral adverse effects	Possible interaction or reaction
Alpha-blockers	Dry mouth	Orthostatic hypotension
Alpha-/beta-blockers	–	Enhanced pressor response to adrenaline (epinephrine)
Angiotensin-converting enzyme inhibitors (ACEIs)	Burning sensation Ulceration Taste changes Dry mouth Angioedema Lichenoid reactions	Impairment by indometacin
Angiotensin II receptor blockers (ARBs)	Facial flushing Taste disturbance Dry mouth Increased gag reflex Lupoid reactions	Good toleration
Antihypertensives (see Table 5.8)	Predisposition to lip cancer (hydrochlorothiazide, nifedipine, triamterene, lisinopril, atenolol)	Photosensitivity
Antiplatelets	Purpura Bleeding	Bleeding tendency enhanced by erythromycin
Beta-blockers (non-cardioselective)	Dry mouth Paraesthesia Lichenoid lesions	Enhanced pressor response to adrenaline (epinephrine)
Calcium-channel blockers (CCBs)	Gingival swelling: 30% using nifedipine develop this Angioedema	–
Digitalis glycosides	Dry mouth	Possible induction of arrhythmias by LA vasoconstrictor Gag reflex increased
Diuretics	Dry mouth	–
Potassium-channel blockers	Ulceration	–
Statins	–	Muscle damage increased by macrolides (erythromycin, clarithromycin, telithromycin) and azoles (fluconazole, itraconazole, ketoconazole, miconazole) but rosuvastatin, pravastatin and fluvastatin do not appear to have this problem

Box 5.3 Manual technique for recording blood pressure

1. Ask patient to avoid alcohol and smoking for 30 min before measurement
2. Allow patient to sit at rest for as long as possible
3. Place sphygmomanometer cuff on right upper arm with about 3 cm of skin visible at antecubital fossa; bladder should encircle at least two-thirds of arm
4. Palpate right brachial pulse
5. After 5 min, inflate cuff slowly to about 200–250 mmHg, or until pulse is no longer palpable
6. Deflate cuff slowly while listening with stethoscope over brachial artery over skin on inside of arm below cuff
7. Record systolic pressure as pressure when first tapping sounds appear (Korotkoff sounds)
8. Deflate cuff further until tapping sounds become muffled (diastolic pressure) and then disappear
9. Repeat; record BP as systolic/diastolic pressures

a progressive rise in BP. Untreated hypertension is one of the most important preventable causes of morbidity and mortality, since it is a major risk factor for ischaemic and haemorrhagic strokes (cerebrovascular events), myocardial infarction, heart failure, chronic kidney disease, cognitive decline and premature death. The risk associated with increasing BP is continuous, with each 2 mmHg rise in systolic BP linked with a 7% rise in risk of mortality from ischaemic heart disease and a 10% increased risk of mortality from stroke. The vascular and renal damage that hypertension may cause can culminate in a treatment-resistant state. The BP is the product of cardiac output and peripheral resistance, and is dependent on the heart and vasculature, autonomic nervous system, endocrine system and kidneys. Regulatory mechanisms, though unclear, involve baroreceptors in various organs that detect changes in BP, and adjust it by altering both the heart rate and the force of contractions, as well as the peripheral resistance. Other factors are the kidney renin–angiotensin system, which responds to a fall in BP by activating a vasoconstrictor (angiotensin II), and the adrenocortical release of aldosterone in response to angiotensin II, causing fluid retention via the kidney – increasing sodium retention and potassium excretion. The most potent vasoconstrictor is endothelin-1, released by vascular endothelium in response to expansion of plasma volume, hypoxia or growth factors, and which regulates vascular tone. Nitric oxide (NO) also modulates vasodilator tone in the control of BP.

The BP will vary, depending on age, gender, ethnicity, environment, emotional state and activity. Since it rises with anxiety, measurements should be made with the patient relaxed and fully at rest. The BP is lowest at night and highest first thing in the morning. It tends to increase with age.

If the clinic BP is 140/90 mmHg or higher, ambulatory blood pressure monitoring (ABPM) is needed to confirm the diagnosis of hypertension (average value of at least 14 measurements taken during the person's usual waking hours). Home BP monitoring (HBPM) can be used to confirm a diagnosis of hypertension, provided that:

- for each BP recording, two consecutive measurements are taken, at least 1 minute apart and with the person seated
- BP is recorded twice daily, ideally in the morning and evening
- BP recording continues for at least 4 days, and ideally for 7 days.

Hypertension is a persistently raised BP. There is no agreed BP cut-off point above which 'hypertension' exists and below which it does not. At least one-quarter of adults (and more than half of those older

HYPERTENSION

General aspects

Hypertension (high blood pressure) is common, often unrecognised and potentially lethal. The blood pressure is measured with a sphygmomanometer (Box 5.3), in units of millimetres of mercury (mmHg). A 'normal' adult blood pressure (BP) is 120/80 (systolic/diastolic) mmHg. High blood pressure (hypertension) is usually associated with

Table 5.5 Blood pressure levels

Stage	Designation	Level
Normal		Systolic: less than 120 mmHg Diastolic: less than 80 mmHg
At risk	Pre-hypertension	Systolic: 120–139 mmHg Diastolic: 80–89 mmHg
Stage 1	Hypertension	Systolic: 140/90 mmHg or higher and subsequent ambulatory monitoring (ABPM) daytime average or home monitoring (HBPM) average is 135/85 mmHg or higher
Stage 2	Hypertension	Systolic: 160/100 mmHg or higher and subsequent ABPM daytime average or HBPM average is 150/95 mmHg or higher
Severe	Hypertension	Systolic: 180 mmHg or higher Diastolic: 110 mmHg or higher

Table 5.6 American Society of Anesthesiologists (ASA) grading of hypertension and dental management considerations

Blood pressure (mmHg; systolic, diastolic)	ASA grade	Hypertension stage	Dental aspects
<140, <90	I	–	Routine dental care
140–159, 90–99	II	1	Recheck BP before starting routine dental care
160–179, 95–109	III	2	Recheck BP and seek medical advice before routine dental care Restrict use of adrenaline (epinephrine) Conscious sedation may help
>180, >110	IV	3	Recheck BP after 5 min quiet rest Medical advice before dental care Only emergency care until BP controlled Avoid vasoconstrictors

than 60) have high BP. Hypertension is thus common, especially with advancing age, when systolic hypertension becomes a more significant problem, as a result of the progressive stiffening and loss of compliance of larger arteries. Diastolic pressure is more commonly raised in people younger than 50 years (Table 5.5). Hypertension nevertheless is generally defined as a BP of at least 140/90 mmHg, based on at least two readings on separate occasions. Indeed, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure defined a BP of 120/80–139/89 mmHg as pre-hypertension – a designation chosen to identify individuals at high risk of developing hypertension. The National Heart, Lung and Blood Institute (NHLBI) has even recommended that ‘pre-hypertension’ should be considered as beginning when BP is 115/75 mmHg. Hypertension may be staged as shown in Tables 5.5 and 5.6.

Some 40% of adults in the developed world have hypertension but in more than 90% the cause is unknown; this is termed ‘primary’, ‘idiopathic’ or ‘essential’ hypertension. In 1–2% of hypertensive patients, an identifiable cause is present and this is termed ‘secondary’ hypertension. Aetiological factors are shown in Table 5.7. Lifestyle factors that can raise the BP include stress, obesity, salt intake, smoking,

Table 5.7 Causes of hypertension

Secondary hypertension	Idiopathic (essential) hypertension
Renal disease (80% of cases) – renal artery disease, pyelonephritis, glomerulonephritis, polycystic disease, post-transplant	Genetic predisposition
Endocrine conditions – pregnancy, Cushing syndrome and corticosteroid therapy, hyperaldosteronism, pheochromocytoma, acromegaly	High alcohol intake
Cerebral disease – cerebral oedema (mainly strokes, head injuries or tumours)	High salt intake (possibly)
Coarctation of aorta – hypertension in upper half of body only	High basal metabolic index (BMI)
Drugs – oral contraceptive pill, corticosteroids, non-steroidal anti-inflammatory drugs (NSAIDs), liquorice	Insulin resistance
Sleep apnoea	Sympathetic overactivity: 40% of hypertensive patients have raised catecholamines (adrenaline [epinephrine] and noradrenaline [norepinephrine])

Table 5.8 Lifestyle risk factors modifying hypertension

Factors raising blood pressure	Factors lowering blood pressure
Obesity	No obesity
High dietary salt intake	Low salt intake
Excess alcohol	Low alcohol intake
Smoking	Stopping smoking
Excessive physical inactivity	Physical activity
Stress/anxiety	Relaxation
	High-fibre diet
	Omega-3 fatty acids possibly
	Fruit and vegetables
	Supplemental potassium

alcohol, illicit drugs (cocaine, amphetamines) or prescribed drugs (e.g. immunosuppressives, glucocorticoids, mineralocorticoids, anabolic steroids), but other factors can lower the BP (Table 5.8).

Clinical features

At least one-third of people with hypertension are asymptomatic or have only trivial complications, such as epistaxes. Hypertension can affect many tissues, however, and especially the brain, heart, eyes and kidneys, with complications that include coronary artery disease, myocardial infarction, heart failure and cerebrovascular events in particular (Table 5.9). Long-standing hypertension accelerates atheroma and predisposes to: coronary artery disease; cerebrovascular disease; chronic kidney disease (hypertensive nephrosclerosis is the term given to long-term essential hypertension, hypertensive retinopathy, left ventricular hypertrophy, minimal proteinuria and progressive renal insufficiency); peripheral vascular disease; and hypertensive retinopathy leading to retinal haemorrhages, retinopathy or optic neuropathy and blindness. Hypertension shortens life by 10–20 years. The risk of these sequelae is greater in people who also have diabetes and cardiac or renal disease.

General management

The National Institute for Health and Care Excellence (NICE)’s clinical guideline 127, *Hypertension: clinical management of primary*

Table 5.9 Features of advanced hypertension

Symptoms	Signs
Headaches	Hypertension on testing
Visual disorders	Retinal changes
Tinnitus	Left ventricular hypertrophy
Dizziness	Proteinuria
Angina	Haematuria

hypertension in adults, is available at <http://publications.nice.org.uk/hypertension-cg127> (accessed 25 May 2013).

Hypertension is diagnosed by standardized serial BP measurements, as above. Investigations to identify a 'secondary' cause and assess end-organ damage include: chest radiography (cardiomegaly is suggestive of hypertensive heart disease); ECG (may indicate ischaemic heart disease); serum urea and electrolytes (deranged in hypertensive renal disease and endocrine causes of secondary hypertension); and urine Stix testing (blood and protein suggest renal disease).

Treatment of hypertension reduces the risk of stroke, heart failure and renal failure but has less effect on ischaemic cardiac events. Hypertension and its complications can be modulated by changing lifestyle (see Table 5.8) through: relaxation, weight loss, a high-fibre diet, reduction in salt intake, restriction of alcohol consumption, restriction of caffeine intake, smoking cessation and greater amounts of exercise. Acute emotion, particularly anger, fear and anxiety, can cause great rises in catecholamine output and transient rises in BP and should, therefore, be avoided or controlled.

Antihypertensive therapy is given with the goal of using the minimum dose of drugs commensurate with achieving the desired BP, and with minimal adverse effects. Therapy is urgently indicated where the systolic pressure exceeds 200 mmHg, or the diastolic 110 mmHg, and is indicated at lower levels particularly if there are vascular complications, diabetes or end-organ damage such as renal impairment. Current guidelines are to offer antihypertensive drug treatment to:

- people below 80 years of age with stage 1 hypertension (see Tables 5.5 and 5.6), who have one or more of the following:
 - ◆ Target organ damage
 - ◆ Established cardiovascular disease
 - ◆ Renal disease
 - ◆ Diabetes
 - ◆ A 10-year cardiovascular risk equivalent to 20% or greater
- people of any age with stage 2 hypertension.

A large number of antihypertensive drugs are available (Table 5.10); beta-blockers are not now a preferred initial antihypertensive therapy. Treatment is stepwise:

A BP of less than 140/90 mmHg is generally the aim. There is strong evidence to support treating hypertensive persons aged 60 years or older to a BP goal of less than 150/90 mmHg and hypertensive persons 30 through 59 years of age to a diastolic goal of less than 90 mmHg. There is moderate evidence to support starting treatment with an angiotensin-converting enzyme inhibitor, angiotensin receptor blocker, calcium channel blocker, or thiazide-type diuretic in the nonblack hypertensive population and in the black hypertensive population, initial therapy is a calcium channel blocker or thiazide-type diuretic. There is moderate evidence to support initial or add-on antihypertensive therapy with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker in persons with CKD to improve renal outcomes.

Table 5.10 Antihypertensive drugs

Antihypertensive agents	Examples
Alpha-adrenergic blockers	Doxazosin, indoramin, prazosin, terazosin
Angiotensin-converting enzyme inhibitors (ACEIs)	Captopril, cilazapril, enalapril, fosinopril, imidapril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril
Angiotensinogen II receptor blockers (ARBs)	Azilsartan, candesartan, eprosartan, losartan, olmesartan, temisartan, valsartan
Beta-adrenergic blockers	Acebutolol, atenolol, bisoprolol, carvedilol, celiprolol, esmolol, labetalol, metoprolol, nadolol, nebivolol, oxprenolol, pindolol, propranolol, timolol
Calcium-channel blockers (CCBs)	Amlodipine, diltiazem, felodipine, isradipine, lacidipine, lercanidipine, nicardipine, nifedipine, verapamil
Diuretics	Amiloride, bendroflumethiazide, bumetanide, chlortalidone, furosemide, indapamide, metolazone, spironolactone, torasemide, triamterene, xipamide
Sympatholytics	Clonidine, methyldopa
Vasodilators	Hydralazine, minoxidil

Step 1

- Offer people <55 years an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin II receptor blocker (ARB).
- Offer a calcium-channel blocker (CCB) to people aged >55 years and to people of African or Caribbean family origin of any age. If a CCB is unsuitable, or if there is evidence or a high risk of heart failure, offer a thiazide-like diuretic. If a diuretic is to be initiated or changed, offer a thiazide-like diuretic (e.g. chlortalidone or indapamide) rather than a conventional thiazide diuretic (bendroflumethiazide or hydrochlorothiazide).

Step 2

If BP is not controlled by step 1 treatment:

- offer a CCB with either an ACEI or an ARB, *but*
- if a CCB is unsuitable, or if there is evidence or a high risk of heart failure, offer a thiazide-like diuretic. For black people of African or Caribbean family origin, consider an ARB in preference to an ACEI, in combination with a CCB.

Step 3

If step 2 treatment is not effective:

- use the combination of ACEI or ARB, CCB and thiazide-like diuretic.

Step 4

If BP remains >140/90 mmHg after treatment with ACEI or ARB plus CCB plus a diuretic, this may be resistant hypertension. In this case:

- treat with spironolactone or a higher-dose thiazide-like diuretic (specialist advice is indicated).

Adverse effects of antihypertensive treatment can sometimes be troublesome and treatment has to be tailored to each patient's response (Table 5.11).

Accelerated (malignant) hypertension

This typically affects young adults, especially those of African or Afro-Caribbean black heritage and, like essential hypertension, often causes no symptoms until complications develop. It may present with headaches, visual impairment, nausea, vomiting, fits (seizures) or

Table 5.11 Adverse effects from antihypertensive and other cardioactive drugs

Group	Comments and adverse effects
Alpha-adrenergic blockers	Thrombocytopenia
Angiotensin-converting enzyme inhibitors (ACEIs)	First dose may cause sudden fall in BP May impede renal function, especially if NSAIDs also given Cough, angioedema
Angiotensin II receptor blockers (ARBs)	Generally well tolerated but olmesartan can cause a sprue-like disease
Beta-blockers	Bronchospasm Contraindicated in asthma, heart failure or heart block Muscle weakness Lassitude Disturbed sleep
Calcium-channel blockers (CCBs)	Headache and flushing Swollen legs
Centrally acting antihypertensives (largely obsolete)	Haemolysis Hepatitis
Diuretics	Hypovolaemia Electrolyte changes
Potassium-channel blockers	Headache May cause flushing
Vasodilators	Lupoid reactions

acute cardiac failure. The chief complication is severe ischaemic damage to the kidneys and renal failure, which can be fatal within 1 year of diagnosis. Other causes of death are cardiac failure or cerebrovascular accidents. Life-threatening accelerated hypertension requires urgent hospital admission with the aim of reducing the BP slowly with oral antihypertensives. Rarely, intravenous antihypertensives (sodium nitroprusside) are used but a sudden drop in BP may result in a stroke (cerebral infarction). Vigorous treatment, if started before renal damage is too far advanced, can greatly improve the life expectancy; about 50% of patients can now expect to live for at least 5 years. Renal sympathetic denervation is a promising recent therapy for resistant hypertension.

Dental aspects of hypertension

There are no recognized orofacial manifestations of hypertension but facial palsy is an occasional complication of malignant hypertension. Antihypertensive drugs can sometimes cause orofacial side-effects, such as hyposalivation (clonidine in particular), salivary gland swelling or pain, lichenoid reactions, erythema multiforme, angioedema, gingival swelling, sore mouth or paraesthesiae (see Table 5.10).

BP should be controlled before elective dental treatment or the opinion of a physician should be sought, since the BP often rises even before a visit for dental care; preoperative reassurance is important and sedation using temazepam may be helpful. Endogenous adrenaline (epinephrine) levels peak during the morning hours and adverse cardiac events are most likely in the early morning, so patients are best treated in the late morning. Those with stable hypertension may receive dental care, in short, minimally stressful appointments. It is essential to avoid anxiety and pain, since endogenous adrenaline released in response to pain or fear may induce arrhythmias. Adequate analgesia must be provided. Both the pain threshold and tolerance are higher in hypertensive than normotensive subjects; the mechanism is

Table 5.12 Causes of orthostatic hypotension

Primary autonomic causes	Secondary autonomic causes	Non-autonomic causes
Familial dysautonomia (Riley–Day syndrome)	B vitamin deficiency	Hypovolaemia
Pure autonomic failure (idiopathic orthostatic hypotension)	Alcoholism	Ageing
Shy–Drager syndrome	Diabetes	Prolonged bed rest
Dopamine	Parkinsonism	Pregnancy
Beta-hydroxylase deficiency	Porphyria	Drugs (e.g. antihypertensives)

unclear but drug treatment of the hypertension normalizes the pain perception. An aspirating syringe should be used to give an LA, since adrenaline given intravenously may (theoretically) increase hypertension and precipitate arrhythmias. BP tends to rise during oral surgery under LA, and adrenaline theoretically can contribute to this, but this is usually of little practical importance. Under most circumstances, the use of adrenaline in combination with LA is not contraindicated in the hypertensive patient unless the systolic pressure is >200 mmHg and/or the diastolic is >115 mmHg. Adrenaline-containing LA should not be given in large doses to patients taking beta-blockers, since interactions between adrenaline and the beta-blocker may induce hypertension and cardiovascular complications. Lidocaine should be used with caution in patients taking beta-blockers. Adrenaline effects may be reversed in patients taking alpha-blockers causing vasodilatation. Gingival retraction cords containing adrenaline should be avoided.

Conscious sedation may be advisable to control anxiety. Continuous BP monitoring is indicated. Raising the patient suddenly from the supine position may cause postural hypotension and loss of consciousness if the patient is using antihypertensive drugs such as thiazides, furosemide or a CCB.

GA agents potentiate antihypertensive drugs, which can induce dangerous hypotension. Intravenous barbiturates in particular can be dangerous, but halothane, enflurane and isoflurane may also cause hypotension in patients on beta-blockers. However, antihypertensive drugs should not be stopped, since rebound hypertension can result, and the risks of cerebrovascular accidents and cardiovascular instability that stem from withdrawal of antihypertensive medication and rebound hypertension outweigh the dangers of drug interactions, which to some extent are predictable and manageable by an expert anaesthetist. Therefore, antihypertensive treatment is usually continued, the management of such patients being a matter for the specialist anaesthetist in hospital. A severely reduced blood supply to vital organs can be dangerous, even in a normal person. In the chronically hypertensive patient, tissues have become adapted to the raised BP, which becomes essential (hence the term ‘essential hypertension’) to overcome the resistance of the vessels and maintain adequate perfusion. A fall in BP below the critical level needed for adequate perfusion of vital organs, particularly the kidneys, can therefore be fatal. Hypertension may be a contraindication to GA if complicated by cardiac failure, coronary or cerebral artery insufficiency, or renal insufficiency. Chronic administration of some diuretics such as furosemide may lead to potassium deficiency, which should, therefore, be checked preoperatively in order to avoid arrhythmias and increased sensitivity to muscle relaxants such as curare, gallamine and pancuronium.

The management of hypertensive patients may also be complicated by diseases such as cardiac or renal failure. Systemic corticosteroids may raise the BP and antihypertensive treatment may have to be

Table 5.13 Risk and protective factors for atheroma

Primary risk factors	Secondary risk factors	Unclear factors	Protective factors
High low-density lipoprotein (LDL)	Low LDL	Low dietary fibre	Raising HDL to LDL ratio
Hypertension	Diabetes	Soft water	More exercise
Smoking	Obesity	High plasma fibrinogen	Moderate red wine or other alcohol
	Family history of coronary heart disease (CAD)	Raised blood factor VII	
	Physical inactivity	Raised lipoprotein levels	
	Type A personality	Homocysteine levels	
	Gout	Folate levels	
	Ethnicity (Asians)	C-reactive protein levels	
	Male gender		
	Increasing age		
	Low social class		
	Chronic renal failure		

Table 5.14 Main sites and results of atheroma

Site	Consequence	Possible clinical syndromes
Coronary arteries	Coronary artery disease	Impairs oxygenation and can lead to chest pain (angina), arrhythmias or myocardial infarction
Carotid and other cerebral arteries	Cerebrovascular disease	Stroke or transient ischaemic attacks
Peripheral arteries	Peripheral vascular disease	Impaired oxygenation, pain (intermittent claudication) and sometimes gangrene

Table 5.15 Blood lipids

	Total cholesterol	LDL ('bad') cholesterol	Lipid HDL ('good') cholesterol	Triglycerides
Significance of high level	May indicate atheroma	Main source of atheroma	Inhibits atheroma <40 mg/dL is a major risk factor for coronary artery disease	May indicate atheroma
Target blood levels for health	<200 mg/dL	<100 mg/dL	≥60 mg/dL	<150–199 mg/dL

adjusted accordingly. Some non-steroidal anti-inflammatory drugs (NSAIDs; indometacin, ibuprofen and naproxen) can reduce the efficacy of antihypertensive agents.

HYPOTENSION

Hypotension is uncommon but can have many causes (Table 5.12). Raising the patient suddenly from the supine position may cause postural (orthostatic) hypotension and loss of consciousness.

ATHEROMA AND ISCHAEMIC HEART DISEASE/ CORONARY ARTERY DISEASE

General aspects

Atheroma (atherosclerosis; arteriosclerosis) is the accumulation of cholesterol and lipids in the intima of arterial walls; it can lead to thromboses (clots), which sometimes break off and move within the vessels to lodge in and occlude small vessels (embolism). Atheroma can thus lead to CAD/IHD with angina, MI, cerebrovascular disease and stroke (Table 5.13). It also affects other arteries and can cause, for example, ischaemic

pain in the calves whilst walking – intermittent claudication – seen especially in young smokers, when it is termed Buerger disease.

In Western populations, atheroma may affect up to 45% of young adult males, and IHD affects at least 20% and increasingly thereafter, and accounts for about 35% of total mortality in Britain and the USA (Table 5.14). Atheroma results from a combination of genetic and lifestyle factors. Irreversible (fixed) risk factors include increasing age, male gender and family history of atheroma. Potentially reversible (modifiable) risk factors for atheroma include:

- cigarette smoking
- blood lipids
- hypertension
- diabetes mellitus
- obesity and lack of exercise
- the metabolic syndrome (Ch. 23).

High blood cholesterol is one of the major risk factors for IHD. Low-density lipoproteins (LDLs) are associated with a high risk of atheroma, whilst high-density lipoproteins (HDLs) appear to be anti-atherogenic (Table 5.15).

Atheroma is predominantly a disease of males, particularly in affluent societies, and is linked to smoking, lack of exercise, hypertension

Table 5.16 Risk factors for ischaemic heart disease^a

H	Heredity
A	Age (older age)
S	Sex (male)
L	Lipidaemia
I	Increased weight (obesity)
P	Pressure (arterial hypertension)
I	Inactivity (sedentary lifestyle)
D	Diabetes
S	Smoking tobacco

^aAdapted from Damjanov I. *Pathology secrets*, 2nd edn. New York, 2004, Mosby.

and hyperlipidaemia. Dietary fat is processed by the liver to form four main lipoproteins – chylomicrons, very-low-density lipoproteins (VLDLs), LDLs and HDLs. VLDL reforms to LDL, and it is these fats that are incorporated into atherosclerotic plaque and associated with a high risk of IHD/CAD. By contrast, HDLs clear cholesterol from the blood via the liver, appear to be anti-atherogenic, and are associated with a lower risk of IHD/CAD (Table 5.16). Cholesterol may be raised genetically and with increasing age in both sexes. Before the menopause, women have lower total cholesterol levels than men of the same age but, after the menopause, women's LDL levels tend to rise with inactivity and excess weight, a diet low in fruit and vegetables, smoking and other diseases such as hypertension and diabetes.

There is a higher incidence of IHD/CAD in patients with diabetes, hyperlipidaemia, the metabolic syndrome and hypothyroidism. Hyperlipidaemia and hypertension seem to be linked, and immigrants from the Indian subcontinent have a higher than average morbidity and mortality from IHD/CAD. Apolipoprotein E genotyping may help confirm a diagnosis of type III hyperlipoproteinaemia (also known as dysbetalipoproteinaemia), to evaluate a possible genetic cause of atheroma.

Periodontal disease could be an independent risk factor for IHD/CAD because oral bacteria, inflammatory mediators and endotoxaemia might contribute. Other infectious agents implicated have included *Chlamydia pneumoniae*, *Helicobacter pylori* and *cytomegalovirus*, but none of these associations has been proven.

Clinical features

Atheroma has a patchy distribution and, depending on the site and extent of disease, can give rise to a variety of clinical presentations. Atheromatous plaques may rupture and 'heal' spontaneously. Alternatively, a platelet–fibrin thrombus (clot) may form, then break up and travel in the bloodstream (thromboembolism), with potentially life-threatening consequences.

IHD/CAD is due to occlusion of the coronary arteries and leads to angina pectoris (pain arising when the myocardial oxygen demand exceeds the supply). Rare causes of IHD/CAD include embolism and coronary artery spasm. Patients with IHD/CAD are at greatest risk from MI, which, if severe, causes cardiac arrest with acute failure of the whole circulation, loss of cerebral blood supply and often death within a few minutes. MI differs from angina in that it causes more severe and persistent chest pain that is not controlled by rest; it leads to irreversible cardiac damage or sudden death. A chronically reduced blood supply to the myocardium progressively damages the heart and may lead to cardiac arrhythmias and cardiac failure (Table 5.17).

Table 5.17 Main consequences of ischaemic heart disease

Site	Consequence	Possible clinical syndromes
Coronary arteries	Coronary occlusion	Arrhythmias or acute coronary syndrome (angina, myocardial infarction)
Carotid and other cerebral arteries	Cerebrovascular occlusion	Stroke or transient ischaemic attacks, dementia
Peripheral arteries	Peripheral vascular disease	Pain (intermittent claudication) and gangrene

Box 5.4 Lifestyle recommendations for lowering ischaemic heart disease risk

- Healthy weight
- Smoking cessation
- Moderate alcohol consumption
- Regular exercise (e.g. brisk walking for at least 30 min daily)
- Fresh fruit and vegetable intake of at least five servings a day
- Grain intake of at least six servings a day with at least one-third wholegrain

Prevention

The primary aim is to prevent or reduce progression of atheroma by lifestyle changes, as shown in Box 5.4. IHD/CAD prophylaxis is by lowering cholesterol levels that are too high. If the total cholesterol is 200 mg/dL or more, or if HDL is less than 40 mg/dL, a lipoprotein profile should be done after a 9–12-hour fast. Abnormal cholesterol levels can be altered by:

- improving diet (reducing saturated fat and cholesterol)
- losing weight, which can help lower LDL and total cholesterol levels, as well as raise HDL and lower triglyceride levels
- increasing physical activity, which can help lower LDL and raise HDL levels, and also helps weight loss
- stopping cigarette smoking
- controlling hypertension
- taking drugs to lower LDL cholesterol if it is 130 mg/dL or more – statins (simvastatin, pravastatin, etc.), which inhibit the *de novo* production of cholesterol via hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase
- taking bile acid sequestrants (colesevelam), resins (colestyramine, colestipol), nicotinic acid-related drugs (nicotinic acid and acipimox) or fibrates (clofibrate, fenofibrate, gemfibrozil) as alternatives to statins.

A diet high in marine triglycerides (and omega-3 fatty acids – though this is contentious) and high in fruit and vegetables may be cardioprotective. Fish such as salmon, tuna and mackerel containing omega-3 fatty acids may offer protection against CAD by reducing inflammation. Polyunsaturated fatty acids of the omega-3 type are present as alpha-linolenic acid, mainly in certain vegetable sources such as soybean, canola oil and English walnuts, and in fish oils such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Fruits and vegetables, and other foods high in antioxidants, are associated with a lower risk of IHD/CAD. Moderate red wine consumption

is also associated with lower mortality (possibly because of the contained antioxidant resveratrol), and eating less salt may reduce the chances of developing high BP.

General management

The diagnosis of IHD/CAD may be suggested by the history. Resting ECG may help but, if normal, exercise ECG is indicated. Coronary arteriography (angiography; CAG) demonstrates the anatomy and patency of the arteries and also allows for intervention if necessary (percutaneous coronary intervention [PCI]). Use of a radionuclide such as thallium-201 or MIBI (2-methoxy isobutyl isonitrile; sestamibi) can enhance the sensitivity. Myocardial perfusion scans (thallium-201) may reveal ischaemic areas, which show as 'cold spots' during exercise. Often an exercise stress test (EST) is the first-choice investigation but this and other non-invasive techniques, such as myocardial perfusion single photon emission computed tomography (SPECT), can only identify patients with advanced CAD. Electron-beam computed tomography (EBCT) can detect and quantify coronary artery calcification (CAC) and there is a strong independent association between CAC and CAD detected with CAG, and also with cerebrovascular disease.

The most effective ways to treat patients with IHD/CAD include the lifestyle changes described above, particularly stopping smoking. Drugs that may help include antiplatelet drugs (aspirin or clopidogrel) to prevent thrombosis; beta-blockers (atenolol, metoprolol, etc.) to lower the BP; ACEIs (enalapril, fosinopril, etc.) to lower peripheral resistance and cardiac workload, and hence BP; and statins to lower blood cholesterol. Statins may cause muscle damage, sleep disturbances, memory loss, depression, sexual dysfunction or interstitial lung disease. Other measures include good control of blood glucose levels in diabetics.

Pain relief and prophylaxis of angina is with GTN 0.3–0.6mg sublingually during attacks or before anticipated physical activity or stress. Long-acting nitrates (e.g. isosorbide dinitrate) may help prevent attacks. When IHD/CAD is extensive and symptoms are worsening despite general measures and optimal medical management, cardiac revascularization techniques should be considered. These include: *coronary angioplasty* – stents may be placed percutaneously (by PCI) to re-establish coronary blood flow and improve myocardial perfusion; or *coronary artery bypass graft (CABG)* – to bridge severe obstructions in the coronary blood vessels.

Dental aspects of ischaemic heart disease

Stress, anxiety, exertion or pain can provoke angina and, therefore, patients should receive dental care, in short, minimally stressful appointments in the late morning. Effective painless LA is essential. An aspirating syringe should be used since adrenaline (epinephrine) in the LA may enter the blood and may (theoretically) raise the BP and precipitate arrhythmias. Adrenaline-containing LA should not be given in excessive doses to patients taking beta-blockers, since the interaction may induce hypertension and cardiovascular complications if excessively large doses are given. Gingival retraction cords containing adrenaline should be avoided.

Conscious sedation should be deferred for at least 3 months after MI, recent-onset angina, unstable angina or recent development of bundle branch block and, in any case, should be given in hospital. GA should be avoided wherever possible and at the least deferred for 3 months after MI.

Drugs and other therapies may affect dental care. Angina can rarely cause pain in the mandible, teeth or other oral tissues. Patients with IHD/CAD appear to have more severe dental caries and periodontal disease than the general population. Whether these infections bear any causative relationship to heart disease remains controversial but periodontal disease could be an independent risk factor because oral bacteria, inflammatory mediators and endotoxaemia might contribute.

Coronary artery stenosis and dental pulp calcification are significantly associated. Dental radiography has the potential to be used as a rapid screening method for the early detection of coronary artery stenosis.

ACUTE CORONARY SYNDROMES (ACS)

General aspects

Acute coronary syndrome is the term used to refer to clinical features attributed to coronary artery obstruction. They are typically due to IHD/CAD but are occasionally caused by cocaine, anaemias or arrhythmias. The most common feature is acute chest pain, often radiating to the left arm or jaw, and sometimes associated with nausea and sweating.

ACS is usually the result of unstable angina (38%) or MI; the latter can be ST-elevation MI (STEMI: 30%) or non-ST-elevation MI (NSTEMI, also known as non-Q-wave MI: 25%). Unstable angina occurs suddenly, often at rest or with minimal exertion, or at lesser degrees of exertion than precipitated previous angina attacks ('crescendo angina'). New-onset angina is also considered as unstable angina.

General management

If a 12-lead ECG suggests STEMI (ST elevations in specific leads, a new left bundle branch block or a true posterior MI pattern), then urgent triage, transfer and treatment with thrombolytics or angioplasty are essential. Troponin I or troponin T is a useful cardiac damage marker. Give pain relief as soon as possible, using GTN, and offer intravenous opioids such as morphine, if an acute MI is suspected. Offer a single loading dose of 300mg aspirin as soon as possible, unless there is clear evidence that the patient is allergic to aspirin. Do not routinely administer oxygen but undertake early coronary angiography with a view to revascularization either by PCI, usually with stent implantation, or CABG.

However, at least 50% of survivors of attacks of sudden cardiac death have no evidence of myocardial damage from the ECG or serum enzyme levels; the pathogenesis appears not to be the same as in typical MI, and therefore the term NSTEMI is used. If the ECG suggests NSTEMI, treatment is with glycoprotein IIb/IIIa inhibitors (eptifibatide or tirofiban), plus aspirin, low-molecular-weight heparin (LMWH) and clopidogrel, with intravenous GTN and opioids if the pain persists; where appropriate, early coronary angiography is undertaken with a view to revascularization either by PCI, usually with stent implantation, or CABG. Abciximab is a monoclonal antibody that targets the glycoprotein IIb/IIIa receptor on platelets. If, 12 hours after onset of the pain, cardiac troponins (cTnT) are positive, urgent coronary angiography is typically indicated, as this is highly predictive of an impending MI. If the troponin is negative, a treadmill exercise test or a thallium scintigram may be indicated.

The NICE guidelines on MI are available at <http://guidance.nice.org.uk> and NICE technology appraisal guidance on the use of

ANGINA PECTORIS**General aspects**

Angina pectoris is the name given to episodes of chest pain caused by myocardial ischaemia secondary to IHD/CAD. It affects around 1% of adults and its prevalence rises with increasing age. The usual underlying causes are atherosclerotic plaques that rupture with resulting platelet activation, adhesion and aggregation, and thrombosis impeding coronary artery blood flow (or, if this is complete occlusion, MI). Arterial spasm alone may, rarely, be responsible. The mortality rate in angina is about 4% per year, the prognosis depending on the degree of coronary artery narrowing.

Clinical features

Angina is often an unmistakable pain described as a sense of strangling or choking, or tightness, heaviness, compression or constriction of the chest, sometimes radiating to the left arm or jaw *but relieved by rest* (Box 5.5). The most common precipitating causes of angina pain are physical exertion (particularly in cold weather); emotion (especially anger or anxiety); and stress caused by fear or pain, leading to adrenal release of catecholamines (adrenaline [epinephrine] and noradrenaline [norepinephrine]) and consequent tachycardia, vasoconstriction and raised BP. Consequently, an increased cardiac workload is accompanied by a paradoxical drop in blood flow and myocardial ischaemia occurs, resulting in angina.

The severity and prognosis of angina depend upon the degree of coronary artery narrowing and there is a varied clinical presentation (Box 5.6). Unstable angina is the term given to a pain pattern changing in occurrence, frequency, intensity, duration or pain at rest, and these patients are at high risk of progression to MI or death. The British Cardiac Society guidelines state the circumstances associated with an increased risk of early adverse outcome, which include:

- age above 65 years
- co-morbidity, especially diabetes
- prolonged (>15 min) cardiac pain at rest
- ischaemic ECG ST-segment depression on admission or during symptoms
- ECG T-wave inversion (associated with an intermediate risk, lying between that associated with ST-segment depression and normal ECG)
- evidence of impairment of left ventricular function (either pre-existing or during MI)
- elevated C-reactive protein (CRP)
- raised levels of cardiac troponin.

Box 5.6 Angina variants

- *Cardiac syndrome X*: clinical features of angina but normal coronary arteries on angiogram (a functional abnormality of the coronary microcirculation)
- *Decubitus angina*: pain on lying down
- *Stable angina*: pain only on exertion, relieved in a few minutes by rest and sublingual glyceryl trinitrate
- *Unstable angina*: angina at rest or of sudden onset with a rapid increase in severity (a medical emergency due to a transient subtotal obstruction of a coronary vessel)
- *Vasospastic (variant or Prinzmetal) angina*: caused by coronary artery spasm

Patients may have repeated attacks of angina over a long period, or have an MI soon after the first one or two attacks. Many patients have *painless* myocardial ischaemia, as shown by arteriography (angiography) and exercise ECG changes. Some even have hyposensitivity to pain.

General management

The diagnosis is primarily clinical. Occasionally, gastro-oesophageal reflux disease (GORD) or chest wall diseases mimic angina, and neither the results of physical examination nor investigations are necessarily abnormal. The latter may especially include resting ECG, which typically shows ST-segment depression with a flat or inverted T wave, but is usually normal between episodes of angina. Exercise ECG testing is positive in approximately 75% of people with severe CAD. Myocardial perfusion scans (thallium-201) highlight ischaemic myocardium. Coronary angiography can assess coronary blood flow in diagnostically challenging cases.

Risk factors for IHD/CAD (cigarette smoking, physical inactivity, obesity, hypertension, diabetes, hypercholesterolaemia) should be identified and corrected. During acute episodes of angina, pain is relieved by oxygen, GTN and reduction of anxiety. The pain, though relieved by rest, is ameliorated more quickly by nitrates – usually GTN – which act by lowering the peripheral vascular resistance and reducing the oxygen demands of the heart. Most patients use GTN in the buccal sulcus or sublingually, as a spray or tablet. Other nitrates, CCBs and occasionally potassium-channel activators such as nicorandil may also be prescribed. Nitrates are not used to relieve an angina attack if the patient has recently taken sildenafil, as there may be a precipitous fall in BP; analgesics should be used.

When angina is frequent, long-acting nitrates (isosorbide mononitrate), beta-adrenergic-blocking drugs (e.g. atenolol) and calcium antagonists (e.g. amlodipine) are used. Many patients with stable angina are given a beta-blocker or a CCB but, if this fails to control symptoms adequately, a combination of a beta-blocker and a dihydropyridine CCB (e.g. amlodipine, felodipine, modified-release nifedipine) may be used. If this combination is inappropriate because of intolerance of, or contraindication to, *either* beta-blockers *or* CCBs *or* both, a long-acting nitrate, ivabradine, nicorandil or ranolazine can be considered (Box 5.7). Ivabradine, a cardiotonic agent, helps to lower the heart rate, which can be helpful in angina (and heart failure). It can be used when beta-blockers fail or can be used in combination with a beta-blocker for people whose symptoms are not adequately controlled with a beta-blocker, providing their heart rate is greater than 60 beats/min). Grapefruit can affect the metabolism of ivabradine. Adverse effects of ivabradine include luminous visual phenomena and there are

Box 5.7 Medical treatments for angina

- Beta-blockers
- Calcium-channel blockers
- Nitrates
- Others:
 - Nicorandil
 - Ivabradine
 - Ranolazine

multiple contraindications to its use. Drugs used to prevent thrombosis in unstable angina in particular include:

- aspirin, which acetylates platelet cyclo-oxygenase (COX) and thereby inhibits platelet function for about 7 days, and also inhibits platelet aggregation by preventing the synthesis of thromboxane A₂; it is more effective when used with clopidogrel
- glycoprotein IIb and IIIa inhibitors, such as abciximab, to prevent adherence of fibrinogen to receptors on platelets and to block their aggregation
- lipid-lowering drugs
- LMWH.

In angina that does not respond to drugs, PCI procedures or CABG may be indicated.

Dental aspects

Preoperative GTN and sometimes oral sedation (e.g. temazepam) are advised. Dental care should be carried out in such a way as to cause minimal anxiety, and with oxygen saturation, BP and pulse monitoring. Effective LA is essential. Ready access to medical help, oxygen and GTN is crucial.

If a patient with a history of angina experiences chest pain in the dental surgery, dental treatment must be stopped and the patient should be given GTN sublingually and oxygen; the patient should be kept sitting upright. Vital signs should be monitored. The pain should be relieved in 2–3 minutes; the patient should then rest and be accompanied home.

If chest pain is not relieved within about 3 minutes, MI is a possible cause (see below) and medical help should be summoned. Pain that persists after three doses of GTN given every 5 minutes, lasts more than 15–20 minutes, or is associated with nausea, vomiting, syncope or hypertension is highly suggestive of MI. If pain persists, the patient should continue on oxygen and *chew* 300 mg of aspirin (Ch. 1).

Tricyclic antidepressants are best avoided, as they can disturb cardiac rhythm. Sumatriptan is contraindicated, as it may cause coronary artery vasoconstriction.

Angina is a rare cause of pain in the mandible, teeth or other oral tissues, or pharynx. Drugs used in the care of patients with angina may cause oral adverse effects, such as lichenoid lesions (CCBs), gingival swelling (CCBs) or ulcers (nicorandil).

Conscious sedation should be deferred for at least 3 months in patients with recent-onset angina, unstable angina or recent development of bundle branch block; in any case, it should be given in hospital.

GA should be deferred for at least 3 months in patients with recent-onset angina, unstable angina or recent development of bundle branch block; in any case, it must be given in hospital. Intravenous barbiturates are particularly dangerous.

Stable angina

For anything but minor treatment under LA, the physician should be consulted and consideration should be given to any other complicating factors, such as beta-blocker therapy, hypertension or cardiac failure. Other medication should not be interfered with. Before dental treatment, patients with stable angina should be reassured and possibly sedated with oral diazepam. Prophylactic administration of GTN may be indicated if the patient has angina more than once a week.

Unstable angina

Elective dental care should be deferred until a physician has agreed to it, because of the risk of infarction. Preoperative GTN should be given, together with relative analgesia monitored by pulse oximetry, and LA; however, such patients are best cared for in hospital, as intravenous nitrates may be indicated.

Emergency dental care should be the least invasive possible, using preoperative GTN, together with relative analgesia monitored by pulse oximetry and LA; however, such patients are best cared for in a hospital environment, as coronary vasodilators may be indicated intravenously. Other medication should not be interfered with.

MYOCARDIAL INFARCTION**General aspects**

Myocardial infarction (coronary thrombosis or heart attack) results from the complete occlusion (blockage) of one or more coronary arteries. It arises when atherosclerotic plaques rupture, causing platelet activation, adhesion and aggregation with subsequent thrombus formation within the coronary circulation. Angina may progress to MI but fewer than 50% of patients with MI have any preceding symptoms.

Clinical features

MI most commonly presents with central chest pain similar to that of angina *but is not relieved by rest or with sublingual nitrates*. MI may appear without warning or is sometimes precipitated by exercise or stress. The pain is often unmistakable and described as an unbearably severe sense of strangling or choking, or tightness, heaviness, compression or constriction of the chest. It sometimes radiates to the left arm or jaw. Sometimes MI is preceded by angina, often felt as indigestion-like pain (Box 5.8). It can persist for hours, if death does not supervene.

The pain of MI may sometimes start at rest, and is not relieved by nitrates. Vomiting, facial pallor, sweating, restlessness, shortness of breath and apprehension are common. Other features may include cough and loss of consciousness, but the clinical picture is variable and fewer than 50% of patients with an MI have any premonitory symptoms. Approximately 10–20% of individuals have silent (painless) infarctions and the first sign may be the catastrophic onset of left ventricular failure, shock, loss of consciousness and death.

Death soon after the onset of the chest pain is common, often from ventricular fibrillation or cardiac arrest. Less often, there is sudden cardiac death characterized by immediate collapse without premonitory symptoms, and loss of pulses. In such cases, the precipitating event is a severe arrhythmia such as ventricular fibrillation. Up to 50% of patients die within the first hour of MI and a further 10–20% within the next few days. The prognosis of MI may be judged from the Killip classification (Table 5.18).

Cardiac failure and arrhythmias may develop in MI survivors and the chances of reinfarction are high in the immediate post-infarction

Box 5.8 Features of myocardial infarction

- Chest pain described as a sensation of pressure, fullness or squeezing in the mid-portion of the thorax, *not relieved by rest or GTN*
- Radiation of chest pain into the jaw/teeth, shoulder, arm and/or back
- Associated dyspnoea or shortness of breath
- Associated epigastric discomfort with or without nausea and vomiting
- Associated sweating (diaphoresis)
- Syncope or near-syncope without other cause
- Impairment of cognitive function without other cause

Table 5.18 Killip classification of acute myocardial infarction

Killip class	Defining features	Mortality rate (%)
I	No clinical signs of heart failure	6
II	Rales or crackles in the lungs, an S3 gallop and elevated jugular venous pressure	17
III	Frank acute pulmonary oedema	38
IV	Cardiogenic shock or hypotension (systolic BP < 90 mmHg), and evidence of peripheral vasoconstriction (oliguria, cyanosis or sweating)	81

Fig. 5.10 Electrocardiogram tracings in myocardial infarction: large Q wave, ST elevation, inverted T wave.

weeks. Dressler syndrome, also known as post-myocardial infarction syndrome or post-cardiotomy pericarditis, is a form of pericarditis complicating MI. Valvular dysfunction and myocardial rupture may also complicate an MI.

General management

MI is diagnosed mainly from clinical features supported by ECG (Fig. 5.10) and changes in serum levels of enzymes termed ‘cardiac enzymes’ (Box 5.9). In the first few hours, T waves become abnormally tall (hyperacute with the loss of their normal concavity) and ST segments begin to rise. Pathological Q waves may appear within hours or up to more than 24 hours. Thus the characteristic pattern of MI is a normal or raised ST segment, with hyperacute T and acute Q waves (see Fig. 5.10). By 24 hours, the T wave becomes inverted as the ST elevation begins to resolve. Long-term ECG changes include persistent Q and T waves.

Damaged (infarcted) cardiac muscle releases several enzymes into the blood, including troponin T (TT), cardiac-specific creatine kinase (CK-MB), aspartate transaminase (AST) and lactic dehydrogenase (LDH). The earliest changes are in cardiac TT, an enzyme expressed only in the myocardium and not in other muscles, and which can be detected in the blood 3–6 hours after onset of the chest pain of MI, reaching peak levels within 16–25 hours. TT is also useful for the late diagnosis of MI because raised blood concentrations can be seen even 5–8 days after MI onset (Table 5.19).

Box 5.9 Diagnosis of myocardial infarction

- Chest pain: severe, unremitting
- Collapse
- Changes in heart rate
- Arrhythmias
- Hypotension
- Shock
- ECG changes
- Rise in serum ‘cardiac’ enzymes (see Table 5.18)
- Fever and leukocytosis

Table 5.19 Serum enzyme level changes after myocardial infarction

Enzyme	Abbreviation	Number of days after MI that maximum rise is seen
Troponin T (troponin 1)	TT	0.5–1.0
Creatine kinase-MB	CK-MB	1.5
Aspartate transaminase	AST	2.0
Lactic dehydrogenase	LDH	3.0

Box 5.10 Immediate treatment of myocardial infarction

- Alert emergency services (if in community) or cardiac arrest team (if in hospital)
- Give aspirin (300 mg): to be chewed
- Rest and reassure patient
- Give pain relief: opioid analgesia (diamorphine) is usually necessary, preferably by slow intravenous injection (2 mg/min) or up to 15 mg i.m. according to size of patient, plus cyclizine 50 mg. Alternatively, nitrous oxide with at least 28% oxygen should be given to relieve pain and anxiety. Pentazocine is contraindicated, as it can cause dysphoria and raises pulmonary arterial pressure. It is less effective than morphine, even when given by injection, but does not relieve and may even increase anxiety
- Give glyceryl trinitrate infusion to relieve pain and prevent pulmonary oedema (fluid accumulation within lungs)
- Treat complications promptly, particularly cardiac arrhythmias, including initiation of cardiopulmonary resuscitation
- Consider:
 - Oxygen or nitrous oxide with at least 28% oxygen by face mask or intranasally (take care if defibrillating)
 - Primary percutaneous intervention or thrombolysis – streptokinase/tissue plasminogen activator (t-PA), alteplase, reteplase or tenecteplase – to dissolve coronary thrombus, provided patient is not at risk of life-threatening haemorrhage
 - Insulin infusion to prevent stress hyperglycaemia (high blood sugar level)

^aSee also Chapter 1.

MI requires immediate hospital admission and treatment (which halves the mortality rate). Management aims to relieve pain, limit myocardial damage (infarct size) and prevent/treat complications (Box 5.10; see also Ch. 1). Ventricular fibrillation is the most common cause of death and nearly 50% of deaths are in the first hour, so immediate defibrillation and CPR can be life-saving (Ch. 1).

In the convalescent stage, ACEIs or beta-blockers can reduce mortality and the risk of recurrence. Early mobilization, a cardiac

Table 5.20 Oral health-care effects on automatic implantable cardiac defibrillators (AICDs)

Procedures that are safe from interference with AICD	Procedures in which interference with AICD can be reduced by safety measures	Procedures in which interference with an AICD is likely
Diagnostic radiography and CT: if the AICD is placed in the upper chest area, the radiography equipment may be adjusted to lessen pressure on the defibrillator Dental procedures; use of equipment such as dental drills, ultrasonic scalers or endosonic instruments; dental radiography ECG Microwave Peripheral nerve stimulators Radiography Ultrasonography Use of laser scalpels	Transcutaneous electrical nerve stimulation (TENS) Ultrasound for diagnostic or therapeutic purposes: keep the transducer head 25 cm from the defibrillator	Cardioversion Diathermy, electrocautery, lithotripsy, radiation therapy Electrocoagulation Electrocutting Electrosurgery External defibrillation: if this is needed, the health-care professional should not place the paddles directly over the defibrillator MRI: <i>contraindicated</i> for a person with a defibrillator. Even if the MRI scanner is off, there is a strong magnetic field that may affect the defibrillator Radiofrequency ablation TENS (with AICD or pacemaker)

rehabilitation programme and correction of risk factors for IHD/CAD (as in angina management) are indicated. Mechanical circulatory support (MCS) may be used for treatment of patients with severe cardiogenic shock, over a period of several days up to months before heart transplantation. A multicentre automatic defibrillator implantation trial showed a 30% relative risk reduction in all-cause mortality from the prophylactic use of an automatic implantable cardiac defibrillator (AICD) in patients after MI. NICE also recommends the use of an AICD in people who have survived a cardiac arrest that was due to either ventricular tachycardia or ventricular fibrillation.

Dental aspects

Dental intervention after MI can precipitate arrhythmias or aggravate cardiac ischaemia. This is more likely in severe MI, when the actual infarct is close in time and in the presence of cardiac complications. The severity of an MI can be assessed from the resulting disability, the length of the acute illness and whether or not the patient was hospitalized; nevertheless, it is important to consult the patient’s physician before undertaking operative treatment.

In general, patients within 6 months of an MI (recent MI) are at greatest risk of further MI, chest pain, arrhythmias or other complications, and have generally been classed as ASA class IV. A level of reinfarction of 50% has been reported in major surgery done during this period; therefore, higher-risk procedures such as elective and major surgery should be deferred. Simple emergency dental treatment under LA may be given during the first 6 months after MI but the opinion of a physician should be sought first.

In symptomatic patients with previous older MI (between 6 and 12 months), elective simple dental care can normally be carried out safely but it is wise to minimize pain and anxiety. Higher-risk procedures such as elective surgery may need to be deferred since a level of reinfarction of 20% has been reported in major surgery and about 5% in minor surgery done during this period.

In asymptomatic patients with previous but older MI (more than 12 months), elective dental care can normally be carried out safely but it is always wise to minimize pain and anxiety. A level of reinfarction of 5% has been reported in major surgery done during this period.

At any time, the level of risk will depend on the type of intervention; surgery is a higher risk, for example, than conservative dentistry. There must be ready access to oxygen and medical help. Anxiety and

pain must be minimized, and the physician may advocate preoperative use of GTN. Effective LA, possibly supplemented with relative analgesia, and monitoring of BP, ECG, pulse and oxygen saturation are indicated. Dental procedures should be stopped if there is chest pain, dyspnoea, a rise in heart rate of 40 beats/min or more, a rise in the ST-segment displacement of above 0.2 mV on ECG, arrhythmias, or a rise in systolic BP of more than 20 mmHg.

The incidence of MI after GA in patients with a documented preoperative MI is up to eight times that of patients with no previous history. Nearly 30% of patients having a GA within 3 months of an infarct have another MI in the first postoperative week and at least 50% die. Elective surgery under GA should therefore be postponed for at least 3 months and preferably a year, since the prognosis of recurrent MI is also influenced by the time after the first attack.

After mechanical circulatory support, management is complicated by a combination of anticoagulant and antiplatelet medication, and sometimes by an increased risk of thromboembolic events and infections. Elective interventions should be postponed.

Adrenaline (epinephrine) or other vasoconstrictors should be used with caution (lower dose and careful monitoring) in patients with AICDs and there are certain procedures where interference with an AICD is possible (especially MRI) (Table 5.20). Patients with AICDs do not need antibiotic cover to prevent endocarditis.

CARDIOMYOPATHIES

General aspects

Cardiomyopathy (from the Latin) means a heart muscle disease. Extrinsic or specific cardiomyopathies include those associated with IHD/CAD; nutritional diseases; hypertension; cardiac valvular disease; inflammatory diseases; or systemic metabolic disease. Intrinsic cardiomyopathy has a number of causes, including drug and alcohol toxicity, certain infections (including hepatitis C), and various genetic and idiopathic causes. Alcohol is a major cause. Four separate and distinct types of intrinsic cardiomyopathy are recognized (Box 5.11).

Clinical features

Frequently, there are no symptoms until complications develop. Most affected individuals have a normal quality and duration of life. Congestive

Box 5.11 Intrinsic cardiomyopathies

- Arrhythmogenic right ventricular cardiomyopathy (ARVC)
- Dilated cardiomyopathy (DCM)
- Hypertrophic cardiomyopathy (HCM)
- Restrictive cardiomyopathy (RCM), the least common form: can be idiopathic or secondary to radiation therapy or rare disorders, such as endomyocardial fibrosis (tropical hypereosinophilic syndrome), infiltrative disorders (amyloidosis, sarcoidosis) and metabolic disorders (Gaucher disease, mucopolysaccharidoses, Fabry disease, carcinoid syndrome)

cardiac failure (CCF) with atrial fibrillation or other serious complications (mitral regurgitation, angina, sudden death or infective endocarditis) can, however, result. Exercise-induced sudden death is a constant risk.

General management

Medical care prolongs life to a variable degree and aims to ameliorate symptoms. Medication, ablation, an implanted pacemaker, defibrillator or ventricular assist device (VAD), or cardiac transplantation often becomes necessary.

Dental aspects

Adrenaline (epinephrine) should be used in limited amounts, and GTN or similar drugs are contraindicated. Conscious sedation with nitrous oxide and oxygen may be used if necessary, with the approval of the physician. Patients with cardiomyopathy are a poor risk for GA because of alcoholism, arrhythmias, cardiac failure or myocardial ischaemia.

If angina pectoris, MI or fibrillation occurs, oxygen should be given and preparations made to perform CPR and to activate the emergency response system.

ARRHYTHMIAS (DYSRHYTHMIAS)

Normally, the heart chambers (atria and ventricles) contract in a co-ordinated manner initiated by an electrical signal in the sinoatrial node (sinus node or SA node), a small mass of heart tissue with characteristics of both muscle and nerve, located in the right atrial wall. The electrical signal is conducted through the atria, stimulating them to contract, and then passes through the atrioventricular node (AV node), where the impulse transmission to the ventricles is delayed transiently while the atria complete their contraction (consistent with the P wave on the ECG) and empty their blood into the ventricles. (These are already partially filled with blood that has drained passively from the large veins – vena cava on the right side and the pulmonary veins on the left side – into the atria during diastole.) Once the impulse leaves the AV node, it descends in the interventricular septum via the bundle of His and reaches the Purkinje fibres of the ventricle walls, causing them to contract (i.e. the ventricular component of systole), as noted on the ECG by the QRS complex. Following excitation and depolarization, the conductive tissue repolarizes to be ready for the next pulse.

In adults, the heart beats regularly, the resting rate ranging from 60 to 100 beats/min. In children the rate is much faster.

General and clinical aspects

Arrhythmia is any disorder of heart rate or rhythm; the heart beats too quickly (tachycardia), too slowly (bradycardia) or irregularly. Some

Table 5.21 Arrhythmia-inducing drugs and foods

Tachycardias	Bradycardias	Other arrhythmias
Adrenaline (epinephrine)	Beta-blockers	Adrenaline (epinephrine)
Alcohol	Calcium-channel blockers	Alcohol
Atropine		Amphetamines
Caffeine	Digitalis	Cocaine
Nicotine	Morphine	Digitalis
		Procainamide
		Quinidine
		Tricyclics

arrhythmias are so brief (e.g. a temporary pause or premature beat) that the overall heart rate or rhythm is not greatly affected. However, if, for any period of time, the heart fails to beat properly (too fast or too slow, regular or irregular) and pumps ineffectively, the lungs, brain and all other organs may malfunction.

Most arrhythmias arise from problems in the cardiac electrical system but some may be provoked by stress, catecholamines or drugs (illegal, prescription or over-the-counter), as well as alcohol, tobacco, foods and other substances (Table 5.21). Arrhythmias may further arise from cardiac, respiratory, autonomic or endocrine disease, fever, hypoxia or electrolyte disturbances. Surgery is sometimes implicated; the trigeminocardiac reflex (TCR), which may be associated with surgery, consists of bradycardia, hypotension, apnoea and gastric hypermotility. The parasympathetic nerve supply to the face is carried in the trigeminal nerve; alternative afferent pathways must exist via the maxillary and/or mandibular divisions, in addition to the commonly reported pathway via the ophthalmic division of the trigeminal in the classic oculocardiac reflex. The efferent arc involves the vagus. Central stimulation of the trigeminal nerve can cause reflex bradycardic responses during maxillofacial or ocular surgical procedures or neurosurgery, but some have followed oral or perioral procedures. Cardiac surgery may also be followed by arrhythmias; junctional ectopic tachycardia is then the most common arrhythmia, presumed to be initiated from a small focus of abnormal automaticity somewhere in the AV node or bundle of His.

The significance of arrhythmias varies from the fatal to the inconsequential (Table 5.22), some being regarded as normal variants, others merely annoying – such as an abnormal awareness of heart-beat (palpitations) – but some reducing cardiac efficiency and output and causing palpitations with dyspnoea, angina or syncope. Some can be life-threatening and lead to cardiac arrest. Others cause no symptoms but still predispose to potentially life-threatening complications such as cerebrovascular events (stroke and transient ischaemic attacks).

Types of arrhythmia

Up to 15% of the population have arrhythmias. There is a wide range of arrhythmias, which may be classified by rate (tachycardia, bradycardia), mechanism (automaticity, re-entry, fibrillation) or origin (Table 5.23). Extrasystoles are the most common true arrhythmia. Sinus arrhythmia is not a true arrhythmia but a normal phenomenon of mild acceleration and slowing of the heart rate that occurs with breathing in and out; it is usually quite pronounced in children and lessens with age.

Table 5.24 shows agents used to treat arrhythmias.

Information about arrhythmias is available from the American Heart Association (AHA) at <http://www.heart.org/>, under the ‘Conditions’ tab (accessed 30 September 2013).

Table 5.22 Arrhythmias posing different levels of risk to the patient (usual level of risk)

High	Medium	Low	None
Atrial fibrillation	Atrial arrhythmias which are symptomatic or under treatment	Atrial arrhythmias which are asymptomatic and not under treatment	Bradycardia in athletes
Bradycardia plus other arrhythmia	Drug-induced arrhythmias	Premature ventricular beats	Extrasystoles (atrial)
Bradycardia plus pacemaker	Pacemaker		
Irregular pulse	Paroxysmal supraventricular tachycardia		
ventricular extrasystoles	Ventricular arrhythmias which are symptomatic or under treatment		
Irregular pulse plus bradycardia			
Tachycardia plus other arrhythmia			
Ventricular fibrillation			
Ventricular tachycardia			
Wolff–Parkinson–White syndrome			

Table 5.23 Significance of arrhythmias

Arrhythmia	Description	Significance
Atrial fibrillation	Quivering	Dangerous because of thromboses
Bradycardia	Too slow	Occasionally dangerous
Premature contraction	Early beat	May be insignificant
Tachycardia	Too fast	Can be dangerous
Ventricular fibrillation	Fluttering	Emergency; cardiac arrest

Table 5.24 Antiarrhythmic agents

Type of arrhythmia	Examples of drugs used	
	Main	Others
Supraventricular	Verapamil	Adenosine, digoxin, beta-blockers
Supraventricular and ventricular	Disopyramide	Amiodarone, beta-blockers, flecainide, procainamide, propafenone
Ventricular	Lidocaine	Mexiletine, moracizine

EXTRASYSTOLES (ECTOPICS)

Extrasystoles are essentially extra beats, or contractions, which occur when there is electrical discharge from somewhere in the heart other than the SA node. Extrasystoles can sometimes be a feature of cardiac disease, and even *in people with otherwise apparently normal hearts*, extrasystoles occurring during exercise and in the recovery period after exercise can have increased mortality risk.

Premature beats are common in normal children and teenagers. An extra beat comes sooner than normal; then there is a pause that causes the next beat to be more forceful. Most people have them at some time and usually no cause can be found. Those without identifiable cause

usually disappear on their own. Only occasionally are premature beats caused by cardiac disease or injury.

Atrial extrasystoles (premature atrial contractions; PACs) are common in healthy people with normal hearts, especially with advancing age, but can also occur when there is increased pressure on the atria, such as in cardiac failure or mitral valve disease; in such cases, they may arise prior to the development of atrial fibrillation. Atrial extrasystoles may also be of little consequence but are exacerbated by alcohol and caffeine (as a former UK Prime Minister found!) (see [Table 5.22](#)).

The ‘sick sinus syndrome’ is when the SA node fires irregularly, the heart rate sometimes changing back and forth between a bradycardia and a tachycardia.

Ventricular extrasystoles occur when the abnormal discharge arises from the ventricles; though they can occur in people with normal hearts, they are more commonly found in heart disease. Ventricular extrasystoles (ectopics) are the commonest type of arrhythmia arising after MI and may also occur in severe left ventricular hyper-trophy, hypertrophic cardiomyopathy and congestive cardiac failure. The British Heart Foundation has stated that ventricular ectopics, in the absence of structural heart disease or a family history of sudden death, are benign and do not require specialist intervention or specific drug therapy.

TACHYCARDIAS

A tachycardia is a resting heart rate of more than 100 beats/min in an adult. It may result in palpitations but is not *necessarily* an arrhythmia.

Sinus tachycardia is an increased heart rate that is a normal response to exercise or emotional stress, mediated by the effects of the sympathetic nervous system and catecholamines on the SA node. Hyperthyroidism and ingested or injected substances, such as cocaine, ecstasy, amphetamines or caffeine, can produce or exaggerate this effect. In sinus tachycardia, the heart beats regularly. It may also be a response to conditions such as:

- anxiety
- emotional distress
- fever
- fright
- strenuous exercise.

Less commonly, it may indicate:

- anaemia
- haemorrhage
- heart muscle damage
- hyperthyroidism.

Treatments address the cause of the sinus tachycardia rather than the condition itself.

Supraventricular tachycardias

Supraventricular tachycardia (SVT or atrial tachycardia) is a fast heart rate that starts in the cardiac upper chambers ([Table 5.25](#)). Some forms are called paroxysmal atrial tachycardia (PAT) or paroxysmal supraventricular tachycardia (PSVT). The rapid heart beat does not allow enough time for the heart to fill before it contracts, so blood flow to the rest of the body is compromised. SVT is most commonly seen in:

- children
- females

Table 5.25 *Supraventricular tachycardias*

Tachycardia	Heart rate	Frequency	Precipitants
<i>Irregular heart rhythm</i>			
Atrial fibrillation	Often rapid onset, rate 60–220 beats/min	Most common pathological tachycardia	Older age, male sex, hypertension, cardiac disease, pulmonary embolism, hyperthyroidism, surgery
Multifocal atrial tachycardia	Gradual onset, rate 100–150 beats/min		Pulmonary disease, theophylline
Atrial premature contractions	Gradual onset, rate 100–150 beats/min		Caffeine or other stimulants
<i>Regular heart rhythm</i>			
Sinus tachycardia	<220 beats/min	Most common supraventricular tachycardia	Physiological; sepsis, hypovolaemia, pain, fear, hyperthyroidism
Atrial flutter	Rapid onset, rate 140–150 beats/min	Common tachycardia	Cardiac disease (congenital heart disease, myocardial infarction, atrial fibrillation); chronic obstructive pulmonary disease, cardiac surgery
Group consisting of atrioventricular nodal re-entrant tachycardia, atrioventricular reciprocating (re-entrant) tachycardia, and atrial tachycardia	Rapid onset, rate 150–250 beats/min	Common tachycardias Atrioventricular nodal re-entrant tachycardia most common among persons >20 y of age, atrioventricular reciprocating tachycardia more frequent in children. Atrial tachycardia is least common of these. Occasionally Ebstein anomaly	

- anxious young people
- people who are fatigued
- people who drink large amounts of coffee
- people who drink alcohol heavily
- people who smoke heavily.

Some people with SVT have no symptoms, while others may experience:

- angina
- dizziness
- dyspnoea
- light-headedness
- palpitations.

In extreme cases, SVT may cause:

- unconsciousness
- cardiac arrest.

Treatment of SVT, considered if episodes are prolonged or frequent, may include:

- vagal stimulation by:
 - ◆ carotid sinus massage – gentle pressure on the neck
 - ◆ gentle pressure on the eyeballs with eyes closed
 - ◆ Valsalva manoeuvre – holding the patient's nostrils closed while blowing air through the nose
- reduction of coffee, alcohol and tobacco use
- sedation
- antiarrhythmic drugs (Table 5.26 and Appendix 5.3)
- cardiac ablation, defibrillation or cardioversion; these may be needed if the measures above do not work (see later; Table 5.27), while anticoagulants and antiplatelet drugs are often also used to reduce the risk of clotting.

Table 5.26 *Treatment of arrhythmias*

Heart rhythm changes	Usual treatments
Atrial fibrillation (AF)	Cardioversion Digoxin Anticoagulants advocated
Atrial tachycardia	–
Bradycardia (pathological)	Atropine may be indicated May need a pacemaker
Extrasystoles	–
Long QT syndrome	Avoidance of precipitants Beta-blockers
Paroxysmal supraventricular tachycardia (SVT)	Vagal pressure or intravenous adenosine Cardiac glycosides or verapamil may be needed
Sinus tachycardia	–
Ventricular fibrillation (VF)	Defibrillation For acute VF, flecainide and disopyramide are indicated. Lidocaine is the usual treatment but bretylium or mexiletine may be required Implantable cardiac defibrillators may be used
Ventricular tachycardia	Cardioversion Lidocaine
Wolff–Parkinson–White syndrome	Medications, or catheter ablation to destroy the abnormal pathway

Wolff–Parkinson–White (WPW) syndrome

This is a syndrome of ventricular pre-excitation due to an accessory conduction pathway (the bundle of Kent) conducting anterogradely. Many people with WPW syndrome have a tachycardia, and may have dizziness, palpitations or faints. It is associated with atrial fibrillation

Table 5.27 *Relevant treatments in certain arrhythmias*

Simple	Medical	Drugs	Surgery
Vagal manoeuvres – can stop or slow some supraventricular arrhythmias:	Catheter ablation	Drugs used to slow a fast heart rate – beta-blockers (metoprolol, atenolol)	Coronary artery bypass grafting (CABG)
• Gagging	Cardioversion	Calcium-channel blockers (e.g. diltiazem and verapamil) and digoxin (digitalis) – often used to treat atrial fibrillation	Maze surgery (small cuts or burns in the atria) – can help atrial fibrillation
• Holding breath and bearing down (Valsalva manoeuvre)	Implantable cardiac defibrillator	Amiodarone, sotalol, flecainide, propafenone, dofetilide, ibutilide, quinidine, procainamide and disopyramide – used to restore normal heart rhythm	
• Immersing face in ice-cold water		Anticoagulants	
• Coughing	Pacemaker		
• Gently pressing fingers on eyelids			

and, in rare instances, results in ventricular fibrillation. Some people with WPW syndrome have no symptoms but still have an increased risk for sudden death.

Treatment depends on symptom severity and frequency, risk for future arrhythmias and patient preference. If medication fails to work, cardioversion (shock) may be used to correct the heart rate. Radiofrequency ablation is the usual therapy to block the unwanted conduction shortcut.

Paroxysmal supraventricular tachycardia (PSVT)

This is an atrioventricular nodal re-entrant tachycardia that occurs most often in young people and infants. Excessive smoking, caffeine and alcohol use, and digitalis toxicity also predispose to it. PSVT may remit spontaneously but can recur. Electrical cardioversion (shock) is successful in conversion of PSVT to a normal sinus rhythm in many other cases. Another way to convert a PSVT rapidly is to administer adenosine or verapamil.

Atrial fibrillation (AF)

Atrial fibrillation is the most common arrhythmia, with a prevalence of 1.0 % in the general population. The risk is fivefold greater in those over 65 years. AF is a common end-point for many cardiac diseases that cause atrial myocyte damage and fibrosis. People with AF do not necessarily have symptoms but others may experience one or more of:

- chest pain or pressure
- dizziness
- dyspnoea
- fainting or confusion
- fatigue
- rapid and irregular heart beat
- sweating
- weakness.

There are 3 types of AF; Paroxysmal AF (last 2-7 days); Persistent AF (longer than 7 days and needs medication or cardioversion) or Permanent AF. AF is associated with thrombus formation, particularly in the left atrial appendage. Both aspirin, clopidogrel and anticoagulants (warfarin or NOACs) have been shown to reduce this and the consequent stroke risk but a patient's absolute risk depends on other risk factors like age, left ventricular function, hypertension and previous thromboembolic events. After stroke risk has been managed, the basis of treatment is either to control the ventricular rate with drugs that block the AV node or to try to maintain sinus rhythm, and restore the heart to a normal rate and rhythm.

Atrial flutter

Rapidly fired signals cause the muscles in the atria to contract quickly, leading to a very fast, steady heart beat. Features may include:

- angina
- dizziness
- dyspnoea
- fainting
- light-headedness
- palpitations.

Ventricular tachycardias

Ventricular tachycardia is usually the result of heart disease, most commonly a previous MI, and is dangerous as it can result in chest pain, cardiac failure, syncope or ventricular fibrillation. In ventricular tachycardia, the rapid heart beat does not allow enough time for the heart to fill before it contracts, so blood flow to the rest of the body is compromised. Causes include:

- cardiac problems, including:
 - ◆ coronary heart disease
 - ◆ cardiomyopathy
 - ◆ mitral valve prolapse
 - ◆ valvular heart disease
- other causes, such as:
 - ◆ sarcoidosis
 - ◆ drugs (e.g. digitalis and antiarrhythmics)
 - ◆ change in posture
 - ◆ exercise
 - ◆ emotional excitement
 - ◆ vagal stimulation.

Ventricular fibrillation is effectively a type of cardiac arrest and is imminently life-threatening. It is typically a consequence of MI or structural heart disease, occasionally of idiopathic fibrosis affecting the conduction mechanism, thyrotoxicosis, halothane anaesthesia, or adrenaline (epinephrine), cocaine or digitalis overdose.

Clinical features

These are dizziness, light-headedness, collapse or cardiac arrest.

General management

Treatment may include:

- cardioversion
- drugs

Table 5.28 Conduction disorders

Type of block	Comments	Management
Bundle branch	One ventricle contracts a fraction of a second slower than the other; often symptomless; may show on ECG	Usually no treatment is required
First-degree heart	The electrical impulse moves through the atrioventricular node more slowly than normal. The heart beat usually has a slower rate and may cause light-headedness and dizziness, or no noticeable symptoms. Can be caused by certain drugs (digitalis, beta-blockers and calcium-channel blockers)	May not require specific treatment
Second-degree heart	Some electrical signals from the atria do not reach the ventricles, resulting in 'dropped beats'. Can be classified as Mobitz type 1 (Wenckebach) and may not cause noticeable symptoms; or Mobitz type 2, typified by symptoms such as chest pain, syncope, faintness and palpitations, breathing difficulties (e.g. shortness of breath with exertion), rapid breathing, nausea and fatigue	Second-degree type 1 may not require treatment but can be a forerunner for type 2 and needs to be monitored regularly Pacemaker may be indicated
Third-degree or complete heart	The electrical impulse does not pass from the atria to the ventricles. Complete heart block in adults is caused by heart conditions, heart surgery or drug toxicity. People with third-degree heart block experience irregular and unreliable heart beats	Because of the potential for cardiac arrest, a permanent pacemaker is often indicated to treat complete heart block

- radiofrequency ablation
- surgery.

BRADYCARDIAS

Bradycardia is a slow cardiac rhythm (<60 beats/min). This may be caused by a slowed electrical signal from the SA node (sinus bradycardia), a pause in the normal activity of the SA node (sinus arrest), or blocking of the impulse between the atria and ventricles (atrioventricular block or heart block). Bradycardia may be unimportant in a young person and is often found in athletes. Physically active adults frequently have a resting heart rate slower than 60 beats/min but it causes no problems. The heart rate may fall below 60 beats/min during deep sleep.

Bradycardia in an older person, however, especially when associated with heart disease, can cause sudden loss of consciousness (syncope). Among the more common causes are IHD, drugs (especially digitalis), surgery, connective tissue disorders, including Sjögren syndrome, and, in the past, rheumatic fever.

First-degree heart block (mild heart block) may only be detectable as PR prolongation on an ECG.

Second-degree heart block (type 1 second-degree heart block [Mobitz I or Wenckebach] or type 2 second-degree heart block [Mobitz II]) may be symptomatic.

Third-degree heart block (complete heart block), when the ventricle contracts at its intrinsic rate of about 30–40 beats/min, causes severely reduced cardiac output with pallor or cyanosis, dyspnoea and synopal (Stokes–Adams) attacks. Such patients may also have convulsions.

Causes of bradycardia include:

- conduction pathway problems (Table 5.28)
- heart disease
- hypothermia
- SA node problems.

Clinical features

The main features arise from cerebral hypoxia and include:

- dizziness
- fatigue
- fainting or near-fainting spells
- light-headedness
- cardiac arrest, in extreme cases.

Severe, prolonged, untreated bradycardia can cause:

- angina
- cardiac failure
- hypertension
- syncope.

General management

Treatment is not usually needed, except with prolonged or repeated symptoms, when bradycardia can normally be corrected with a pacemaker. Medication may need to be adjusted.

LONG QT SYNDROME

Patients with long QT syndrome (LQTS) are liable to sudden death. They have lengthening of the cardiac cycle repolarization phase, which shows on ECG. The typical changes can include a long QT interval (the time between the start of the Q wave and the end of the T wave) with delayed ventricular repolarisation; T wave abnormalities; and progression to torsades de pointes (TdP; a French term meaning 'twisting of the spikes') and ventricular fibrillation, especially in females, and sometimes to sudden cardiac death. LQTS affects about 1–2% of the population and is probably the second most common cause of sudden cardiac arrest in children and young adults, next to hypertrophic cardiomyopathy. More than half of individuals with inherited LQTS die within 10 years. A history of unexplained syncope in a young person (age 10–25 years usually), or a family history of sudden death, should raise suspicions.

LQTS often is inherited, and there are several known types:

- LQTS 1, with arrhythmias triggered by emotional stress or exercise (especially swimming)
- LQTS 2, with arrhythmias triggered by extreme emotions, such as surprise, or by noise, exercise or rest
- LQTS 3, with arrhythmias triggered by a slow heart rate during sleep.

LQTS 4, 5 and 6 are rare, as is the Jervell and Lange-Nielsen syndrome (LQTS and deafness). The term Romano-Ward syndrome is sometimes used when there is LQTS without deafness. LQTS can also be acquired, in which case it is mainly caused by a number of factors (Appendix 5.4). Adrenaline (epinephrine), stress, drugs such as olanzapine, erythromycin

or azithromycin, and use of more than one psychotropic, such as a selective serotonin reuptake inhibitor (SSRI), increase the QT interval and pose a hazard of TdP, especially in:

- cardiac disease
- female patients
- older patients (>65 years)
- hypokalaemia.

Clinical features

The clinical presentations of LQTS range from dizziness to syncope and sudden death. Sometimes families are mistakenly diagnosed with 'seizure disorders' when the cause of their 'seizures' is brain hypoxia caused by a cardiac problem. Some children with LQTS are misdiagnosed as having 'exercise-induced' asthma.

General management

The diagnosis of LQTS is based on the clinical features, family history and ECG. However, for about 10% of people with LQTS, the condition is not apparent on an ECG until it is triggered by drugs such as those mentioned above.

Lifestyle changes and treatments that may prevent complications include:

- avoidance of competitive physical activity
- avoidance of startling noises
- increase in dietary potassium
- beta-blockers for LQTS 1 and 2 (mexiletine for some types)
- implantable cardiac devices
- left stellectomy.

Dental aspects

Evaluation by a cardiac specialist is advisable before any dental intervention. Stress and GA must be avoided. Beta-blockers are often used. Use of anxiolytic protocols, avoidance of adrenaline (epinephrine) and other drugs that might prolong the QT interval (see Appendix 5.4 and <http://crediblemeds.org/everyone/drugs-avoid-congenital-lqts/?rf=All>), and provision of treatment in a setting in which emergencies can be managed expeditiously are appropriate. LA containing adrenaline or bupivacaine, antimicrobials such as erythromycin, azole antifungals and GA-associated agents, including ketamine, succinylcholine and atropine, are contraindicated, particularly if there is any other factor predisposing to TdP.

Lidocaine and mepivacaine, which have a lesser cardiac effect than some other local anaesthetics, may be preferred for analgesia. Midazolam or propofol may be used. Isoflurane is the GA agent of choice.

If an LQTS arrhythmia progresses to sudden cardiac arrest, the only known treatment is prompt shock from an automated external defibrillator (AED).

SUDDEN ARRHYTHMIA DEATH SYNDROME (SADS)

This term refers to the sudden death of an apparently fit and healthy young person. The conditions responsible for SADS precipitate ventricular arrhythmia, the main causes being the uncommon ion channelopathies, including:

- long QT syndrome (LQTS)
- Brugada syndrome (an inherited disorder characterized by one of several ECG patterns with incomplete right bundle

branch block and ST elevations in the anterior precordial leads predisposing to ventricular tachycardia, with syncopal episodes usually in sleep, that can be misinterpreted as epilepsy. An ICD may be considered. Drugs to be avoided include bupivacaine, carbamazepine, ketamine and propofol (see <http://www.brugadadrugs.org>)

- catecholaminergic polymorphic ventricular tachycardia (PVT)
- progressive cardiac conduction defect (PCCD)
- short QT syndrome
- early repolarization syndrome
- sodium channel disease
- familial atrial fibrillation.

Less frequently, SADS can be caused by extra electrical pathways or cardiomyopathies. In about 1 in every 20 cases of all-age sudden cardiac arrest, and up to 1 in 5 of young cases, no definite cause can be found.

GENERAL MANAGEMENT OF ARRHYTHMIAS

An ECG is needed to diagnose and assess the risk of an arrhythmia. Management includes:

- *Radiofrequency ablation (catheter ablation)*. This is used for most simple arrhythmias and many more complex rhythm disorders (e.g. atrial fibrillation and ventricular tachycardia). Catheter ablation uses a flexible catheter with an electrode at its tip, which is introduced under radiographic guidance (fluoroscopy) via the blood vessels. A burst of radiofrequency energy or cautery with heat, cold, or electrical or laser probes allows abnormal areas of conduction to be located and destroyed.
- *Cardiovascular implantable electronic devices (CIEDs)*. If the arrhythmia is serious, the patient may need to have one of two devices implanted under the skin: a cardiac pacemaker (CP) or an automatic implantable cardioverter defibrillator (AICD). Pacemakers and AICDs (also called cardiovascular implantable electronic devices [CIEDs] or implantable rhythm devices [IRDs]) work by sensing intrinsic cardiac electrical activity. The number of patients with CIEDs is rising dramatically due to an ageing population, and clinical trials show benefits in reducing both mortality and morbidity (<http://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001150/>; accessed 30 September 2013).

Pacemakers

A pacemaker monitors the cardiac electrical impulses and, by delivering low-energy electrical pulses, helps overcome the faulty electrical signalling. Pacemakers may be needed for people with:

- Heart block or sick sinus syndrome
- Atrial fibrillation
- Cardiac syncope
- Cardiac failure.

Pacemakers can create a more normal rhythm by:

- speeding up a bradycardia
- controlling tachyarrhythmias
- coordinating electrical signalling between the atria and ventricles
- coordinating electrical signalling between ventricles (cardiac resynchronization therapy [CRT])
- ensuring that the ventricles contract normally if there is atrial fibrillation

Fig. 5.11 Pacemaker. (Courtesy of Google).

- preventing dangerous arrhythmias caused by the long QT syndrome.

Some modern pacemakers can also monitor blood temperature, breathing rate and other factors.

Pacemakers can be:

- *temporary* – used to treat short-term heart problems, such as bradycardia caused by an MI, cardiac surgery or a drug overdose
 - *permanent* – used to control long-term arrhythmias
- and
- *single-chamber* – use one lead in the right atrium or right ventricle to pace the heart; often employed for patients whose SA node signals too slowly
 - *dual-chamber* – use two leads, one in the right atrium and one in the right ventricle; the electrical pulses are timed to ensure that the beats in the atria and ventricles are synchronized.

Modern pacemakers have non-rechargeable lithium batteries that can last up to 10 years, are bipolar and are implanted transvenously via the subclavian or cephalic vein. They are typically sited in the right ventricle; on the chest wall, either within the pectoral muscle or beneath the skin (Fig. 5.11); or in the abdominal wall. Most work mainly on demand, are rate-adaptive and can be programmed to adjust the heart rate by tracking sinus node activity or by responding to sensors that monitor body motion and depth or rate of respiration. Adjustments to the pacemaker can be made non-invasively, using a specially designed radiofrequency programmer, with a wand placed on the skin over the device. Patients should carry a pacemaker registration card bearing details of the make and model.

Automatic implantable cardioverter defibrillators (AICDs)

Electric shock across the heart (defibrillation or cardioversion), either externally to the chest or internally to the heart via implanted electrodes, may be needed, via:

- *defibrillation* – the application of a shock that is *not synchronized*; this is needed for the chaotic rhythm of ventricular fibrillation and for pulseless ventricular tachycardia
- *cardioversion* – the application of a shock *synchronized* to the underlying heart beat; this is used for the treatment of supraventricular tachycardias, such as atrial tachycardia, including atrial fibrillation.

Defibrillation or cardioversion accomplished by an AICD is the most successful treatment to prevent ventricular fibrillation and is 99% effective in stopping life-threatening arrhythmias. An AICD is similar to a pacemaker and most newer models can act as both pacemakers and defibrillators. If the AICD detects an irregular ventricular rhythm, it will use low-energy electrical pulses to restore normal rhythm; if the low-energy pulses fail to restore normal rhythm, the AICD will switch to high-energy pulses for defibrillation. An AICD also can use high-energy pulses to treat life-threatening arrhythmias, especially those that can cause sudden cardiac arrest. Though the high-energy pulses last only a fraction of a second, they can be painful. An AICD continuously monitors the heart rhythm, automatically functions as a pacemaker for heart rates that are too slow, and delivers life-saving shocks if a dangerous rhythm is detected. Because AICDs must be built both to pace and to deliver shocks, they are larger than pacemakers and their batteries do not last as long.

Interference with pacemakers/defibrillators

Soon after the introduction of non-competitive, ‘demand’ pacemakers, examples of extraneous signals causing undesired triggering or inhibition of pacemaker output were identified; this was termed electromagnetic interference (EMI). Coupled with the increase in the number of patients with CIEDs is the proliferation of technology that emits electromagnetic signals, which can potentially interfere with it. EMI has two components: an electric and a magnetic field. EMI can come from radiofrequency (RF) waves (e.g. radio and television transmitters, electrical power and electrosurgery); microwaves (e.g. radar transmitters, mobile phones and microwave ovens); ionizing radiation; acoustic radiation; static and pulsed magnetic fields; and electrical currents.

High-frequency external electromagnetic radiation, ionizing radiation, ultrasonic and EMI from a wide range of sources can interfere with the sensing function of both pacemakers and AICDs (Table 5.29). The most frequent responses of CIEDs to EMI are inappropriate inhibition or triggering of pacemaker stimuli, reversion to asynchronous pacing, and spurious AICD tachyarrhythmia detection.

Device interactions have occurred in hospitals, where EMI sources are ubiquitous, especially from exposures to:

- radiation
- electrocautery
- MRI (Appendix 5.5).

MRI is the main EMI contraindication for patients with pacemakers or AICDs. EMI sources should be avoided where possible. Guidelines generally suggest that all handheld electronic devices be kept 15 cm away from an IRD. However, hermetic shielding in metal cases, filtering and interference rejection circuits, together with bipolar sensing, have made contemporary pacemakers and AICDs relatively immune to most EMI in household and workplace environments.

Sources of EMI

Many sources of EMI are predictable and avoidable. EMI can be conducted by direct contact (e.g. electrosurgery) or by contact with inadequately grounded equipment, or can radiate from a distance. The degree of EMI depends on the external source of power, distance from the device, signal duration, and its frequency, orientation and modulation. New technologies that use more of the electromagnetic spectrum (i.e. wireless telephones, electronic article surveillance [EAS] devices)

Table 5.29 Sources of possible interference with cardiac pacemaker function

Electrically coupled	Magnetic	Galvanic	Ultrasonic	Ionizing radiation
Medical sources				
Electrical appliances – particularly those with large motors and/or large power supplies. Problems more likely if appliance is in poor working condition, with motors or relays that are arcing or sparking	Magnetic resonance imaging (MRI)	Defibrillation/cardioversion Electrocautery Diathermy Transcutaneous electrical nerve stimulation (TENS)	Ultrasound equipment (see text) Lithotripsy	Radiotherapy
Non-medical sources				
Petrol-powered lawn mowers Petrol-powered saws High-voltage power lines Ham radios Arc welders Mobile phones High-power car ignition systems Metal detectors	Close proximity to powerful and large loudspeakers Induction furnaces, e.g. those used in steel industry Large generators, e.g. those used in power industry Electromagnets, e.g. those used in car-wrecking yards	Workplace situations (e.g. in electrical/computer manufacturing industry) Domestic situations (e.g. current leakage due to defective or poorly maintained house or appliance wiring)	Ultrasound equipment	Ionizing radiation sources
Comments				
Interference requires no direct contact with patient ^a	Interference requires no direct contact with patient ^a	Interference requires pacemaker patient to be in direct contact with electrical current ^a Disengaging contact from source of interference will usually return pacemaker to normal behaviour		

^aThe likelihood of interference from these sources of interference increases with the strength of the source and with the proximity of the pacemaker to the source.

have, however, reignited interest in EMI risks. Radiated EMI can arise from energy emitted for communication purposes or as an unintended effect of other electrical activity (e.g. motor operation in an electric razor). EMI from electric power can occur if patients are in proximity to high-voltage overhead power lines (accidentally or by occupation) or it may be caused by electrical appliances held close to or in direct contact with the chest. EMI from household appliances is more likely with improper grounding (Appendix 5.6).

Interference with pacemakers

The responses of pacemakers to interference are varied, usually transient and only seen while the patient remains in range of the source of interference; moving away from the source will usually return the device to its normal behaviour. The response largely depends on the interference signal characteristics and includes a single-beat inhibition (where the pacemaker may not pace the heart for a single cardiac cycle); total inhibition (where the pacemaker ceases to pace the heart); asynchronous pacing (where the pacemaker paces the heart at a fixed rate); and rate rise or erratic pacing rate. The most common pacemaker response to EMI is oversensing, which may cause transient or, rarely, permanent damage to the pacemaker. In extreme cases, where the interference is of a sufficiently high magnitude, the circuitry may be damaged, leading to persistently abnormal pacing. Modern bipolar pacemakers have improved titanium-insulated, interference-resistant circuitry and the risk of EMI is thus very small; the main and real hazard is with MRI because of the static magnetic, alternating magnetic and RF fields (Table 5.30). The pacemaker's stainless steel metal casing, and some of its components, can also trigger security devices, typically found in airports, shops and libraries, but the pacemaker function is *not* significantly affected by them. Brief exposure of a pacemaker to electromagnetic antitheft or surveillance devices causes no significant disruption of

Table 5.30 Oral health-care equipment effects on cardiac pacemakers

Equipment unlikely to cause interference	Equipment likely to cause interference
Amalgamator	Diathermy units
Composite curing lights	Electronic dental analgesia units
Dental chair or light	Electrosurgical units
Dental handpieces	Ferromagnetic (magnetostrictive) ultrasonic scalers
Dental radiography unit	Lithotripsy units
Electric toothbrushes	Magnetic resonance imaging (MRI)
Electronic apex locators	Transcutaneous electrical nerve stimulation (TENS) units
Electronic pulp testers	Ultrasonic instrument baths
Microwave ovens	
Piezoelectric ultrasonic scalers	
Sonic scalers	

function. Digital mobile phones, and even television transmitters and faulty or badly earthed equipment, may also cause EMI, but the risk is very small and only present when they are used close to the pacemaker. With most digital phones, EMI has no effect on most pacemakers now in use unless the phone is closer than about 15 cm to the implanted pacemaker. Domestic electrical appliances – even remote controls, CB radios, electric blankets, heating pads, shavers, sewing machines, kitchen appliances and microwave ovens – are safe, but some old microwave ovens (20 years or older) may leak and cause a pacemaker temporary confusion.

If a pacemaker does shut off, all possible sources of interference should be switched off and the patient given CPR in the supine position. Artificial respiration should force the heart to resume its rhythm and the pacemaker to restart.

Patients with pacemakers do not need antibiotic cover to prevent endocarditis.

Interference with AICDs

If the AICD's magnetic switch is affected by an external magnetic field, erroneous detection and shocks may occur. AICDs are also subject to noise that can be misinterpreted as ventricular tachycardia or ventricular fibrillation, with consequent inappropriate delivery of shocks. Not only will an AICD trigger airport security alarms but also the use of strong magnets over the device may adversely affect its function and even render it non-operational. It is sensible to alert security staff to the presence of an AICD.

Patients with AICDs do not need antibiotic cover to prevent endocarditis.

DENTAL ASPECTS OF ARRHYTHMIAS

Most sudden cardiac arrests arise during endogenous adrenaline (epinephrine) peak levels (8–11 a.m.) and appointments therefore are best made for late morning or early afternoon. Arrhythmias can be induced, particularly in older patients and those with IHD or aortic stenosis, by:

- manipulation of the neck, carotid sinus or eyes (vagal reflex)
- LA (rarely)
- supraventricular or ventricular ectopics, which may develop during dental extractions or dentoalveolar surgery (these are rarely significant)
- drugs – GA agents, especially halothane (isoflurane is safer), digitalis, erythromycin or azole antifungal drugs, especially in patients taking terfenadine, cisapride or astemizole.

Ventricular fibrillation is clinically indistinguishable from asystole and is one of the most serious emergencies that may have to be managed in the dental surgery (Ch. 1). Syncope can also result from bradycardia, heart block or atrial tachycardia, and may need to be distinguished from a simple fainting attack by the slowness or irregularity of the pulse. Patients with atrial fibrillation may be treated with anticoagulants, which influence operative care (Ch. 8). As far as conscious sedation is concerned, a physician should decide whether this is acceptable for any given patient. GA is generally to be avoided. If unavoidable, it is a matter for an expert anaesthetist in hospital.

Dental aspects of CEIDs

Patients with CEIDs are usually advised to avoid elective dental care for the first few weeks after receiving the device. An aspirating syringe is recommended, as always for LA. Adequate analgesia is essential since pain can cause an outpouring of endogenous adrenaline (epinephrine). Vasoconstrictors such as adrenaline or levonordefrin in LA may raise BP or lead to atrial or ventricular arrhythmias, including fibrillation or even asystole. Intraosseous or intraligamental injections with LA agents containing vasoconstrictor should usually be avoided to prevent excessive systemic absorption. Gingival retraction cords containing adrenaline should be avoided. Adrenaline accidentally entering a blood vessel may (theoretically) increase hypertension and precipitate arrhythmias. BP tends to rise during oral surgery under LA, and adrenaline theoretically can contribute to this – though this is usually of little practical importance.

In large doses, LA may adversely interact with digoxin, non-selective beta-adrenergic-blocking drugs, antidepressants or cocaine. Adrenaline-containing LA should not be given in large doses to patients on these

agents; interaction may induce hypertension and cardiovascular complications. Mepivacaine 3% is thought to be preferable to lidocaine.

Dental aspects of pacemakers

Some dental electrical devices capable of generating electromagnetic radiation may pose a threat to dental patients with a pacemaker *but this is usually low-grade and only present if the devices are placed very close to the pacemaker* (see Table 5.30). Cardiac pacemakers usually now have two (bipolar) electrode leads and present few problems for dental treatment. In patients with pacemakers, MRI, electrosurgery, diathermy and transcutaneous nerve stimulation are contraindicated. Pacemaker single-beat inhibition of little consequence may occasionally be caused by dental equipment, such as piezoelectric ultrasonic scalers and ultrasonic baths, older ferromagnetic ultrasonic scalers, pulp testers, electronic apex locators, dental induction casting machines, belt-driven motors in dental chairs, and older radiography machines. Modern piezoelectric scalers have no significant effect, but activity rate-responsive devices may exhibit faster pacing rates. The only safe procedure under such circumstances is to avoid the use of all such equipment whenever a patient with a pacemaker is being treated, as it is difficult to assess the level of risk in any individual patient. Patients with pacemakers should be treated supine; electrical equipment kept over 30cm away; and rapid, repetitive switching of electrical instruments avoided. Diagnostic radiation and ultrasonography have no effect on pacemakers, even with cumulative doses, but faulty equipment may cause problems. After experiencing EMI, the IRD will usually revert to normal functioning as soon as the patient moves away from the EMI source. If procedures associated with increased EMI risk are indicated, the dependency status should be verified and the device temporarily reprogrammed to the optimal setting. Post-procedure device verification is recommended if there is any evidence of or any doubt about EMI.

Patients with permanent pacemakers do not need antibiotic cover to prevent endocarditis. If a temporary transvenous pacemaker is present, however, the physician should be consulted first.

Dental aspects of AICDs

Adrenaline (epinephrine) or other vasoconstrictors should be used with caution (lower dose and careful monitoring) in patients with AICDs.

AICDs may activate without significant warning, possibly causing the patient to flinch, bite down or perform other sudden movements that may result in injury to the patient or clinician. Some patients with AICDs may lose consciousness when the device is activated. This is less likely with newer devices, which initially emit low-level electrical bursts followed by stronger shocks if cardioversion does not follow immediately. After experiencing EMI, the AICD will usually revert to normal functioning as soon as the patient moves away from the EMI source. If procedures associated with increased EMI risk are indicated, the dependency status should be verified and the device temporarily reprogrammed to the optimal setting. Post-procedure device verification is recommended if there is any evidence of or any doubt about EMI.

Patients with AICDs do not need antibiotic cover to prevent endocarditis.

Several antiarrhythmic drugs can cause oral lesions. Verapamil, enalapril and diltiazem can cause gingival swelling; some beta-blockers may rarely cause lichenoid ulceration; and procainamide can cause a lupus-like reaction.

THYROID-RELATED HEART DISEASE

See also Chapter 6.

General aspects

Hyperthyroidism raises the metabolic rate and activity of the heart, and sensitizes the myocardium to sympathetic activity. The heart may be unable to meet the greater demands resulting from the raised metabolic activity of the rest of the body, particularly in the elderly.

Hypothyroidism slows the metabolic rate and activity of the heart and other tissues.

Clinical features

Untreated thyrotoxicosis causes tachycardia and a tendency to arrhythmias, which can lead to cardiac failure or MI, especially in the elderly.

Hypothyroidism slows the heart rate and myxoedema patients may have hypercholesterolaemia associated with atheroma. IHD often develops but is unusual in that it predominantly affects women.

General management

Beta-blockers are useful to control hyperthyroid heart disease.

Dental aspects

Patients with uncontrolled hyperthyroidism can sometimes be difficult to manage, as a result of heightened anxiety, hyperexcitability and excessive sympathetic activity.

Effective analgesia must be provided. An aspirating syringe should be used to give an LA, and LA containing adrenaline (epinephrine) should, in theory, be avoided because of the possible risk of dangerous arrhythmias. However, there seems little clinical evidence for this and the risk is probably real only if an overdose is given. There is no evidence that prilocaine with felypressin is any safer.

Gingival retraction cords containing adrenaline should be avoided.

Conscious sedation, preferably with nitrous oxide and oxygen, may be beneficial in that it calms the patient. The same reservations about GA apply to patients with uncontrolled thyroid heart disease as to those with other dangerous heart diseases.

Hypothyroid patients may be at risk in the dental surgery if they have CAD. Sjögren syndrome is occasionally associated. In severe myxoedema, diazepam and other CNS depressants can precipitate coma.

PULMONARY HEART DISEASE (COR PULMONALE)

General aspects

Cor pulmonale is heart disease resulting from the excessive load imposed on the right ventricle by diseases of the lungs or pulmonary circulation, especially chronic obstructive pulmonary (airways) disease (COPD, COAD; Ch. 15).

Clinical features

Right ventricular hypertrophy may lead to right-sided failure with systemic venous congestion and persistent hypoxia. In the early stages, there is dyspnoea, a chronic cough, wheezing and often cyanosis. Later, there is also ankle oedema and ascites.

General management

Oxygen, diuretics, vasodilators, salbutamol and ipratropium are among the measures that may be needed.

Dental aspects

Ipratropium can cause a dry mouth.

Local analgesia is the main means of pain control. Conscious sedation with diazepam or midazolam is contraindicated because of the respiratory depressant action in a hypoxic patient. Nitrous oxide and oxygen may be acceptable. Intravenous barbiturates are also contraindicated because of their respiratory depressant effect.

KAWASAKI DISEASE (MUCOCUTANEOUS LYMPH NODE SYNDROME)

General aspects

Kawasaki disease is an acute febrile illness with lymphadenopathy and desquamation of lips, fingers and toes, simulating scarlet fever and erythema multiforme. It is now a considerably more common cause of severe childhood heart disease than rheumatic fever in many countries. It is significantly more prevalent in Japanese and Korean people.

Although an infection is probably causal, presumably in persons of certain genetic backgrounds, no agent has yet been consistently isolated. Superantigens (bacterial toxins that stimulate T lymphocytes) are another possible cause. The main pathological process is a widespread vasculitis, which can, in approximately 25%, affect the coronary arteries – with aneurysm formation.

Clinical features

Eighty per cent of affected children are aged less than 5 years, with a male preponderance in a ratio of more than 2 to 1.

Fever lasting at least 5 days, erythema and oedema of the extremities, followed by desquamation, a polymorphous rash, labial and oral mucosal erythema, cervical lymphadenopathy, conjunctival injection and mood changes (extreme misery) are seen. The mortality is 5–10%, death mainly stemming from MI secondary to aneurysmal thrombus formation.

General management

Erythrocyte sedimentation rate (ESR) and CRP are raised; liver function is abnormal; there may be pyuria and normocytic anaemia. Ultrasonography may show an enlarged gallbladder; ECG and echocardiography may demonstrate abnormalities; and lumbar puncture may provide evidence of aseptic meningitis. Patients should be admitted to hospital for intravenous gammaglobulin treatment. Aspirin or a systemic steroid is usually also given.

Dental aspects

Characteristic oral changes include a strawberry tongue, labial oedema, crusting or cracking of the lips, pharyngitis, oropharyngeal erythema and cervical lymphadenopathy – usually unilateral but occasionally massive. Facial palsy is sometimes seen, but is self-limiting and usually associated with cardiovascular disease. Treatment is unlikely to be given to a young child in the acute phase but, for a dental emergency, LA may be given. Conscious sedation is inappropriate and GA is contraindicated.

VALVULAR HEART DISEASE

RHEUMATIC FEVER

General aspects

Rheumatic fever sometimes follows a sore throat caused by certain strains of beta-haemolytic streptococci (*Streptococcus pyogenes*). Rheumatic fever is now a very rare disease in the Western world but is common in countries such as the Indian subcontinent, the Middle East and some of the Caribbean islands. Children between 5 and 15 years are predominantly affected.

Rheumatic fever may occasionally be followed by chronic rheumatic carditis with permanent cardiac valvular damage. The inflammatory reaction of rheumatic carditis appears to result from immunological cross-reactivity with streptococcal antigens and immunologically mediated tissue damage, which may lead, after the lapse of years, to fibrosis and distortion of the cardiac valves (chronic rheumatic heart disease).

Clinical features

A sore throat may be followed after about 3 weeks (2–26 weeks) by an acute febrile illness with pain flitting from one joint to another (migratory arthralgia). Usually there is resolution within 6–12 weeks without apparent after-effects. Pain in the large joints (which gives rheumatic fever its name) is conspicuous but heals without permanent damage in about 3 weeks.

Other effects may include: cerebral involvement – causing spasmodic involuntary movements (Sydenham chorea, St Vitus dance); a characteristic rash (erythema marginatum); lung involvement; and subcutaneous nodules (usually around the elbows).

The most serious cardiac complication is subendocardial inflammation, particularly along the lines of closure of the mitral and aortic valve cusps, resulting in the formation of minute fibrinous vegetations and later scarring. There is usually little detectable effect on cardiac function in the acute phase but, in unusually severe cases, myocarditis can cause death from cardiac failure. The essential features of chronic rheumatic heart disease are fibrotic stiffening and distortion of the heart valves, often causing mitral stenosis. This is essentially a mechanical, haemodynamic disorder, in which the defective valves may become infected at any time, leading to infective endocarditis. Cardiac failure can develop, often after many years.

General management

The clinical manifestations of acute rheumatic fever are so variable that the diagnosis is made only if at least two of the major criteria are fulfilled (Table 5.31).

Preceding streptococcal infection is confirmed by a high or rising titre of antistreptolysin O antibodies (ASOT), which is suggestive, but not diagnostic, of rheumatic fever; a low ASOT virtually excludes the diagnosis.

Streptococcal sore throat is an indication for treatment with antibiotics, usually penicillin. Prompt antimicrobial treatment (within 24 hours of onset) prevents the development of rheumatic fever in most cases. Complications such as cardiac failure are treated along conventional lines. Chorea may recur during pregnancy or in patients taking the contraceptive pill, but does not indicate recurrent carditis.

After an attack of rheumatic carditis, there is a risk of recurrence, and continuous antibiotic prophylaxis becomes necessary to lessen the risk of permanent cardiac damage. The drug of choice is usually

Table 5.31 Rheumatic fever: diagnostic criteria

Major	Minor
Carditis	Pyrexia
Polyarthritits	Arthralgia
Chorea	Previous rheumatic fever
Erythema marginatum	Raised ESR and CRP
Subcutaneous nodules	Characteristic ECG changes

oral phenoxymethylpenicillin until the age of 20. For those allergic to penicillin, sulfadimidine should be given.

In the past, approximately 60% of children who survived acute rheumatic fever developed a cardiac lesion detectable after 10 years, but heart failure frequently took 10 or more years to emerge. However, such complications have become increasingly rare in the high-income world and chronic rheumatic heart disease is only likely to be seen now in the middle-aged and some immigrants. The mitral valve is usually affected, either alone in 60–70% or with the aortic valve in a further 20%. The aortic valve alone is affected in only 10%. Valve narrowing (stenosis) and regurgitation (incompetence) are associated in varying degrees. The earliest sign of valve damage is a murmur. Later effects, particularly enlargement of the heart, may be detected clinically, radiographically and by ECG and echocardiography changes. Treatment is by mitral balloon valvuloplasty, using an Inoue balloon.

Dental aspects

Acute rheumatic fever patients are exceedingly unlikely to be seen during an attack but emergency dental treatment may be necessary. Most patients with chronic rheumatic fever are anticoagulated; treatment can be done under LA in consultation with the physician. Conscious sedation with nitrous oxide may be given if cardiac function is good and with the approval of the physician.

DRUG-INDUCED CARDIAC VALVULAR LESIONS

Use of a combination of the appetite suppressants fenfluramine and phentermine has been associated with a risk of cardiac valve regurgitation, particularly aortic regurgitation. All patients who have taken these drugs for longer than 3 months should have a clinical examination and, if any abnormality is detected, should be referred to a cardiologist for echocardiography.

INFECTIVE (BACTERIAL) ENDOCARDITIS

Infectious endocarditis (IE) results from bacterial or fungal infection of the endocardium, and is associated with significant morbidity and mortality. It is rare but potentially life-threatening, predominantly affecting damaged heart valves. Risk factors include the presence of a prosthetic heart valve, structural or congenital heart disease, intravenous drug use and a recent history of invasive procedures. IE has changed in profile, moving from being a streptococcal disease in patients with previously known heart disease to a staphylococcal health-care-associated disease in older patients suffering from many co-morbidities or having intracardiac devices.

Individuals who have had uncomplicated myocardial infarcts, coronary angioplasty or CABG, or who have had cardiac pacemakers inserted, do not have an increased risk of developing IE. Natural heart valves (native valve endocarditis), sometimes damaged by disease

Table 5.32 Main groups affected by infective endocarditis

Aetiology	Approximate % of all cases of infective endocarditis
No obvious cardiac valve disease	40
Chronic rheumatic heart disease	30
Congenital heart disease	10
Prosthetic cardiac valves	10
Intravenous drug abuse	10

Box 5.12 Patients at highest risk from infective endocarditis

- Prosthetic valves
- Previous infective endocarditis
- Complex cyanotic congenital heart defect, e.g. tetralogy of Fallot, transposition of the great arteries or Gerbode defect
- Surgically constructed systemic–pulmonary shunts or conduits
- Mitral valve prolapse with regurgitation or thickened leaflets

(e.g. rheumatic carditis), are usually affected by IE, but it can also affect people with CHD or patients who have undergone valve surgery (Table 5.32). Cardiac valves already damaged by infective endocarditis, or prosthetic cardiac valves (prosthetic valve endocarditis), are particularly at risk of infection (Box 5.12).

Platelet–fibrin deposits may accumulate along the free margins of valves, where there is turbulent blood flow; here they form sterile vegetations (aseptic thrombotic endocarditis) that may become infected with microorganisms, resulting in large friable vegetations (IE). Most bacteraemias are transient, self-limiting and not associated with any systemic complications. The factors that determine the development of IE are complex, but a susceptible surface (damaged endocardium) and high bacterial loads in the circulation appear to be important. Oral viridans streptococci (*Streptococcus mutans* and *sanguis*) from plaque enter the bloodstream (bacteraemia) during chewing, oral hygiene, tooth extractions and other oral procedures. They have complex attachment mechanisms, which enable them to adhere to damaged endocardium. Other microorganisms are also implicated, particularly *Staphylococcus aureus* and enterococci. Very few healthy ambulant patients, probably less than 5%, acquire IE as a result of dental treatment, and it is also clear that bacteria enter the blood from the mouth (and other sites) on innumerable occasions unrelated to operative intervention but usually cause no harm. In statistical terms, the chance of dental extractions causing IE, even in a patient with valvular disease, may possibly be as low as 1 in 3000.

Intravascular access devices, such as central intravenous lines, Hickman lines or Uldall catheters, often become infected but there is no evidence for a dental focus for such infections. An uncommon but dangerous type of right-sided IE in a previously healthy heart results from intravenous drug abuse, when highly virulent bacteria such as staphylococci can be introduced from the skin into the bloodstream with the addict's needle.

Guidelines from the AHA on the prevention of endocarditis can be found by searching on 'infective endocarditis' at <http://circ.ahajournals.org> or <http://www.americanheart.org> (accessed 30 September 2013).

Clinical features

The clinical features of IE are highly variable. It often has an insidious onset but should be considered in any individual presenting with fever

and a new or changing heart murmur. IE cases range from fulminantly acute to chronic.

Pallor (anaemia) or light (café-au-lait) pigmentation of the skin, joint pains and hepatosplenomegaly are typical, but the main effect of endocarditis is progressive heart damage (valve destruction and heart failure). Increasing disability is associated with changing cardiac murmurs indicative of progressive heart damage, infection or embolic damage of many organs, especially the kidneys (fever, malaise, night sweats and weight loss). Release of emboli can have widespread effects (on brain, lungs, spleen and kidneys), ranging from loss of a peripheral pulse to (rarely) sudden death from a stroke. Embolic phenomena include haematuria, cerebrovascular occlusion, petechiae or purpura of skin and mucous membranes, and splinter haemorrhages under the fingernails. Roth spots are small retinal haemorrhages. Immune complex formation from the antigens and resultant antibodies can lead to vasculitis, arthritis, and retinal and renal damage. Osler's nodes are small, tender, vasculitic lesions in the skin.

Endocarditis should be suspected in patients with unexplained fevers, night sweats or signs of systemic illness.

General management

Diagnosis is made using the Duke criteria, which include clinical, laboratory and echocardiographic findings, and is based on changing murmurs, ECG (may show conduction abnormalities), echocardiography (may identify vegetations and enables assessment of valvular and cardiac function) and blood culture. The latter is essential when IE is suspected and must be carried out before antimicrobial treatment is started; at least three samples of blood should be taken aseptically, at half-hourly intervals, to increase the chances of obtaining a positive culture. Urine Stix may detect microscopic haematuria. Serological testing helps identify atypical organisms (e.g. *Legionella*).

Common blood culture isolates include *Staphylococcus aureus*, viridans streptococci, enterococci and coagulase-negative staphylococci. Antibiotic treatment of IE depends on whether the involved valve is native or prosthetic, as well as the causative microorganism and its antibiotic susceptibilities. Without treatment, IE is fatal in approximately 30% of cases, so the patient should be admitted to hospital for intravenous antibiotic therapy, usually benzylpenicillin and gentamicin. If staphylococcal endocarditis is suspected, vancomycin should be substituted in place of penicillin. In severe cases, such as prosthetic valve endocarditis, early removal of the infected valve and insertion of a sterile replacement may be needed.

After completion of antibiotic therapy, patients should be educated about the importance of daily dental hygiene and regular visits for oral health care.

According to 2007 AHA guidelines, the only individuals who will need antibiotic pre-medication are those who:

- have a prosthetic cardiac valve
- have a history of previous IE
- have a history of CHD:
 - ◆ an unrepaired cyanotic congenital heart defect, including palliative shunts and conduits
 - ◆ a completely repaired congenital heart defect with prosthetic material or prosthetic device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
 - ◆ a repaired congenital heart defect with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

- are cardiac transplantation recipients who develop cardiac valvulopathy.

The AHA and American Dental Association (ADA) recommend the following ‘talking points’ to assuage the concerns of patients and colleagues:

- IE is much more likely to result from frequent exposure to random bacteraemias associated with daily activities than from bacteraemia caused by a dental, gastrointestinal tract or genitourinary tract procedure.
- Prophylaxis may prevent an exceedingly small number of cases of IE, if any, in individuals who undergo a dental, gastrointestinal tract or genitourinary tract procedure.
- The risk of antibiotic-associated adverse events exceeds the benefit, if any, from prophylactic antibiotic therapy.
- Maintenance of optimal oral health and hygiene may reduce the incidence of bacteraemia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk of IE.

Dental aspects

The main points are as follows:

- The cardiac endocarditis risk is now stratified into high, moderate and low. The low-risk categories do not require antibiotic prophylaxis for dental procedures.
- Dental procedures associated with bleeding are no longer exclusively indicated for antibiotic prophylaxis:
 - ◆ Only procedures with a statistically significant difference in bacteraemia between a pre- and a post-procedure blood sample are recommended for prophylaxis. This provides a logical and easily identifiable way of identifying procedures requiring antibiotic prophylaxis.
 - ◆ The use of azithromycin syrup for children who refuse tablets or capsules and for patients with dysphagia, already advocated by the *British National Formulary* (BNF), has now been formally recommended but this can affect cardiac QT (see ‘Long QT syndrome’ above).

Patients at risk of endocarditis should receive intensive preventive dental care to minimize the need for dental intervention. However, this aspect of care is frequently neglected; a very high proportion of patients attending cardiology clinics have periodontal disease. There is no reliable evidence to suggest that oral hygiene aids, such as electric toothbrushes, water-piks or similar devices, pose a risk.

In many countries, there are national guidelines on the use of antimicrobial prophylaxis against IE, if dental interventions are needed. However, the efficacy of such antimicrobial prophylaxis has been questionable and antibiotic prophylaxis is no longer mandatory for IE-susceptible patients who are to undergo dental care (Box 5.13).

There is always a risk of adverse reactions to the antimicrobial (such as anaphylaxis), which can approach 5% and can be as high from the oral administration of amoxicillin as from intramuscular administration of the same. Estimates suggest that deaths from an anaphylactic reaction to antibiotics are possibly 5–6 times more likely than deaths from IE.

Medico-legal and other considerations suggest that one should err on the side of caution in relation to antibiotic prophylaxis of IE by following these guidelines:

- Fully inform the patient about antimicrobial prophylaxis against IE and discuss it with them.
- Take medical advice in any case of doubt.

Box 5.13 Reasons for abandoning use of antibiotic prophylaxis for endocarditis

- Dental treatment is a proven cause of few cases of IE. One US study showed that in the 3 months before IE diagnosis, dental treatment was no more frequent than in controls, concluding that few cases would be prevented even if antibiotic prophylaxis were provided and were 100% effective. Another study concluded that, if antibiotic prophylaxis were 100% effective and provided for all at-risk patients receiving dental treatment, only a fraction of cases (5.3%) would be potentially prevented
- Prophylactic antibiotic regimens fail in some instances
- Adverse reactions to antimicrobials are possible, including anaphylaxis
- The cost-effectiveness of antimicrobial prophylaxis is questionable
- There is an increased risk of resistant bacteria

- Remember that, in countries where there are national guidelines, it is mandatory, for medico-legal reasons, to give such prophylaxis to patients at risk. For example, in 2007, the ADA, endorsed by the Infectious Diseases Society of America and the Pediatric Infectious Diseases Society, recommended prophylaxis, but only in the high-risk circumstances described above.

In the UK, over the years, a number of regimens have been suggested for endocarditis cover. In 1992, the British Society for Antimicrobial Chemotherapy (BSAC) recommended cover for all procedures associated with bleeding. The British Cardiac Society/Royal College of Physicians (BCS/RCP) suggested in 2004 that antibiotic prophylaxis be given for all bacteraemic dental procedures and for a large range of cardiac defects and/or surgery. However, in 2006, the BSAC recommended antibiotic prophylaxis in only three (high-risk) circumstances:

- Previous IE
- Prosthetic valves
- Surgically constructed pulmonary shunts or conduits.

NICE then issued recommendations in 2008, completely removing the need for antibiotic prophylaxis in relation to dentistry. *Antibiotic prophylaxis is now not recommended for patients at risk of endocarditis undergoing dental procedures.* Patients at risk of endocarditis should achieve and maintain high standards of oral health. NICE recommended that patients at risk for endocarditis should receive intensive preventive oral health care, to try to minimize the need for dental intervention. See also Appendix 5.7.

CARDIAC FAILURE

General aspects

Not to be confused with cardiac *arrest*, cardiac or heart failure is when any structural or functional impairment of the pumping action of the heart leads to blood output insufficient to meet the body’s demands. Lack of tissue and organ perfusion with congestion results, and thus the term ‘congestive cardiac failure’ is often used. Heart failure (HF; or congestive heart or cardiac failure [CHF, CCF]) is common and the prevalence is rising. It is associated with considerable morbidity and mortality (Table 5.33), being the leading cause of hospitalization in people over 65 and having an annual mortality rate of 10%.

The most common cause of cardiac failure is IHD but there are many others (Table 5.34), and cardiac failure may arise as a consequence of myocardial, valvular, pericardial, endocardial or electrical problems (or some combination). The remainder have a non-ischaemic

Table 5.33 New York Heart Association (NYHA) heart failure classification and treatment		
NYHA class	Features	Therapy
I	No limitation: ordinary physical exercise does not cause undue fatigue, dyspnoea or palpitations	ACE inhibitor (ACEI) Beta-blocker
II	Slight limitation of physical activity: comfortable at rest but ordinary activity results in fatigue, palpitations or dyspnoea	ACEI Beta-blocker Candesartan (initiation requires specialist advice)
III	Marked limitation of physical activity: comfortable at rest but less than ordinary activity results in symptoms	ACEI Beta-blocker
IV	Unable to carry out any physical activity without discomfort: symptoms of heart failure are present even at rest with increased discomfort with any physical activity	Spironolactone (initiation requires specialist advice) For patients in sinus rhythm with drug-refractory symptoms of heart failure due to left ventricular systolic dysfunction and who have a QRS duration of >120 ms, cardiac resynchronization should be considered

Table 5.34 Main causes of heart failure		
Left-sided mainly	Right-sided mainly	Biventricular
Ischaemic heart disease	Chronic obstructive pulmonary disease	Ischaemic heart disease
Aortic valve disease	Pulmonary embolism	Aortic valve disease
Mitral valve disease		Mitral valve disease
Hypertension		Hypertension
		Cardiomyopathies
		Hyperthyroidism
		Chronic anaemias
		Arrhythmias

cardiomyo-pathy, with either an identifiable cause (e.g. hypertension, thyroid disease, valvular disease, alcohol excess or myocarditis) or an unknown cause (e.g. idiopathic dilated cardiomyopathy). The term ‘acute heart failure’ is used to mean acute (cardiogenic) dyspnoea characterized by signs of pulmonary congestion, including pulmonary oedema. Chronic HF is a complex syndrome that can result from any structural or functional cardiac or non-cardiac disorder that impairs the ability of the heart to respond to physiological demands for increased cardiac output.

Clinical features

HF is characterized by fatigue, exertional breathlessness and signs of fluid retention. CHF can be associated with left ventricular systolic dysfunction (LVSD) and/or left ventricular diastolic dysfunction (LVDD). It can progress to involve right ventricular dysfunction (RVD). The result is an inadequate supply of oxygenated blood to the circulation. Features depend on which side of the heart – left or

Fig 5.12 Pressure on ankle in a person with suspected ankle oedema.

Fig. 5.13 Pitting oedema, indicating oedema and probable cardiac failure.

right – is predominantly involved and on the type of failure, either diastolic or systolic. The following signs are specific for heart failure:

- Raised jugular venous pressure (JVP)
- Lateral displacement of the apex beat
- Presence of a third heart sound (S3)
- Basal lung crepitations
- Peripheral oedema.

Symptoms can be few until activity becomes limited by breathlessness (dyspnoea), cyanosis and dependent oedema (usually swollen ankles or sacral oedema; Figs 5.12 and 5.13). CHF is often undiagnosed, owing to lack of a universally agreed definition and difficulties in diagnosis, particularly when the condition is considered ‘mild’.

Left-sided heart failure results in damming of blood back from the left ventricle to the pulmonary circulation with pulmonary hypertension, pulmonary oedema and dyspnoea. Lying down worsens pulmonary congestion, oedema and dyspnoea (orthopnoea). It also makes respiration less efficient, and cyanosis likely, because the abdominal viscera move the diaphragm higher and reduce the vital capacity of the lungs. Coughing is another typical consequence; the sputum is frothy and, in severe cases, pink with blood. In the more advanced stages of left-sided heart failure, there is inadequate cerebral oxygenation leading to symptoms such as loss of concentration, restlessness and irritability or, in older people, disorientation.

Right-sided heart failure causes congestion of the main venous systems and thus affects the liver, gastrointestinal tract, kidneys and subcutaneous tissues primarily. It presents with peripheral (dependent) oedema, fatigue and hepatomegaly due to passive congestion, causing

abdominal discomfort and, in severe cardiac failure, raised portal venous pressure, which also leads to the escape of large amounts of fluid into the peritoneal cavity (ascites).

Failure of one side of the heart usually leads to failure of the other – biventricular failure. The pulse may then become rapid and irregular, particularly if there is atrial fibrillation; in extreme cases, patients are cyanotic, polycythaemic, dyspnoeic at rest and oedematous with pulmonary oedema and distension of the neck veins (raised JVP). Arrhythmias and sudden death may result. The American College of Cardiology/AHA/New York Heart Association (NYHA) has defined four stages in the progression of cardiac failure (see [Table 5.33](#)).

General management

Heart failure is diagnosed clinically and by chest radiography (cardiomegaly), echocardiography, ECG and biochemistry (*B-type natriuretic peptide* [BNP]). Echocardiography determines the *stroke volume* (SV; the amount of blood that exits the ventricles with each heart beat), the *end-diastolic volume* (EDV; the amount of blood at the end of diastole), and the SV in proportion to the EDV (the *ejection fraction*; EF). Normally, the EF should lie between 50 and 70% but, in cardiac failure, it is less than 40%. A raised BNP is a specific test result indicative of cardiac failure. There may also be abnormal liver and renal function tests, hyponatraemia and alkalosis.

Heart failure is managed by treating the symptoms and signs via reduction of the heart workload and correction of precipitating factors (e.g. hypertension, anaemia, valvular disease and thyrotoxicosis). General measures may include rest, stress reduction, control of hypertension, weight loss, smoking cessation and salt restriction. Treatment aims to prevent HF progressing, thereby reducing symptoms, hospital admissions and mortality. Many treatments reduce either one or more (often all) of these but each can produce adverse effects. Careful monitoring is essential to maximize benefit and minimize adverse effects.

First-line therapies

These are ACEIs (e.g. enalapril, ramipril, quinapril, perindopril, lisinopril and benazepril) or angiotensin II receptor blockers (ARBs) or sartans (e.g. valsartan, telmisartan, losartan, irbesartan and olmesartan). These delay progression and reduce mortality, improving myocardial contractility, tissue and organ perfusion, and oxygenation. ACEIs reduce the relative risk of mortality by 25% and should be considered in patients with all NYHA functional classes of heart failure due to LVSD. Adverse effects include cough, hypotension, renal impairment, a sprue-like syndrome, and hyperkalaemia. Angioedema is rare but can be life-threatening (due to laryngeal involvement). ACEI-induced renal dysfunction is likely to occur in those with unsuspected renovascular disease. Concomitant ACEI and aspirin use is safe and effective in reducing cardiovascular events in patients with HF.

Beta-blockers

Beta-blockers may be indicated for patients with systolic heart failure due to LVSD after stabilization with ACEIs and diuretics. Beta-blockers are needed in all patients with HF due to LVSD of all NYHA classes. Beta-blocker therapy is needed as soon as their condition is stable (unless contraindicated by a history of asthma, heart block or symptomatic hypotension). Beta₁-selective (bisoprolol, metoprolol, nebivolol) or non-selective (carvedilol) blockers produce a consistent reduction in mortality of approximately one-third.

Angiotensin receptor blockers (ARBs)

ARBs block the biological effect of angiotensin II, mimicking the effect of ACEIs without cough as an adverse effect. Patients with chronic heart failure due to LVSD alone, or HF, LVSD or both following MI who are intolerant of ACEIs should be considered for an ARB. Patients with heart failure due to LVSD who are still symptomatic despite therapy with an ACEI and a beta-blocker may benefit from the addition of candesartan, following specialist advice.

Aldosterone antagonists

Aldosterone antagonists, such as spironolactone, added to an ACEI reduce mortality by 30%. Spironolactone can produce gynaecomastia, hyperkalaemia and renal dysfunction. Following specialist advice, patients with moderate to severe HF due to LVSD should be considered for spironolactone, unless this is contraindicated by renal impairment or a high potassium concentration. Eplerenone is an alternative aldosterone receptor antagonist that is less likely to produce sexual adverse effects such as gynaecomastia, breast pain or menstrual irregularities. Patients who have suffered an MI, and who have a left ventricular EF of 40% or less and either diabetes or clinical signs of HF, should be considered for eplerenone unless this is contra-indicated by the presence of renal impairment or a high potassium concentration. Even when added to maximum medication therapy in patients with mild to moderate heart failure, eplerenone reduces the risk of both death and hospitalization.

Diuretics

Diuretics (mainly loop diuretics such as furosemide or bumetanide) increase sodium and water excretion. Diuretics/loop diuretics/metolazone should be considered for HF patients with dyspnoea or oedema (ankle or pulmonary). The dose should eliminate ankle or pulmonary oedema without dehydrating the patient and placing them at risk of renal dysfunction or hypotension.

Digoxin

Digoxin may help when failure is associated with atrial fibrillation and should be considered as an add-on therapy for HF patients in sinus rhythm who are still symptomatic after optimum therapy. Digoxin improves symptoms but not survival, and benefit must be weighed against the possibility of an increase in sudden deaths associated with digoxin. The risk of digoxin toxicity is increased by hypokalaemia. In patients with HF and atrial fibrillation, a beta-blocker is preferred for control of the ventricular rate, though digoxin may be used initially while the beta-blocker is being introduced. If excessive bradycardia occurs with both drugs, digoxin should be stopped.

Vasodilators

Vasodilators, particularly isosorbide dinitrate plus hydralazine, may be valuable for people who fail to respond to ACEIs. Recombinant BNP (nesiritide) is indicated for patients with acute HF who have dyspnoea at rest. Antagonists of vasopressin (tolvaptan and conivaptan) and aldosterone (spironolactone and eplerenone) receptors are newer therapies. Phosphodiesterase inhibitors (enoximone or milrinone) may help to support cardiac function. Drug treatment is shown in [Box 5.14](#).

Other therapies

Nesiritide, the recombinant form of B-type natriuretic peptide despite earlier promise, appears of little benefit. The *BNF* advises that, due to interactions with prescribed medications, certain supplements and fruit juices should be avoided:

- Patients with CHF who are taking warfarin should be advised to avoid cranberry juice (which may increase drug potency).

Box 5.14 Treatment of heart failure**Medical**

- Diuretic
- Angiotensin-converting enzyme inhibitor (ACEI)
- Beta-blocker
- Aldosterone antagonist

Devices

- Pacemaker
- Cardiac resynchronization device
- Implantable cardiac defibrillator

Surgical

- Valve surgery
- Coronary artery bypass graft
- Transplant

- Patients with CHF who are taking simvastatin should be advised to avoid grapefruit juice (which may interfere with liver metabolism of statins).
- Patients with CHF should not take St John's wort due to the interaction with warfarin, digoxin, eplerenone and SSRIs.

Supplemental oxygen may be required and surgery (heart transplantation) is occasionally used to treat severe cardiac failure. New technologies include:

- **Heart pump** – this involves a left ventricular assist device (VAD) implanted into the abdomen and attached to the heart. A mechanical pump supports heart function and blood flow by taking blood from the ventricle and helping pump it to the body and vital organs. For patients with severe decompensated HF, ventricular mechanical support can be considered as a bridge to transplantation. VADs or total artificial hearts (TAHs) are used for HF, as bridges to transplantation or cardiectomy. VADs are used during or after heart surgery, or whilst a patient is awaiting a heart transplant. A small tube carries blood out of the heart into a pump and another carries it back to the blood vessels, to deliver the blood to the body. A control unit monitors the VAD functions. Some VADs work with a pumping action, while others keep up a continuous blood flow. The most common type is a left ventricular assist device, which conveys blood back to the aorta. A right ventricular assist device is used only for short-term support of the right ventricle after heart surgery; it helps the right ventricle pump blood to the pulmonary artery. If both ventricles are failing, both types of VAD are used simultaneously as a biventricular assist device. An alternative treatment option for this is a TAH. A transcutaneous VAD has its pump and power source located outside of the body. Tubes connect the pump to the heart through small holes in the abdomen. This type of VAD might be used for short-term support during or after surgery.
- **Biventricular cardiac pacemaker** – this sends specifically timed electrical impulses to the ventricles for cardiac resynchronization therapy.
- **Xenotransplantation** – a genetically manipulated pig's heart is transplanted into a human.
- **Artificial heart** – all-mechanical artificial hearts have already been implanted in humans.

- **Cardiac resynchronization therapy** – this is considered for patients in sinus rhythm with drug-refractory symptoms of HF due to LVSD (left ventricular ejection fraction $\leq 35\%$) and who are in NYHA class III or IV and have a QRS duration of >120 ms.
- **Implantable cardiac defibrillator** – this is an important part of management of CHF.

The Scottish Intercollegiate Guidelines Network (SIGN) national clinical guideline 95 on the management of chronic heart failure is available at <http://www.sign.ac.uk/pdf/sign95.pdf> (accessed 25 May 2013).

Dental aspects

For patients with poorly controlled or uncontrolled cardiac failure (worsening dyspnoea with minimal exertion, dyspnoea at rest or nocturnal angina), medical attention should be obtained before any dental treatment. Elective dental treatment should be delayed until the condition has been stabilized medically. Emergency dental care should be conservative, principally with analgesics and antibiotics.

Routine dental care can usually be provided with little modification for patients with mild controlled cardiac failure. Appointments for patients with cardiac failure should be short and in the late morning. Endogenous adrenaline (epinephrine) levels peak during the morning hours and cardiac complications are most likely in the early morning.

The dental chair should be kept in a partially reclining or erect position. It is dangerous to lay any patient with left-sided heart failure supine, as this may severely worsen dyspnoea.

Pain and anxiety may precipitate arrhythmias, angina or heart failure, and thus effective analgesia must be provided. Lidocaine or prilocaine can be used but bupivacaine should be avoided, as it is cardiotoxic. An aspirating syringe should be used to give the LA. Adrenaline (epinephrine) may theoretically increase hypertension and precipitate arrhythmias. BP tends to rise during oral surgery under LA, and adrenaline can theoretically contribute, but this is usually of little practical importance. Adrenaline-containing LA should not be given in large doses to patients taking beta-blockers. Interactions between adrenaline and the beta-blocker may induce hypertension if excessive doses of the LA are given. Gingival retraction cords containing adrenaline should be avoided. Cardiac monitoring is desirable and supplemental oxygen should be readily available.

Conscious sedation can usually be used safely. However, consideration must be given to the underlying cause of the cardiac failure (see Table 5.34). GA is contraindicated in cardiac failure until it is under control. Care should be taken after GA since there is a predisposition to venous thrombosis and pulmonary embolism.

Some drugs used in HF may complicate dental treatment (Table 5.35).

ARTERIAL DISSECTION**General aspects**

Arterial dissection is an abnormal, usually abrupt, formation of a tear along the inside wall of an artery. Aortic aneurysm (AA) is a ballooning or dilatation of the aorta; in the chest, it is called a thoracic AA, in the abdomen an abdominal AA (AAA), and across both areas a thoracoabdominal AA.

Risk factors for aortic aneurysm include:

- male gender
- advancing age
- smoking
- family history of aortic aneurysm

Table 5.35 Cardiac failure treatment drugs in oral health care

Medical drugs	Oral complications/complications that may disturb dental care	Dentistry drugs to be used with caution	Possible complications
ACE inhibitors (ACEIs)	Coughing Erythema multiforme, angioedema, burning mouth	Itraconazole NSAIDs other than aspirin	Can aggravate cardiac failure Increases the risk of renal damage from ACEI
Digitalis	ECG changes (e.g. ST-segment depression during dental extractions) Vomiting	Erythromycin Tetracycline	May induce digitalis toxicity by impairing its gut flora metabolism
Diuretics	Orthostatic hypotension	Carbamazepine	Hyponatraemia

- hypertension
- high cholesterol
- atherosclerosis
- Marfan syndrome and similar inherited conditions
- infection
- trauma.

Clinical features

Aortic dissection occurs when the lining of the aorta tears and this can lead to aneurysm formation. The most common symptom is pain; thoracic AA causes chest or upper back pain, while AAA results in pain in the abdomen or lower back that may radiate to buttocks, groin or legs.

General management

AA can be diagnosed by ultrasound and CT. When it reaches a certain size or interferes with surrounding blood vessels or organs, surgical repair or placement of an aortic stent may be necessary. AA prevention is by smoking cessation and control of BP and cholesterol.

Carotid or vertebral artery dissection is uncommon but the arteries can be damaged by neck injuries or forceful neck movements. Spontaneous dissection of the carotid and vertebral arteries may arise in Marfan or Ehlers–Danlos syndromes, osteogenesis imperfecta or polycystic kidney disease, and is an uncommon cause of stroke. Features may include:

- pain on one or both sides of the face, head or neck
- eye pain or one unusually small pupil (unilateral Horner syndrome)
- ptosis or diplopia
- vertigo, tinnitus
- facial paralysis.

Dental aspects may also include changes in or loss of taste.

Patients undergoing vascular surgery have a high incidence of periodontal disease.

CARDIAC SURGERY

Cardiac (heart) surgery can:

- replace occluded coronary arteries
- repair or replace heart valves
- repair abnormal or damaged structures
- use implant devices to help control the heart beat or support function and blood flow
- replace a damaged heart.

The most common cardiac surgery for adults is coronary artery bypass grafting (CABG), in which a healthy artery or vein from outside the heart is grafted to a blocked coronary artery.

Car drivers should avoid driving for 1 week after PTCA or pacemaker insertion, and for 1 month after MI or CABG, or when they have unstable angina. Patients with implantable defibrillators usually lose their driving licence but may regain it if they are shock-free for at least 6 months.

OPEN HEART SURGERY

Traditional heart surgery, called *open-heart surgery*, is done by splitting the sternum to open the chest wall for access to the heart. Often, the patient is connected to a heart–lung bypass machine to allow the surgeon to operate on a non-beating heart that has no blood flowing through it. In *off-pump, or beating heart, surgery* such as is carried out in CABG, however, a heart–lung bypass machine is not used.

PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY (PTCA)

This aims to open up the coronary blood flow by inserting a balloon-tipped catheter through the groin and up via the femoral artery and aorta into the area of arterial blockage. However, 40–50% of coronary arteries block again within 6 months, though this may be partially prevented with clopidogrel, aspirin or other antiplatelet drugs. PTCA has a lower morbidity than coronary bypass. Stents (miniature wire coils) may be inserted at the time of angioplasty to keep the arteries open, but re-narrowing (restenosis) follows in about 25% of patients. Stents coated with the immunosuppressive drug sirolimus reduce this restenosis. Minute amounts of beta-radiation in vascular brachytherapy

SURGERY

VASCULAR SURGERY

Bypass grafts to the aorta and lower limb vasculature (femoropopliteal bypass) are often made of synthetic materials. They remain non-endothelialized and are liable to infection, typically with *Staphylococcus epidermidis*. There is no evidence for odontogenic infection of such grafts, nor any good evidence that antimicrobial prophylaxis should be given for dental procedures.

MRI is contraindicated where ferromagnetic vascular clips have been placed.

(intravascular brachytherapy or endovascular brachytherapy) can inhibit or reduce restenosis.

CORONARY ARTERY BYPASS GRAFTING (CABG)

Coronary artery bypass grafts are vascular grafts made to bridge the obstructions in the coronary blood vessels. Saphenous veins (from the leg) are placed, accessing the heart by full sternotomy. Minimally invasive CABG uses arteries such as the internal mammary artery without the need for full sternotomy. CABG results in a 5-year survival of over 85% and a 10-year survival of around 70%. Goals may include:

- improving quality of life and reducing angina and other CHD symptoms
- allowing a more active lifestyle
- improving the heart pumping action
- lowering the risk of a heart attack
- improving survival.

CABG usually improves or completely relieves angina for as long as 10–15 years and may also reduce the risk of having a heart attack.

MINIMALLY INVASIVE HEART SURGERY

Minimally invasive heart surgery is also known as limited access coronary artery surgery and includes port-access coronary artery bypass (PACAB or PortCAB) and minimally invasive coronary artery bypass graft (MIDCAB). It is an alternative to standard bypass surgery (CABG). Access to the heart is gained via small incisions ('ports') between the ribs; the sternum is not opened. The surgeon views these operations on video monitors rather than directly. In PACAB, the heart is stopped and blood is pumped through an oxygenator or heart–lung machine; MIDCAB is used to avoid the use of a heart–lung machine.

CARDIAC CATHETERIZATION

In this procedure, radio-opaque dye is injected into blood vessels via a catheter; angiography is then used to examine the inside of the cardiac blood vessels.

ANGIOPLASTY

Angioplasty is done because it can:

- increase blood flow through the blocked artery
- decrease angina
- increase ability for physical activity
- reduce the risk of a heart attack
- open neck arteries to help prevent stroke (carotid endarterectomy).

Also known as percutaneous coronary intervention (PCI), balloon angioplasty and coronary artery balloon dilation, angioplasty involves threading special tubing with an attached deflated balloon up from the groin to the coronary arteries. The balloon is inflated to widen blocked areas, where blood flow to the heart muscle has been reduced. This procedure is often followed by insertion of a small wire mesh tube (a stent) in the coronary artery to keep it open and to decrease the chance of another blockage.

A coronary artery stent physically opens the lumen of an artery during and after angioplasty. The stent is collapsed to a small diameter and placed over a balloon catheter for insertion. The stent is

then moved into the area of blockage through the artery. When the balloon is inflated, the stent expands and locks into place, forming a scaffold that endothelializes and holds the newly dilated artery open. The stent stays in the artery permanently and improves blood flow. However, stent-mediated arterial injury causes neointimal hyperplasia, leading to restenosis and the need for repeat revascularization in up to one-third of patients. Therefore, drug-eluting stents with controlled local release of antiproliferative agents were developed; they have reduced the risk of repeat revascularization, although their long-term safety has been questioned. Current recommendations are to extend dual antiplatelet therapy (see below) for at least 12 months after stent implantation. Stents are made of stainless steel, cobalt–chrome or platinum–chrome, and coated with a polymer; they are able to release sirolimus, everolimus or zotarolimus. Restenosis is now very uncommon.

Patients with stents in place receive dual antiplatelet/antithrombotic medications consisting of aspirin and a platelet receptor (P2Y₁₂) inhibitor to reduce the risk of ischaemic events and to decrease the chances of restenosis. When these patients are being treated for other medical or dental problems, concerns include the effects of possible bacteraemia on recently stented vessels, the risk of post-treatment bleeding and the possibility of interactions with drugs.

Considered less invasive than some other techniques because the body is not cut open, angioplasty takes 30 minutes to several hours to perform. Laser angioplasty catheter has a laser tip that opens the blocked artery; pulsating beams of light vaporize the plaque build-up. In atherectomy, the catheter has a rotating shaver on its tip to cut away plaque from the artery. After angioplasty, patients are usually given aspirin on a permanent basis, as well as clopidogrel, prasugrel or ticagrelor for 1–12 months.

Perioperative antithrombotic management is based on risk assessment for thromboembolism and bleeding. Dental anaesthetics with standard concentrations of adrenaline (epinephrine) seem to alter heart rate and BP, although no cardiac ischaemic alterations or any other cardiovascular complications are observed.

The AHA provides an educational module on stent insertion at http://watchlearnlive.heart.org/CVML_Player.php?moduleSelect=costent (accessed 25 May 2013).

TRANSMYOCARDIAL REVASCULARIZATION (TMR)

This procedure may be used to relieve severe angina in very ill patients who are not candidates for bypass surgery or angioplasty. TMR involves an incision on the left breast to expose the heart. A laser is then used to drill a series of holes from the outside of the heart into the interior. In some patients, TMR is combined with bypass surgery, in which case an incision through the breastbone is used for the bypass.

CARDIAC VALVE SURGERY

Heart valve defects may be corrected by valvotomy, grafts or prosthetic valves.

Dental aspects of cardiac surgery

Dental management of patients on anticoagulants or antiplatelets is summarized in [Table 5.36](#).

Post-angioplasty

Elective dental care should be deferred for 6 months; emergency dental care should be given in a hospital setting.

Table 5.36 Dental management of patients on anticoagulants or antiplatelets

Patient status	Antithrombotic management
At low risk for thromboembolism	Do not give bridging anticoagulation
Requiring vitamin K antagonist (VKA) interruption before surgery	Stop VKA 5 days before surgery
At high risk for thromboembolism and having a mechanical heart valve, atrial fibrillation or venous thromboembolism	Give bridging anticoagulation
At moderate to high risk for thromboembolism and receiving acetylsalicylic acid (ASA)	Continue ASA perioperatively
Requiring a dental procedure	Continue VKA with an oral prohaemostatic agent
Requiring surgery and having a coronary stent	Defer surgery for >6 weeks after bare-metal stent placement and >6 months after drug-eluting stent placement
Requiring surgery within 6 weeks of bare-metal stent placement or within 6 months of drug-eluting stent placement	Continue antiplatelet therapy perioperatively

Patients with coronary artery bypass graft

These patients should not receive an adrenaline (epinephrine)-containing LA, since it may possibly precipitate arrhythmias. For the first couple of weeks after surgery, the patient may feel severe pain when reclining in the dental chair as a side-effect of the surgery.

Patients with vascular stents that are successfully engrafted

The main points have been discussed earlier. It may be prudent to provide antibiotic coverage if emergency dental treatment is required during the first 6 weeks after the operation. Elective dental care should be deferred. Patients may require long-term anticoagulant medication. Appropriate action is required to deal with any bleeding tendencies (Ch. 8), but most patients are on aspirin or clopidogrel rather than warfarin.

Cardiac valve surgery

Patients scheduled for cardiac surgery should ideally have excellent oral health established before operation. Generally speaking, teeth with a poor pulpal or periodontal prognosis are best removed, particularly before a valve replacement, major surgery for congenital anomalies or a heart transplant. Teeth with no more than shallow caries and periodontal pocketing should be conserved.

Elective dental care should be avoided for the first 6 months after cardiac surgery. Some patients are on anticoagulant treatment, immunosuppressives or other drugs, or may also have a residual lesion. Prosthetic valves are particularly susceptible to IE and in that case there is a high mortality rate. Endocarditis within the first 6 months is usually caused by *Staphylococcus aureus*, is rarely of dental origin and has a mortality rate of around 60%.

CARDIAC (HEART) TRANSPLANTATION

General aspects

Heart transplantation is increasingly used to treat patients with otherwise uncontrollable cardiac failure, especially cardiomyopathy, CHD, CAD, heart valve disease and life-threatening arrhythmias.

Fig. 5.14 Heart transplantation.

Table 5.37 Average survival of patients after cardiac transplant

At year	1	3	5
% survival	>80	>75	>70

The procedure uses a heart that has usually come from a brain-dead organ donor (*allograft*). The recipient patient's own heart may be either removed (*orthotopic procedure*) or, less commonly, left *in situ* to support the donor heart (*heterotopic procedure*; Fig. 5.14). Survival after cardiac transplantation is improving (Table 5.37) and some patients have lived for around 30 years. Heart–lung transplantation is also increasingly performed. Outcomes using a heart from another species (*xenograft*) or an *artificial heart* have been less successful.

All transplant recipients require lifelong immunosuppression to prevent a T-cell, alloimmune rejection response, usually with ciclosporin, mycophenolate or azathioprine, corticosteroids and antithymocyte globulin, or tacrolimus.

Patients may be anticoagulated or taking aspirin and dipyridamole to reduce platelet adhesion and prolong the bleeding time. They are often given a statin to minimize the risk of atheroma in the transplanted heart.

Since the vagus nerve is severed during the transplant operation, the donated heart will beat at around 100 beats/min until nerve regrowth occurs. There is evidence of increased cardiac sensitivity to catecholamines such as adrenaline (epinephrine). Owing to the absence of innervation, angina is rare and patients may experience ‘silent’ MI or sudden death.

Dental aspects

The following points should be noted, in addition to those discussed in Chapter 35. Immunosuppressive therapy can lead to liability to infections and to a bleeding tendency.

A meticulous pre-surgery oral assessment is required and dental treatment should be undertaken with particular attention to establishing optimal oral hygiene and eradicating sources of potential infection. Dental treatment should be completed before surgery.

For 6 months after surgery, elective dental care is best deferred. If dental surgical treatment is needed during the 6 months that follow the heart surgery, or until the ECG is normal, antibiotic prophylaxis against endocarditis (see ‘Infective endocarditis’ above) may be requested by the surgeons.

It has been suggested that heart transplant patients cannot show any vasovagal reaction because the donor heart is completely deprived of

any vagal or sympathetic innervation. However, episodes of vasovagal syncope in heart transplant patients undergoing periodontal surgery have been reported.

LA without adrenaline (epinephrine) is indicated.

APPENDIX 5.1 GENETIC SYNDROMES WITH ASSOCIATED CARDIAC DEFECTS

Names of disorder	Further information
<i>Chromosomal disorders</i>	
Down	Ch. 28
Edwards	Ch. 28
Patau	Ch. 28
Turner (XXY)	Ch. 28
XXXY	Learning disability, hypogonadism
XXXXX	Learning disability, small hands
<i>Hereditary disorders</i>	
Ehlers–Danlos	Ch. 16
Marfan	Ch. 16
Osteogenesis imperfecta	Ch. 16
The mucopolysaccharidoses (Hurler and related syndromes)	Ch. 23
Ellis–van Creveld	Ch. 37
TAR	Thrombocytopenia, absent radius
Holt–Oram	Hypoplastic clavicles, upper limb defect
Multiple lentiginos	Basal cell naevi, rib defects
Rubenstein–Taybi	Broad thumbs and toes, hypoplastic maxilla

APPENDIX 5.2 MAIN CONGENITAL HEART DEFECTS THAT MAY BE ASSOCIATED WITH VARIOUS EPONYMOUS SYNDROMES

Syndrome	Defects
Down	Atrioventricular defect and also patent ductus arteriosus and Fallot tetralogy
Ehlers–Danlos	Mitral valve prolapse
Friedreich	Hypertrophic cardiomyopathy
Holt–Oram	Atrial septal defect, ventricular septal defect
Klinefelter	Atrial septal defect
Marfan	Mitral valve prolapse, aortic regurgitation
Noonan	Pulmonary stenosis, sometimes Fallot tetralogy
Turner	Coarctation, aortic stenosis
Williams	Supravalvular aortic stenosis

APPENDIX 5.3 VAUGHAN-WILLIAMS CLASSIFICATION OF ANTI-ARRHYTHMIC AGENTS

Mechanism	Class	Examples	Main uses
Membrane stabilizers (sodium-channel blockers)	Ia	Disopyramide	Ventricular arrhythmias
		Procainamide	Wolff-Parkinson-White syndrome
		Quinidine	
	Ib	Lidocaine	Ventricular tachycardia
	Ic	Phenytoin	Atrial fibrillation
		Flecainide	Paroxysmal atrial fibrillation
Beta-blockers	II	Propafenone	
		Atenolol	Tachyarrhythmias
		Metoprolol	
		Propranolol	
		Sotalol	
Unknown	III	Timolol	
		Amiodarone	Atrial fibrillation
		Dofetilide	Ventricular tachycardias
		Nibentan	Wolff-Parkinson-White syndrome
		Sotalol	
Calcium-channel blockers	IV	Diltiazem	Paroxysmal supraventricular tachycardia
		Verapamil	Atrial fibrillation

APPENDIX 5.4 DRUGS TO AVOID IN LONG QT SYNDROME (MAY PROLONG THE QT INTERVAL AND INDUCE TORSADES DE POINTES)

- Amiodarone
- Arsenic trioxide
- Astemizole
- Azithromycin
- Bepridil
- Chloroquine
- Chlorpromazine
- Cisapride
- Citalopram
- Clarithromycin
- Disopyramide
- Dofetilide
- Domperidone
- Droperidol
- Erythromycin
- Flecainide
- Halofantrine
- Haloperidol
- Ibutilide
- Levacetylmethadol (levomethadyl)
- Mesoridazine
- Methadone
- Moxifloxacin
- Pentamidine
- Pimozide
- Probuco
- Procainamide
- Quinidine
- Sotalol
- Sparfloxacin
- Terfenadine
- Thioridazine
- Vandetanib

Drugs that may prolong QT

- Alfuzosin
- Amantadine
- Dihydroartemisinin (artemimol) + piperazine
- Atazanavir
- Chloral hydrate
- Clozapine
- Dolasetron
- Dronedarone
- Eribulin
- Escitalopram
- Famotidine
- Felbamate
- Fingolimod
- Fosarnet
- Fosphenytoin
- Gatifloxacin
- Gemifloxacin
- Granisetron
- Iloperidone
- Indapamide
- Isradipine
- Lapatinib
- Levofloxacin
- Lithium
- Moexipril/hydrochlorothiazide (HCTZ)
- Nicardipine
- Nilotinib
- Octreotide
- Ofloxacin
- Ondansetron
- Oxytocin

(Continued)

- Paliperidone
- Perflutren lipid microspheres
- Quetiapine
- Ranolazine
- Risperidone
- Roxithromycin
- Sertindole
- Sunitinib
- Tacrolimus
- Tamoxifen
- Telithromycin
- Tizanidine
- Vardenafil
- Venlafaxine
- Voriconazole
- Ziprasidone

Others drugs that may affect the ECG

- Amisulpride
- Amitriptyline
- Ciprofloxacin
- Clomipramine
- Desipramine
- Diphenhydramine
- Doxepin
- Fluconazole
- Fluoxetine
- Galantamine
- Imipramine
- Itraconazole
- Ketoconazole
- Nortriptyline
- Paroxetine
- Protriptyline
- Ritonavir
- Sertraline
- Solifenacin
- Trazodone
- Trimethoprim/sulfamethoxazole (co-trimoxazole)
- Trimipramine

Drugs to avoid in congenital long QT syndrome

- Adrenaline (epinephrine)
- Albuterol
- Alfuzosin
- Amantadine
- Amiodarone
- Amisulpride
- Amitriptyline
- Amphetamine
- Arsenic trioxide
- Dihydroartemisinin (artenimol) + piperaquine
- Astemizole
- Atazanavir
- Atomoxetine
- Azithromycin
- Bepidil
- Chloral hydrate
- Chloroquine
- Chlorpromazine
- Ciprofloxacin
- Cisapride

- Citalopram
- Clarithromycin
- Clomipramine
- Clozapine
- Cocaine
- Desipramine
- Dexmethylphenidate
- Diphenhydramine
- Disopyramide
- Dobutamine
- Dofetilide
- Dolasetron
- Domperidone
- Dopamine
- Doxepin
- Dronedarone
- Droperidol
- Ephedrine
- Eribulin
- Erythromycin
- Escitalopram
- Famotidine
- Felbamate
- Fenfluramine
- Fingolimod
- Flecainide
- Fluconazole
- Fluoxetine
- Foscarnet
- Fosphenytoin
- Galantamine
- Gatifloxacin
- Gemifloxacin
- Granisetron
- Halofantrine
- Haloperidol
- Ibutilide
- Iloperidone
- Imipramine
- Indapamide
- Isoproterenol
- Isradipine
- Itraconazole
- Ketoconazole
- Lapatinib
- Levofloxacin
- Levacetylmethadol (levomethadyl)
- Levosalbutamol (levalbuterol)
- Lisdexamfetamine
- Lithium
- Mesoridazine
- Methadone
- Methylphenidate
- Midodrine
- Moexipril/HCTZ
- Moxifloxacin
- Nicardipine
- Nilotinib
- Noradrenaline (norepinephrine)
- Nortriptyline
- Octreotide

(Continued)

- Ofloxacin
- Olanzapine
- Ondansetron
- Orciprenaline (metaproterenol)
- Oxytocin
- Paliperidone
- Paroxetine
- Pentamidine
- Perflutren lipid microspheres
- Phentermine
- Phenylephrine
- Phenylpropanolamine
- Pimozide
- Probucol
- Procainamide
- Protriptyline
- Pseudoephedrine
- Quetiapine
- Quinidine
- Ranolazine
- Risperidone
- Ritodrine
- Ritonavir
- Roxithromycin*
- Salmeterol

- Sertindole
- Sertraline
- Sibutramine
- Solifenacin
- Sotalol
- Sparfloxacin
- Sunitinib
- Tacrolimus
- Tamoxifen
- Telithromycin
- Terbutaline
- Terfenadine
- Thioridazine
- Tizanidine
- Tolterodine
- Trazodone
- Trimethoprim/sulfamethoxazole (co-trimoxazole)
- Trimipramine
- Vandetanib
- Vardenafil
- Venlafaxine
- Voriconazole
- Ziprasidone

APPENDIX 5.5 MODIFICATION OF CLINICAL PROCEDURES IN PATIENTS WITH CEIDS

INVESTIGATIONS AND PROCEDURES

MRI

Avoid MRI scanning in patients with pacemakers. Concerns about exposure of AICDs to MRI are similar to pacemakers – with the additional risk of interpreting noise as ventricular arrhythmias and the consequent delivery of shocks and/or rapid ventricular pacing.

Radiotherapy

There is little risk as long as the irradiation field avoids pacemakers. Although the effect of radiation on the newest AICDs is variable, the AICD may inappropriately deliver anti-tachycardia therapy if tachycardia monitoring and therapies are active during irradiation:

- Avoid the CEID location.
- Avoid the betatron.
- Evaluate device and pacemaker dependency prior to therapy.
- Plan radiotherapy to minimize the total dose (including scatter) received by the generator.
- Avoid direct irradiation.
- Maximize shielding and distance of the pulse generator from the radiation beam.
- Consider moving the pulse generator away from the field if the estimated dose is over 10 Gy.
- Institute an appropriate level of monitoring:
 - ◆ If the estimated dose is less than 2 Gy and the patient is not pacemaker-dependent, clinical monitoring suffices.

- ◆ If the estimated dose is over 2 Gy or the patient is pacemaker-dependent, high-level monitoring is necessary.
- Ensure continuous ECG monitoring during treatments.
- Have staff competent in advanced cardiac life support nearby.
- Check device function after each therapy session and regularly for several weeks thereafter.

External cardioversion and defibrillation

The newer IRDs are better protected and thus more resistant to external cardioversion and defibrillation currents, but all devices are at risk of reversion to back-up mode, transient increase in capture threshold, loss of capture, destruction of the pulse generator and circuitry, and thermal damage to myocardial tissue in contact with the lead(s).

Electrocautery/electrosurgery

Radiofrequency currents may be interpreted by an IRD as an intra-cardiac signal, which can inhibit pacing, trigger ventricular pacing, switch mode in a pacemaker, and spuriously detect tachyarrhythmia in an AICD. Patients with pacemakers should have continual ECG monitoring during electrosurgery. The following additional precautions should be observed for children with pacemakers:

- Ensure the distance between the active electrode and the dispersive electrode is as short as possible.
- Keep all electrosurgery cables away from the pacemaker and its leads.
- Have a defibrillator immediately available for emergencies.
- Use a bipolar pacemaker where possible.
- Have a magnet or control unit available.

All patients with AICDs should have a defibrillator immediately available and the AICD device should be deactivated before the electrosurgery is initiated.

Lithotripsy

Extracorporeal shock wave lithotripsy can theoretically damage pacemakers and AICDs by emitting a shock wave. The lithotripter should be placed at least 5 cm away from the IRD.

Transcutaneous electrical nerve stimulation (TENS)

TENS may be sensed by unipolar IRD systems. Although TENS is relatively safe for use with pacemakers, these patients should undergo monitored assessment during first-time use, and repeatedly if therapy is applied to different locations. TENS should be discouraged in patients with AICDs since there may be inappropriate shocks, and noise reversion may inhibit appropriate AICD shocks.

OTHER EQUIPMENT

Mobile (cellular) phones

The recommended distance between the operating phone and the pacemaker is 15 cm; alternatively, the contralateral ear should be used. Modern mobile phones have little effect on AICDs, but manufacturers recommend a 15-cm distance between active telephones and AICDs.

Personal digital assistants (PDAs)

PDAs fitted with wireless local area network technology may run electromagnetic interference (EMI) risks so the advised precautionary measure is to maintain a 15-cm safety margin between PDAs and IRDs.

Portable media players (e.g. iPods)

Despite the fact that portable media players appear to have no EMI effects on IRDs, manufacturers recommend that they should not be stowed in ipsilateral pockets, shoulder bags or arm carrier straps.

Security systems

Metal detectors may cause EMI but with PMs there is no atrial oversensing, inappropriate mode switching, ventricular oversensing, atrial or ventricular loss of capture, pacing in the magnet mode or spontaneous reprogramming. In AICD patients, ventricular oversensing does not result in inappropriate detection, spontaneous reprogramming or temporary suspension of therapies. Nevertheless, IRD casings may trigger alarms, so patients should forewarn security agents. Patients should be advised to carry their device identification card, to request alternate search methods if possible, and to walk through detectors at a normal pace, avoiding leaning or lingering within the field of the detector.

EMERGENCY PROCEDURES

(After <http://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001150/>; accessed 30 September 2013)

- Ensure that cardiopulmonary resuscitation, temporary external/transvenous pacing, and external defibrillation equipment are readily available.
- Where the presence of a device is suspected but not confirmed, use normal radiographic procedures to identify any such devices. Note that:
 - ◆ Most devices are implanted in the anterior left pectoral region.

- ◆ Older implants may be implanted abdominally.
- ◆ X-ray identification symbols can be used to identify the manufacturer (consult a cardiac pacing clinic for the manufacturer).
- Obtain pacemaker/AICD details from the patient's device registration card/'passport', which holds the pertinent details. Where possible, obtain the following key information and alert the cardiology department for assistance:
 - ◆ Device manufacturer, model number, serial number
 - ◆ Implanting hospital, follow-up hospital
 - ◆ Reason for implant.
- Where possible, contact the cardiac pacing department to determine to what extent support may be required in pacemaker/AICD reprogramming. AICDs may need to be programmed to 'monitor only' mode to prevent inappropriate sensing and shock delivery. Securing a magnet over the AICD implant site may, in many cases, inhibit the delivery of shock therapy. However, this cannot always be guaranteed. Similarly, securing a magnet over the pacemaker implant site will not necessarily guarantee asynchronous (non-sensing) pacing. Magnet response may vary between manufacturers' models and according to particular programmed settings.
- If the AICD is deactivated, consider connecting the patient to an external defibrillator using remote pads, if access to the anterior chest wall will interfere with surgery or sterile field.
- Monitor the patient's ECG before the induction of anaesthesia.
- Since some ECG monitors (having a 'paced' mode) may misinterpret pacing spikes as the patient's QRS complexes and incorrectly display a heart rate (when the patient is in asystole), an alternative method of detecting a patient's pulse, such as a pulse oximeter or an arterial line, should be used.
- Monitoring systems that use thoracic impedance measurements can cause an increase in paced rate for pacemakers that use the minute ventilation system to determine the patient's exercise level. Where interaction is suspected, consider using a patient monitoring system that does not employ thoracic impedance measurements.
- On detection of any pacemaker inhibition or rate increase, inform the surgeon immediately and use diathermy either intermittently or not at all.
- Consider using an external pacemaker to overdrive and inhibit pacing from the implanted pacemaker (when necessary).
- Use monopolar diathermy/electrocautery as a last resort and:
 - ◆ use in short bursts
 - ◆ ensure that the return electrode is anatomically positioned so the current pathway is far away from the pacemaker/defibrillator (and leads)
 - ◆ keep diathermy/electrocautery cables well away from the site of implant
 - ◆ consider alternative external/transvenous pacing where pacing from the implant is significantly affected during the use of monopolar diathermy.
- On completion of surgery, or as soon as possible, contact the cardiac pacing clinic to request a pacemaker/AICD check to ensure the correct functioning of the device.

There are no scientific data to support the use of antimicrobial prophylaxis for dental or other invasive procedures in people with CIEDs.

APPENDIX 5.6 NON-HEALTH-CARE SOURCES OF ELECTROMAGNETIC INTERFERENCE (EMI) AFFECTING MODERN DEVICES, WITH THEIR SAFETY LEVELS

Safe	Used with caution	To be avoided
<u>Personal care</u>		
Electric razors	Do not place directly over IRD:	Electrolysis (hair removal)
Hair dryers	Hand-held massagers	
Tanning beds	Power toothbrushes	
Thermolysis (hair removal)		
<u>Domestic items</u>		
Air purifiers	Keep 15cm away or in contralateral ear/pocket:	Hand-held body fat measuring scales
Blenders	Mobile phones	Magnetic mattresses and chairs
Clothes dryers	Cordless phones	
Convection ovens	Personal digital assistants (with mobile phone features)	
Electric blankets		
Electric ovens and stoves		
Electric can openers		
Gas ovens and stoves		
Heating pads		
Microwave ovens		
Pagers		
Patient-alert devices		
Personal digital assistants (without mobile phone features)		
Portable space heaters		
Radio-controlled clocks		
Vacuum cleaners		
Washing machines		
Watches		
<u>Radio, TV, security, etc., equipment</u>		
AM/FM radio	Keep 60cm away:	
CD/DVD players	CB and police radio aerials	
Remote controls (TV, stereo, garage door, video equipment, cameras)	Keep 30cm away:	
TV/video recorder	Slot machines	
Video games	Stereo speakers	
	Keep 15cm away:	
	Bingo games	
	Magnetic wands	
	Do not linger near:	
	Electronic antitheft systems	
	High-voltage lines	
	Radio/TV towers	
	Residential power generators	
	Transformers	
	Walk through airport security systems at normal pace, tell security and show device ID card	
	Request alternative search method with security wands: should not be held over pacemaker for >2s every 10s, or over AICD for >2s every 30s	
<u>Workplace</u>		
Electric invisible fences	Keep 60cm away:	Jackhammers
Fax machines	Arc welding equipment	Neodymium–iron–boron magnets
Personal computers	Running motors or alternators	
Photocopiers	Keep 30cm away:	
	Battery-powered power tools	
	Chainsaws	
	Cordless drills	
	Lawn mowers	
	Leaf blowers	
	Power tools such as drills and saws	
	Snow blowers	
	Soldering guns	

(Continued)

Safe	Used with caution	To be avoided
Daily life		
Electronic article surveillance (EAS) devices (also known as antitheft devices or antishoplifting gates)	EAS devices are ubiquitous in retail stores and libraries. There are several major types of system: Magnetic, also known as magnetoharmonic	
Improperly grounded appliances held in close contact with body	Acoustomagnetic, also known as magnetostrictive	
Metal detectors	Radiofrequency	
Mobile phones	Microwave	
Slot machines	Video surveillance (to some extent)	
Some home appliances (e.g. electric razor)	On interacting, the tag emits a signal that is detected by the receiver. All EAS systems emit electromagnetic energy and thus can interfere with electronics; there are reported instances where magnetic or acoustomagnetic EAS systems have caused a pacemaker to fail and a defibrillator to trigger	
Toy remote controls		
Industrial environment		
Degaussing coils	Arc or spot welders	
Electric motors	Industrial welding machines	
High-voltage power lines	Additional general precautions include ensuring appropriate grounding of equipment and avoiding close contact with EMI source	
Induction furnaces		
Transformers		
Welders		

APPENDIX 5.7 DO PATIENTS UNDERGOING DENTAL PROCEDURES REQUIRE ENDOCARDITIS PROPHYLAXIS?

(Reproduced with permission from UK Medicines Information (UKMi) pharmacists for NHS health-care professionals)

BACKGROUND

Infective endocarditis is an inflammation of the inner lining of the heart (endocardium), particularly affecting the heart valves and caused mainly by bacterial infection. Patients with structural abnormalities of the heart, hypertrophic cardiomyopathy, replacement heart valves or with a history of infective endocarditis are considered to be at risk of developing infective endocarditis.

Traditionally, prophylactic antibiotics have been given to patients at risk of infective endocarditis before undergoing dental procedures. Typically, three grams of oral amoxicillin would be taken one hour beforehand. The rationale for using antibiotics was that dental procedures lead to increased numbers of bacteria in the blood (bacteraemia) and it was assumed that bacteraemia was a key factor in the development of infective endocarditis.

In recent years, there have been conflicting guidelines as to which patients and dental procedures warranted the use of prophylactic antibiotics.^{1,2,3} This led to confusion for health professionals and patients. The National Institute for Health and Care Excellence (NICE) has now issued definitive, evidence-based guidance on the prophylaxis of infective endocarditis.⁴ This guidance has been

adopted nationally and is reflected in the current British National Formulary, published March 2008.⁵

ANSWER

Antibiotic prophylaxis is not recommended for the prevention of infective endocarditis in adults or children undergoing any dental procedure.⁴

The basis for this recommendation is:

- *There is no consistent association between dental procedures and an increased risk of infective endocarditis;*
- *Bacteraemia associated with dental procedures is no greater than that from toothbrushing;*
- *Regular toothbrushing almost certainly presents a greater risk of infective endocarditis than a single dental procedure because of repetitive exposure to bacteraemia;*
- *Antibiotics are not proven to reduce the risk of infective endocarditis;*
- *Antibiotics are themselves not without risk and can cause fatal anaphylaxis.*

Patients who previously received endocarditis prophylaxis for dental procedures will require a clear explanation as to why prophylaxis is no longer recommended. A summary of the NICE guideline for patients⁶ and a ‘quick reference leaflet’⁷ are available online. Printed copies can be ordered from NICE Publications via 0845 003 7783 (quote reference numbers N1488 and N1487 when ordering the patient summary and quick reference leaflet, respectively).

(Continued)

NICE states that healthcare professionals should offer clear and consistent advice to patients on four points, details of which are on page 2 of this document.

The NICE summary for patients⁶ includes a list of questions that patients might ask their healthcare team; answers are suggested on page 3 of this document.

ADVICE FOR HEALTHCARE PROFESSIONALS TO OFFER TO PATIENTS

Patients at risk of infective endocarditis should be reassured that antibiotic prophylaxis is no longer recommended and offered information regarding:

The benefits and risks of antibiotic prophylaxis, and an explanation of why antibiotic prophylaxis is no longer recommended

Patients at risk of infective endocarditis have traditionally received prophylactic antibiotics prior to dental procedures. Procedures that disturb bacteria in the mouth increase the number of bacteria in the blood (bacteraemia). High levels of bacteraemia have been shown (in animal models) to increase the risk of infective endocarditis. On this basis, it was considered prudent to provide antibiotic prophylaxis to reduce bacteraemia in patients considered to be at risk of infective endocarditis. Over recent years, there have been conflicting guidelines as to which patients required antibiotic prophylaxis and for which dental procedures.

NICE has reviewed the evidence regarding infective endocarditis and concluded that there is no clear association between dental procedures and infective endocarditis. Evidence shows that levels of bacteraemia associated with dental procedures are no greater than those associated with regular toothbrushing. The risk of infective endocarditis is almost certainly greater from toothbrushing than from a single dental procedure due to repeated exposure to bacteraemia.

Antibiotic prophylaxis given before dental procedures has not been shown to eliminate bacteraemia or to reduce the risk of infective endocarditis and is associated with risks of its own. Antibiotics can cause adverse reactions including fatal anaphylaxis. Using antibiotics when not indicated puts patients at risk from adverse effects and can increase bacterial resistance to antibiotics. For all these reasons, antibiotic prophylaxis is no longer recommended for the prevention of infective endocarditis in patients undergoing dental procedures.

The importance of maintaining good oral health

Maintaining good oral health reduces the numbers of bacteria in the mouth and helps prevent tooth decay and gum disease. Patients should be advised to keep their mouth and teeth clean with twice-daily toothbrushing, to have regular dental check-ups and not to let any dental problems such as abscess or gum disease go untreated.

Symptoms that may indicate infective endocarditis and when to seek expert advice

Infective endocarditis is rare and patients are unlikely to develop it. Early symptoms of infective endocarditis are similar to flu symptoms: fever, night sweats and chills, weakness and tiredness, and also breathlessness, weight loss and joint pain. Patients at risk of infective endocarditis should be advised to see a GP if they have such symptoms for longer than a week.⁸

The risks of undergoing invasive procedures, including non-medical procedures such as body piercing or tattooing

Bacteraemia can develop following piercing or tattooing, particularly if non-sterile equipment or techniques are involved. Patients at risk of infective endocarditis should be discouraged from having procedures such as piercing or tattooing.⁸

People with the following cardiac conditions are considered to be at risk of developing infective endocarditis and would have received antibiotics for endocarditis prophylaxis in the past:

- Previous infective endocarditis,
- Replacement heart valve,
- Structural congenital heart disease (but not isolated atrial septal defect, fully repaired septal defect, fully repaired patent ductus arteriosus or congenital heart disease repaired with closure devices that are judged to be endothelialised)
- Valvular heart disease with stenosis or regurgitation,
- Hypertrophic cardiomyopathy.

QUESTIONS PATIENTS MAY ASK

In the past I have been given antibiotics to prevent infective endocarditis for the same dental procedure but have not been offered them now. Why has this changed?

In the past, guidelines recommended that people at risk of infective endocarditis were given prophylactic (preventative) antibiotics before certain procedures. The National Institute for Health and Care Excellence (NICE) has reviewed the evidence regarding infective endocarditis and concluded that prophylactic antibiotics are not required for dental procedures.

To understand why the guidelines have changed, it is helpful to know why antibiotics were recommended in the first place: Dental procedures (such as scaling or tooth extraction) disturb bacteria in the mouth and these bacteria can then enter the bloodstream. It was thought that the rise in the number of bacteria in the bloodstream (bacteraemia) that occurred following dental procedures increased the risk of getting endocarditis, and antibiotics were given to combat this rise.

NICE has found that the levels of bacteria in the bloodstream associated with dental procedures are no higher than those associated with toothbrushing. So, patients undergoing dental procedures are not at any greater risk of getting endocarditis than they are from brushing their teeth. The bacteria that enter the bloodstream are killed by the body's immune system.

Antibiotics can cause side effects, some of which can be very serious, or even fatal. Taking antibiotics when they are not needed puts patients at unnecessary risk. Because antibiotics have not been shown to reduce the chance of getting endocarditis, and because dental procedures are no longer thought to be a cause of endocarditis, taking antibiotics before dental procedures is no longer recommended.

I've used a chlorhexidine mouthwash when I have had dental treatment in the past. Is this helpful?

Chlorhexidine mouthwash is not recommended to prevent infective endocarditis. It has not been shown to reduce the chance of getting endocarditis and, as explained above, dental procedures are no longer thought to be a cause of endocarditis.

Is there some written material (like a leaflet) about infective endocarditis that I can have?

The British Heart Foundation has information about infective endocarditis on its website. Go to the home page and type 'endocarditis' in the search box at the top of the screen.

What can I do to improve my oral health?

Keep your teeth and mouth clean with twice-daily toothbrushing. Visit your dentist for regular check-ups and don't let any dental problems such as a dental abscess or gum disease go untreated.

What are the symptoms of infective endocarditis? What should I do if I think I have it?

Infective endocarditis is very rare. Symptoms are flu-like, and include fever, night sweats and chills, weakness and tiredness as well as breathlessness, weight loss and joint pain. It is very unlikely that you will ever suffer from endocarditis but if you are at risk (e.g. if you have a replacement heart valve, valvular heart disease or hypertrophic cardiomyopathy) and have flu-like symptoms for longer than a week you should see a GP.

What do I do if I think I have an infection?

Guidelines for the treatment of infections have not changed. If you think you have an infection, contact a healthcare professional (e.g. pharmacist, GP, dentist or optician) as you would normally.

NICE provides guidance for the NHS in England and Wales. Further information about NICE, its work and how it reaches decisions is available online.

SUMMARY

Antibiotic prophylaxis is not recommended for the prevention of infective endocarditis in patients undergoing dental procedures.

LIMITATIONS

This document does not relate to the use of pre-procedural antibiotics to prevent infections other than infective endocarditis.

April 2008.

KEY POINTS

- Diabetes is common; it is the main endocrine disorder and is increasing
- Hypoglycaemia must be avoided

The endocrine system is widespread and consists of glands that exert their effects by means of chemicals (hormones) secreted into the blood circulation (Fig. 6.1). Hormones are chemical messengers of various types, which usually act at some distance from their source, and can be classified according to their main function.

Nervous and endocrine control mechanisms normally maintain body homeostasis, coordinated via the neuroendocrine system and most apparent in the hypothalamus. The hypothalamus, along with the pituitary gland, controls many other endocrine functions.

Fig. 6.1 Main endocrine glands (hormones are also produced by other tissues).

Pregnancy and the menopause cause important endocrine changes (Ch. 25). It is also common to see endocrine disorders in people who overexercise or who are anorectic, starving, stressed or ill (Table 6.1). Obesity may be due to endocrine disease (e.g. hypothyroidism, insulinoma, Cushing syndrome, polycystic ovary disease).

Endocrine glands can underproduce (hypofunction) or overproduce (hyperfunction) their hormones. Endocrine disorders (endocrinopathies) may be caused by diminished hormone release (e.g. hypothyroidism), by hormone resistance (e.g. type 2 diabetes) or by excess (e.g. primary hyperparathyroidism). Endocrinopathies can cause a range of symptoms and signs but fatigue is common to many (e.g. thyroid dysfunction, hyper- or hypoglycaemia, dyslipidaemia and gonadal dysfunction).

Endocrine function can be assessed by measuring the hormone in the blood plasma (many have a circadian rhythm – the level varies over 24 hours), or the hormone or its metabolite in the urine; alternatively, dynamic tests of hormone secretion or regulation may be performed – by suppressing (tests hormone excess) or stimulating (tests hormone deficiency) hormone release; or by assessing levels of hormone receptors or effects on the target tissues.

The most common and important specific endocrine disorder is diabetes mellitus, but the hypothalamus is the conductor of the endocrine ‘orchestra’ (Table 6.2).

Table 6.1 Endocrine responses to severe stress or illness

Plasma levels of hormone rise	Plasma levels of hormone fall	Resistance of hormone increases
Adrenaline (epinephrine)	Luteinizing hormone and follicle-stimulating hormone	Insulin
Glucagon	Sex steroids	
Glucocorticoids and adrenocorticotrophic hormone	Thyroid hormones and thyroid-stimulating hormone	
Growth hormone		
Prolactin		

Table 6.2 Hormones – classified by function

Electrolyte/fluid/vascular	Metabolic	Liver and digestive	Reproductive	Stress
Aldosterone	Adrenaline (epinephrine) and noradrenaline (norepinephrine)	Cholecystokinin	Aetiocholanolone	Adrenaline (epinephrine) and noradrenaline (norepinephrine)
Androstenedione		Gastrin	Chorionic gonadotropin	
Bradykinin	Cortisol	Vasoactive intestinal peptide	Oestradiol	Adrenocorticotrophic hormone
Calcitonin	Growth hormone		Oestriol	Corticosterone
Erythropoietin	Glucagon		Oestrone	Growth hormone
Neurotensin	Insulin		Progesterone	Hydrocortisone (cortisol)
Vasopressin (antidiuretic hormone)	Parathyroid hormone		Prolactin	
	Thyroid hormone		Testosterone	
	Vitamin D			

HYPOTHALAMUS AND PITUITARY GLAND

The hypothalamus is the part of the brain that controls many other endocrine glands, via pituitary function and hypophysiotropic hormones sometimes termed ‘releasing factors’.

The anterior pituitary (adenohypophysis) originates as an outgrowth from the stomatodeum (Rathke pouch) and, although anatomically distinct from the hypothalamus, falls under its influence by factors passing through a portal venous system (Fig. 6.2). Hypothalamic hormones that act on the anterior pituitary gland include *thyrotropin-releasing hormone* (TRH), *gonadotropin-releasing hormone* (GnRH), *growth hormone-releasing hormone* (GHRH), *corticotropin-releasing hormone* (CRH) and *somatostatin* (Table 6.3).

The posterior pituitary (neurohypophysis) is a downgrowth from the base of the brain and is connected with the hypothalamus by neurons. Two hypothalamic hormones act on the posterior pituitary gland – *antidiuretic hormone* (ADH) and *oxytocin*.

The hypothalamus is under the control of higher centres in the brain and inhibited by the hormone somatostatin (octreotide). Feedback control influences the amount of hypothalamic hypophysiotropic hormone secreted. *Dopamine* inhibits pituitary release of *prolactin* (PRL).

Pituitary hyperfunction is sometimes caused by pituitary tumours, usually microadenomas (smaller than 1 cm), which can have pressure effects on adjacent structures such as the rest of the anterior pituitary gland and the optic chiasm (Fig. 6.3), causing headaches and visual defects as well as effects on hormone release. Around 50% of pituitary adenomas are hormone-secreting – half producing prolactin, the rest producing growth hormone, adrenocorticotrophic hormone (ACTH) or thyroid-stimulating hormone (TSH).

Pituitary hormones, used to stimulate growth, have been implicated in the transmission of some cases of iatrogenic Creutzfeldt–Jakob disease (Ch. 13).

Fig. 6.2 Hypothalamopituitary control. ADH = antidiuretic hormone; CRH = corticotropin-releasing hormone; FSH = follicle stimulating hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

POSTERIOR PITUITARY HYPOFUNCTION

Diabetes insipidus

General aspects

Diabetes insipidus is a rare disease caused by lack of ADH effect. Rarely, this is because of renal insensitivity to ADH (nephrogenic diabetes insipidus – a rare X-linked disorder affecting renal tubular ADH

Table 6.3 Hypothalamic hormones

Hypothalamic hormone	Primary activities	Effects
Thyrotropin-releasing hormone (TRH)	Stimulates pituitary release of thyroid-stimulating hormone (TSH) and prolactin (PRL)	Stimulates thyroid hormone synthesis and release
Gonadotropin-releasing hormone (GnRH)	Stimulates pituitary release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)	LH stimulates follicle to secrete oestrogen in first half of menstrual cycle, triggers completion of meiosis and egg release (ovulation) in mid-cycle, and stimulates empty follicle to develop into corpus luteum, which secretes progesterone during latter half of cycle LH acts on interstitial cells of testes, stimulating them to synthesize and secrete testosterone. FSH acts on follicle to stimulate it to release oestrogens and on spermatogonia, stimulating (with aid of testosterone) sperm production
Growth hormone-releasing hormone (GHRH)	Stimulates pituitary release of growth hormone (GH)	Growth (also diabetogenic)
Corticotropin-releasing hormone (CRH)	Stimulates pituitary release of adrenocorticotrophic hormone (ACTH)	Stimulates glucocorticoid synthesis and release
Somatostatin	Inhibits pituitary release of TSH and GH	Pituitary control
Antidiuretic hormone (ADH)	Promotes water absorption in renal tubules	Water control
Oxytocin	Stimulates uterine contraction and breast-milk ejection	Lactation

Fig. 6.3 Anatomical relations of the pituitary gland.

receptors, or due to hypercalcaemia, hypokalaemia, renal disease or drugs such as lithium). More commonly, it is because of reduced ADH secretion – cranial diabetes insipidus, which is caused by head injuries (when it may be temporary), a tumour (usually craniopharyngioma), infiltration or vascular disease in the region of the hypothalamus or pituitary, or it may be idiopathic.

Clinical features

Diabetes insipidus is characterized by an excessive volume of dilute urine (polyuria) and by persistent thirst and drinking (polydipsia). Cranial diabetes insipidus may also cause pressure on the optic chiasm, leading to visual or cranial nerve defects, or raised intracranial pressure and headaches.

General management

The diagnosis is established by assessing the relation of plasma to urine osmolality and by demonstrating an inability to concentrate the urine during a water-deprivation test. The local extent of disease is assessed by imaging (skull radiography and magnetic resonance imaging [MRI]), visual field charting and tests of anterior pituitary function.

Diabetes insipidus is treated with the ADH-like peptide desmopressin or antidiuretic drugs such as chlorpropamide or carbamazepine.

Dental aspects

Local anaesthesia (LA) is the most satisfactory means of pain control. Conscious sedation (CS) may be needed to control anxiety. Dentistry is usually uncomplicated by this disorder except for dryness of the mouth.

Carbamazepine used in the treatment of trigeminal neuralgia may have an additive effect with other drugs used to treat diabetes insipidus. Transient diabetes insipidus can be a complication of head injury, but head injury can also cause the opposite effect – excessive ADH levels.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH)

Excessive ADH levels may be caused by: maxillofacial injury or even elective maxillofacial surgery, head injury or intracranial lesions; general anaesthesia (GA); pain; fits; smoking; tumours (especially some lung cancers); or drugs (carbamazepine, chlorpropamide, vinca alkaloids).

Inappropriate ADH secretion causes water retention, overhydration, confusion, behavioural disturbances, ataxia and dysphagia. Diagnosis is by finding hyponatraemia with concentrated urine and high plasma and urinary ADH, and an abnormal water-excretion test.

Patients with SIADH are treated with fluid restriction, corticosteroids or demeclocycline.

ANTERIOR PITUITARY HYPOFUNCTION

General aspects

The usual causes of hypopituitarism are local hypothalamic or pituitary lesions, such as tumours, or irradiation (similar factors to those causing cranial diabetes insipidus) or infarction of the pituitary following postpartum haemorrhage (Sheehan syndrome).

Clinical features

The results of hypopituitarism (Table 6.4) are essentially hypofunction of the target glands (the gonads, thyroid and/or adrenal cortex) with soft skin, hypotension, hypoadrenalism and hypothyroidism.

Multiple (panhypopituitarism) hormone deficiencies can result (Fig. 6.4).

General management

Hormone substitution therapy (corticosteroids and thyroxine) is needed. Surgery may be required if there are tumours, cranial nerve defects or hydrocephalus.

Dental aspects

Patients are at risk from adrenal crisis (Ch. 1) and from hypopituitary coma, which is precipitated by stress (trauma, surgery, GA, sedatives).

Table 6.4 Hypopituitarism: clinical effects

Sequence of hormone deficiencies		Effects
1	LH	Impotence
	FSH	Amenorrhoea
		Infertility
		Loss of pubic hair
2	GH	Impaired growth in children
3	Prolactin	Failure of lactation if postpartum (Sheehan syndrome)
4	ACTH	Hypoadrenocorticism
5	TSH	Hypothyroidism

Fig. 6.4 Hypopituitarism.

Box 6.1 *Gonadotropin deficiency syndromes*

- Kallmann
- Laurence–Moon–Biedl
- Moebius
- Prader–Labhart–Willi
- Rud
- Syndromes of cerebellar ataxia

or hypnotics, or infection), much in the way that an adrenal crisis may be.

Hypopituitary coma should be treated by laying the patient flat and giving an immediate intravenous injection of 200 mg hydrocortisone sodium succinate. Blood should be taken for assay of glucose, thyroid hormones and cortisol, and 25–50 g dextrose should be given intravenously if there is hypoglycaemia (defined as a blood glucose <3.0 mmol/L). Oxygen should be given by face mask, medical assistance summoned and emergency admission to hospital arranged.

Gonadotropin (GnRH) deficiency

Hyposecretion of GnRH may be seen most commonly in intense physical training or anorexia nervosa, and rarely in syndromes (Box 6.1).

Kallmann syndrome (hypogonadotropin eunuchoidism) is the most frequent form of isolated gonadotropin deficiency – a rare X-linked recessive disease caused by a defect in a cell adhesion protein that participates in the migration of the GnRH neurons. These normally originate in olfactory tissues and migrate to the hypothalamus. Impaired sense of smell is caused by the absence of the olfactory bulbs. Kallmann syndrome mainly affects males and becomes apparent when they fail to develop secondary sexual characteristics. Thus, hypogonadism and anosmia, with underdeveloped genitalia and sterile gonads, are classic presentations. Treatment involves oestrogen or testosterone replacement, and pulsatile GnRH injections.

ANTERIOR PITUITARY HYPERFUNCTION

Growth hormone excess: gigantism and acromegaly

General aspects

Overproduction of growth hormone by an anterior pituitary adenoma causes gigantism before the epiphyses have fused, and acromegaly thereafter.

Clinical features

In *gigantism*, all the organs, soft tissues and skeleton enlarge, leading to excessively tall stature, thickening of the soft tissues with prominence of the supraorbital ridge, coarse oily skin, thick spade-like fingers and deepening of the voice.

In *acromegaly*, only those bones with growth potential, particularly the mandible, can enlarge. There is thickening of the soft tissues and the hands become large and spade-like. Acromegaly is one of the few endocrine diseases that should be instantly recognized – even in a passer-by – by the gross prognathism and the thickened facial features and hands (Fig. 6.5).

In both *gigantism* and *acromegaly*, local pressure effects from the pituitary tumour may cause hypopituitarism plus compression of the optic chiasma, with visual field defects and raised intracranial pressure with severe headaches.

Fig. 6.5 Acromegaly showing prominent supraorbital ridges and prognathism.

Growth hormone disorders may be complicated by diabetes mellitus, hypertension, cardiomyopathy, sleep apnoea, hypercalcaemia and osteoarthritis (Fig. 6.6). Life expectancy is also shortened by diseases such as colonic carcinoma.

General management

Family photographs may clearly demonstrate the increasingly coarse features. Skull radiography, computed tomography (CT) and MRI scans (for pituitary – sella turcica – enlargement) are indicated. Sella enlargement is also sometimes due to other causes, such as hypothalamic masses or cysts or the empty sella syndrome (this is caused by herniation of a sac of leptomeninges into the sella). Rhinorrhoea may warrant surgical correction, but no other treatment is needed.

Other investigations in growth hormone excess are visual field assessment (to detect optic chiasm involvement), glucose tolerance tests (to exclude diabetes and to assess the plasma growth hormone response), levels of growth hormone and insulin-like growth factor 1 (IGF-1), and assessment of function of the remaining pituitary.

The pituitary adenoma may be resected trans-sphenoidally or the whole gland may have to be irradiated (e.g. by transnasal yttrium). Hypopituitarism or diabetes insipidus follows such treatment.

Bromocriptine or octreotide (an analogue of the hypothalamic release-inhibiting hormone somatostatin) may also help treatment.

Dental aspects

Local analgesia is suitable. CS may be given, if necessary, provided the airway is clear. GA may be hazardous because of complications (see later).

Dental management may be complicated by:

- blindness, diabetes mellitus, hypertension, cardiomyopathy, arrhythmias and hypopituitarism

Fig. 6.6 Acromegaly.

- kyphosis and other deformities affecting respiration, which may make GA hazardous. The glottic opening may be narrowed and the cords' mobility reduced. A goitre may further embarrass the airway
- rarely, the development of Cushing syndrome or hyperparathyroidism due to associated multiple endocrine adenoma syndrome.

Mandibular enlargement leads to prognathism (class III malocclusion) with spacing of the teeth and thickening of all soft tissues, but most conspicuously of the face. Orthognathic surgery may be needed and fatalities have followed such surgery in the past because of airway obstruction. The paranasal air sinuses are enlarged and the skull thickened. Sialosis may develop.

PANCREAS

All carbohydrate eaten is digested into glucose, which passes from the stomach and intestine into the blood and is the main source of energy. Glucose homeostasis depends mainly on the pancreatic hormones insulin (from the beta-cells of the islets of Langerhans) and glucagon from the alpha-cells in the islets.

Insulin facilitates glucose transport into cells and thus lowers blood sugar (glucose) levels. Glucagon stimulates the liver to convert glycogen into glucose, thus raising glucose levels and having the opposite effect to insulin (Fig. 6.7). The beta-cells also produce amylin, which modulates gastric emptying and satiety, and decreases the postprandial

Fig. 6.7 Glucose absorption and homeostasis.

rise in glucagon. Also involved in glucose homeostasis are gastric inhibitory polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) – small intestine hormones (incretins) secreted when eating. GLP-1 has a glucose-lowering effect via stimulation of insulin production and inhibition of glucagon (as well as preserving pancreatic beta-cell function, slowing gastric emptying and suppressing food intake). Several other hormones that can influence glucose include catecholamines (adrenaline [epinephrine] and noradrenaline [norepinephrine]), corticosteroids, thyroid hormone and growth hormone.

DIABETES MELLITUS

General aspects

Diabetes mellitus (DM) is a disorder caused by an absolute or relative lack of insulin; there can be a low output of insulin from the pancreas, or the peripheral tissues may resist insulin. In diabetes, with insulin lacking or its action blocked, glucose cannot enter cells and, without energy, weakness results. Glucose also then accumulates in the blood (hyperglycaemia) and spills over into the urine (glucosuria), taking with it, osmotically, a large amount of water (polyuria). This leads to dehydration and thus thirst and the need to drink excessively (polydipsia). As glucose is then no longer a viable energy source, fat and protein stores are metabolized with weight loss, peripheral muscle wasting and, in type 1 diabetes, the production of ketone bodies (acetoacetate, β -hydroxybutyrate and acetone). In severe cases, ketone bodies may be detected on the breath (in particular, acetone) and accumulate in the blood (ketonaemia), as well as being excreted in the urine (ketonuria). The resultant metabolic ketoacidosis leads to a compensatory increase in respiratory rate (hyperventilation) and a secondary respiratory alkalosis.

Chronic hyperglycaemia causes microvascular complications and atherosclerosis, and is a leading cause of death and disability.

Diabetes affects about 3–4% of the general population but may be recognized in only 75% of those individuals, yet it is a leading cause of death and disability. Worldwide, about 246 million people are affected. Risk factors for diabetes include family history (the risk of developing diabetes rises if a close relative, such as a parent or sibling, has the disease); being overweight; inactivity; age (the risk of developing type 2 diabetes rises with age, especially after age 45); and race. Genetics has a role. Type 1 diabetes is more common in Caucasians and in European countries, such as Finland and Sweden. Type 2 diabetes is especially common in people of African heritage, Asians and Hispanics, and has a stronger genetic background. Diabetes affects up to one-third of the elderly from the Asian subcontinent. Among the Pima Indians in the USA and in Nauru in the Pacific, around half of all adults have type 2 diabetes – the highest rates in the world. The prevalence of diabetes appears to be rising, mainly as more children and adolescents become overweight. In contrast, fewer diabetics remain undiagnosed, and associated ischaemic heart disease and retinal disease are falling.

Diabetes may be primary, or secondary to some other factor(s), as shown in Table 6.5. Type 2 is by far the most common type (Table 6.6).

Type 1 diabetes (T1DM)

Type 1 diabetes develops when the immune system attacks insulin-producing cells of the pancreatic islets of Langerhans. Weight reduction and exercise increase sensitivity to insulin, thus helping to control blood glucose elevations, but these patients still require insulin.

Type 1 diabetes – formerly termed insulin-dependent (IDDM) or juvenile-onset diabetes – is most commonly diagnosed at about 12 years of age and commonly presents before the third decade, but can appear at any age. Associated with other organ-specific autoimmune diseases, it is characterized by antibodies directed against insulin and the pancreatic islets of Langerhans. It may have a viral (possibly Coxsackie or rubella) aetiology. Latent autoimmune diabetes in adults

(LADA) is essentially a slow presentation of type 1 diabetes, which is seen in slimmer patients who progress quickly to insulin requirement. Anti-glutamic acid decarboxylase (GAD) antibodies may be helpful in the diagnosis.

Type 2 diabetes (T2DM)

Type 2 diabetes – formerly termed non-insulin-dependent (NIDDM) or maturity-onset diabetes – accounts for at least 90% of diabetics. Generally, it occurs in genetically predisposed individuals over the age of 40, who are typically overweight. Patients are insulin-resistant and have diminished beta-cell function. Alcohol binge drinking may induce insulin resistance independent of caloric intake and increase the risk for developing metabolic syndrome and T2DM. Maturity-onset diabetes of the young (MODY) is a rare form of type 2 diabetes; it caused by autosomal dominant mutations and so there is vertical transmission of diabetes within families. The phenotype varies from mild glucose intolerance to insulin-requiring diabetes, typically diagnosed before the age of 25 years.

Type 3 diabetes (T3DM)

Gestational diabetes is basically an insulin-resistant state exposing the patient to a future risk of type 2 diabetes (see Table 6.6).

Clinical features

Patients with diabetes may be asymptomatic and detected on routine or opportunistic screening, or present in a variety of ways related to severity and degree of onset (Table 6.7).

Table 6.5 Classification of diabetes mellitus

Primary	Type 1 – insulin-dependent (IDDM); juvenile onset
	Type 2 – non-insulin-dependent (NIDDM); maturity onset
Secondary	Drugs (corticosteroids, thiazide diuretics, beta-blockers)
	Endocrine disorders (phaeochromocytoma, acromegaly, Cushing syndrome)
	Pancreatic disease (pancreatitis), haemochromatosis
	Pregnancy (gestational diabetes) – usually represents type 2 diabetes exposed by the increased insulin resistance of pregnancy

Table 6.7 Acute and chronic presenting features of diabetes mellitus

Acute	Chronic
Thirst	Thirst
Polyuria and polydipsia	Polyuria and polydipsia
Weight loss and weakness	Weight loss and weakness
Lethargy	Lethargy
Confusion/aggression/behavioural changes	Irritability
Abdominal pain	Recurrent skin, oral and genital infections
Nausea and vomiting	Visual deterioration
Ketoacidosis	Paraesthesia (hands and feet)
Dehydration	
Renal failure	
Coma	

Table 6.6 Types of diabetes mellitus

Type	Formerly called	Typical time of onset	% of all diabetes	Aetiopathogenesis	Autoantibodies	Other factors
1	Insulin-dependent (IDDM)	Juvenile onset	5–10	Insulin deficiency	Islet cell antibodies in up to 90%	Genetic: HLA-DR3/4 in 95%. Viruses (mumps or Coxsackie) affect beta-cells: implicated in autoimmune disease
2	Non-insulin-dependent (NIDDM)	Maturity onset	90–95	Insulin resistance	None	Overweight, often family history of diabetes; no HLA association Subtypes result from mutations in glucokinase gene, changes in insulin signalling, defective phosphatidylinositol kinases or other mechanisms
3	Gestational	Appears usually in second or third trimester of pregnancy	Rare	Affects up to 5% of pregnant women. Placental hormones interfere with insulin	None	Most common in people of African heritage or with a family history of diabetes. Increased risk of type 2 diabetes later

Fig. 6.8 Diabetes mellitus.

Lethargy is the most common symptom but hyperglycaemia, polyuria and thirst (polydipsia) are prominent. Since glucose is lost as an energy source in type 1 diabetes, fats must be metabolized, leading to weight loss from fat breakdown to fatty acids and ketone bodies, which appear in the blood, causing acidosis and hyperventilation, in the urine (ketonuria) and to some extent in the breath (acetone). Overproduction of acetoacetate is converted to the other ketone bodies, hydroxybutyrate and acetone. Diabetes is also associated with immune deficiencies, particularly polymorph dysfunction, leading to susceptibility to infections (mainly skin infections and mucosal candidosis; Fig. 6.8).

Type 1 diabetes develops most often in children and young adults, generally before the age of 25. Symptoms usually develop over a short period. Excessive thirst and urination, constant hunger, weight loss, blurred vision and extreme fatigue are typical. Life-threatening diabetic coma (diabetic ketoacidosis) is a significant risk. Insulin is required daily for treatment, for life, and diet must be controlled. Hypoglycaemia is a risk.

Type 2 diabetes develops most often in overweight patients. Symptoms usually develop gradually. Fatigue, frequent urination, unusual thirst, weight loss, blurred vision, frequent infections, and slow healing of wounds or sores are seen. Most patients with type 2 diabetes can be managed on diet and oral hypoglycaemic drugs. Many will eventually need insulin but are often resistant. About 80% of people with type 2 diabetes have the *metabolic syndrome*, which includes obesity, elevated blood pressure and high levels of blood lipids (Ch. 23).

Factors that affect the blood glucose level are shown in Box 6.2.

Box 6.2 Factors that affect blood glucose level

- Food – carbohydrates raise blood glucose, which is highest 1–2 h after a meal
- Exercise and physical activity – lower blood glucose
- Medications – insulin and oral diabetes medications lower blood glucose (steroids, thiazides, beta-blockers and niacin may raise blood glucose)
- Illnesses such as infections – can raise blood glucose
- Alcohol – even about 2 units can cause blood glucose to fall
- Hormones – oestrogen typically increases cells’ response to insulin, and progesterone makes them more resistant

Table 6.8 Causes of hypoglycaemia

Common (diabetics)	Rare (non-diabetics)
Excess insulin or hypoglycaemic drug	Insulinoma
Missed meal	Hepatic disease
Unaccustomed exercise	Hypoadrenocorticism
Alcohol (the effect of which is delayed)	Hypopituitarism
	Functional hypoglycaemia
	Beta-blockers

Acute complications

Diabetes can lead to coma. Hypoglycaemic coma is the main acute complication of diabetes, is growing in frequency with the trend towards tighter metabolic control of diabetes, and is usually the result of one or more of the above factors. Less common causes are shown in Table 6.8. Many insulin-treated patients are liable to hypoglycaemia, due to an imbalance between food intake and usage, and insulin therapy. Hypoglycaemia can be of rapid onset and may resemble fainting. Adrenaline (epinephrine) is released, leading to a strong and bounding pulse, sweaty skin, and often anxiety, irritability and disorientation, before consciousness is lost. Occasionally, the patient may convulse.

The patient should be treated immediately (Table 6.9); hypoglycaemia must be quickly corrected with glucose or brain damage can result. Glucose will cause little harm in hyperglycaemic coma but will improve hypoglycaemia. Never give insulin since this can cause severe brain damage or kill a hypoglycaemic patient. Assess the glucose level with a testing strip.

If the patient is conscious, give glucose solution or gel (GlucoGel) immediately by mouth or 10 g sugar but, if the patient is comatose, give 10–20 mL of 20–50% sterile dextrose intravenously or, if a vein cannot readily be found, glucagon 1 mg intramuscularly. On arousal, the patient should also be given glucose orally, usually in the form of longer-acting carbohydrate (e.g. bread, biscuits).

Other diabetics are difficult to control (brittle diabetes – a term usually used in association with adolescent girls who may be self-harming) and more prone to ketosis, severe acidosis and hyperglycaemia (diabetic coma), the result of a relative or absolute deficiency of insulin. In patients under treatment, it may be precipitated by factors such as infections.

Hyperglycaemic coma usually has a slow onset over many hours, with deepening drowsiness (but unconsciousness is rare, so an unconscious diabetic should always be assumed to be hypoglycaemic), signs of dehydration (dry skin, weak pulse, hypotension), acidosis (deep breathing), and ketosis (acetone smell on breath and vomiting) mainly in type 1 diabetes. If it is certain that collapse is due to hyperglycaemic

Table 6.9 Hypoglycaemic and hyperglycaemic comas and their treatment

Hypoglycaemic coma	Hyperglycaemic coma
Diabetes usually known	Diabetes may be unrecognized
Too much insulin or too little food, or too much exercise or alcohol	Too little insulin, infection or myocardial infarct
Adrenaline (epinephrine) release causes:	Acidosis in some variants causes:
Sweaty warm skin	Vomiting
Rapid bounding pulse	Hyperventilation
Dilated (reacting) pupils	Ketonuria
Anxiety, tremor, aggression	Acetone breath
Tingling around mouth	Osmotic diuresis and polyuria cause:
Cerebral hypoglycaemia causes:	Dehydration
Confusion, disorientation, aggression	Hypotension
Headache	Tachycardia
Dysarthria	Dry mouth and skin
Unconsciousness	Abdominal pain
Focal neurological signs (e.g. fits)	
Management	
Take blood for baseline glucose, electrolytes, urea, Hb and packed cell volume (PCV)	
If conscious, give Hypostop (Glucogel) or 25 g glucose orally (2 teaspoons sugar, 3 lumps sugar, 3 Dextrosol tablets, 60 mL Lucozade, 15 mL Ribena, 90 mL cola drink (<i>not</i> 'diet' variety) or 170 mL milk)	Put up infusion to rehydrate and give insulin
If comatose, give 20 mg 20% or 50% dextrose i.v. and on arousal 25 mg orally	
If i.v. injection impossible, give glucagon 1 mg i.m.	
Call ambulance (Ch. 1)	

ketoacidotic coma, the immediate priority is to establish an intravenous infusion line. This enables rapid rehydration to correct dehydration and electrolyte (especially potassium) losses, and the administration of insulin. Blood should be taken for baseline measurements of glucose, electrolytes, pH and blood gases. Raised plasma ketone body levels can be demonstrated with a testing strip such as Ketostix (Ames). Insulin is then started, such as 20 units i.m. stat. Medical help should be obtained as soon as possible.

Coma in a diabetic patient, though usually due to hypo- or hyperglycaemia, may have other causes such as myocardial infarction (Ch. 5).

Chronic complications

Diabetes is associated with long-term microvascular and macrovascular complications that can affect almost every part of the body (Table 6.10). It is a leading cause of death and disability due to premature cardiovascular disease; the risk of myocardial infarction is at least tripled. Renal and retinal complications are also incapacitating, as is gangrene of toes.

Smoking increases the risk of many chronic complications. Phagocytic defects contribute to an immune defect and liability to infections. Babies born to women with diabetes are often large and sometimes have birth defects. Occasionally, there are associations of type 1 diabetes with autoimmune disorders, especially Addison disease. There may be a predilection to oral cancer.

Table 6.10 Chronic complications of diabetes

Cardiovascular	Atherosclerosis leading to ischaemic heart disease, cerebrovascular disease and peripheral gangrene
	Cardiorespiratory arrest
Renal	Renal damage and failure
Ocular	Retinopathy
	Cataracts
Neuropathies	Peripheral polyneuropathy
	Mononeuropathies
	Autonomic neuropathy (postural hypotension)
Infections	Candidosis
	Staphylococcal infections
	Systemic mycoses (rarely)

Table 6.11 Glucose assays in the diagnosis of diabetes

Test	Confirms diabetes ^a	Excludes diabetes
Fasting plasma glucose (after a person has fasted for 8 h)	>7.0 mmol/L	<6 mmol/L
Random blood glucose (taken at any time of day)	≥11.1 mmol/L	<8 mmol/L ^b
Plasma glucose taken 2 h after a person has consumed a drink containing 75 g of glucose in oral glucose tolerance test (OGTT)	>11.1 mmol/L ^a	<11.1 mmol/L

^aIf associated with symptoms, or abnormal on repeat testing.

^bMust be checked with fasting glucose.

General management

Glycosuria is *usually* indicative of diabetes, but absence of glycosuria does not completely exclude it and confirmation by blood glucose levels is essential. Diagnosis is from the presence of raised blood (venous plasma) glucose level (Table 6.11).

A diagnosis of diabetes is made when any one of the glycosuria, random blood glucose and fasting blood glucose tests is positive, with a second test positive on a different day (not needed if symptomatic). *Pre-diabetes* is the term applied when there is either of the following:

- An impaired glucose tolerance (IGT) test – blood glucose during the oral glucose tolerance test (OGTT) is higher than normal but not high enough for a diagnosis of diabetes (7.8–11.0 mmol/L)
- An impaired fasting glucose (IFG; impaired fasting glycaemia) test – fasting plasma glucose is higher than normal (6.1–6.9 mmol/L) but less than the level confirming the presence of diabetes.

Patients with IGT and IFG are more likely to develop type 2 diabetes, and have an increased risk of cardiovascular disease.

Prevention

- Weight should be reduced and physical activity stepped up.
- Diet may help diabetic control; recommendations are to:

Eat more starches, such as bread, cereal and starchy vegetables
 Eat five portions of fruits and vegetables every day. Soluble fibres, found mainly in fruits, vegetables and some seeds, are especially useful as they help slow down or reduce intestinal absorption of glucose. Legumes, such as cooked kidney beans, are among the highest soluble-fibre foods. Other fibre-containing foods, such as carrots, also have a positive levelling effect on blood glucose.

Eat fewer sugars and sweets.

Fig. 6.9 Diabetes wristband.

Treatment

Treatment objectives are:

- reduction of hyperglycaemia – to alleviate presenting symptoms
- prevention of hypoglycaemia and other acute complications
- maintenance of near-normal blood glucose levels – to minimize microvascular complications
- reduction of other cardiovascular risk factors (smoking, exercise, hypertension and lipids).

Individuals should be educated about the importance of good long-term diabetic control; they should have a thorough knowledge of the disease and may wish to warn others that they have it (Fig. 6.9). All diabetics should carry a card indicating the diagnosis, treatment schedule and physician in charge, and should be encouraged to wear a MedicAlert-type device.

The progressive nature of diabetes, its complications and management aims should be well understood. Patients should also be aware of the range of diabetic services available and how to make appropriate use of them. A multidisciplinary team approach is required for their effective management. Meals should be taken at regular intervals, with a high fibre and relatively high carbohydrate content but avoiding sugars, and with a caloric intake strictly related to physical activity. Lifestyle changes, such as exercise, diet, fasting, travel (including changing time zones) and changes in working practices, can have an impact on diabetic control.

Urine testing has little or no place in the assessment or control of diabetes. Control is assessed by blood glucose levels and used to guide medication. A glucometer allows glucose readings to be taken easily by the patient at home. Fasting glucose <6mmol/L is normal. Long-term assessment of glucose control is made by estimation of the blood level of glycosylated haemoglobin (HbA_{1c}). HbA_{1c} is normal adult haemoglobin that binds glucose and remains in the circulation for the life of the erythrocyte, therefore acting as a cumulative index of diabetic control over the preceding 3 months; the higher the glycosylated haemoglobin level, the greater the risk of chronic complications. Patients should have an HbA_{1c} test every 3–6 months; glycosylated haemoglobin below 4.8% of total haemoglobin is normal. Fructosamine is an alternative assay of long-term diabetic control.

Optimum control would be to aim to keep blood glucose levels at 4–7mmol/L before meals (preprandial) and at no higher than

Fig. 6.10 Insulin injection sites.

Table 6.12 Different insulins

Insulin type	Protocol	Peak activity	Approximate duration of activity
Rapid-acting analogues	Injected just before, with or after food	0–3 h	2–5 hours
Long-acting analogues	Injected once a day, not necessarily with food	–	24 h
Short-acting insulins	Injected 15–30 min before a meal to cover the rise in blood glucose levels that occurs after eating	2–6 h	8 h
Medium- and long-acting insulins	Injected once or twice a day to provide background insulin or in combination with short-acting insulins/rapid-acting analogues	4–12 h	30 h
Mixed insulin	Combination of medium- and short-acting insulin	Varies	Varies
Mixed analogue	Medium-acting insulin and rapid-acting analogue	Varies	Varies

10 mmol/L 2 hours after meals (postprandial), and HbA_{1c} (long-term glucose level) at 7% or less.

Type 1 diabetes

Basic treatment of type 1 diabetes is subcutaneous insulin, the amount being balanced against food intake and daily activities, and monitored via home blood glucose testing. Insulin cannot be taken orally but must be given via injection, subcutaneously, either in the abdominal wall (Fig. 6.10), buttocks, thighs or upper arms, using a syringe, pen device or insulin pump. An artificial pancreas, a “closed loop” system that monitors blood glucose levels to adjust the insulin being administered by a pump is being developed. There are three groups of insulins – animal, human (actually synthetic) and analogues. There are six main types of insulin, available in various combinations and all working in different ways (Table 6.12). Most insulin regimes are based on a long-acting insulin combined with a smaller amount of faster-acting insulin, all normally taken via two or more injections each day. Insulin pump therapy (continuous subcutaneous insulin infusion [CSII]) is fast-acting insulin given continually day and night, at a rate preset according to needs. An insulin pump is not a closed loop system; rather, patients learn to set the dose according to diet, activity and blood glucose levels. Most test a minimum of four times a day, in order to obtain the information needed to set an appropriate insulin dose. An advantage of insulin pump therapy is that it can help improve control and minimize the frequency of ‘hypos’. The types of insulin used include those shown in Table 6.12.

Table 6.13 Hypoglycaemic drugs other than insulin

Group	Principles of action	Comments
Sulphonylureas	Increase pancreatic output of insulin	Sulfa-containing drugs, which should be avoided by patients who are allergic to sulfas. Bind to insulin-producing cell receptors and lower blood glucose by increasing pancreatic release of insulin, but run the risk of hypoglycaemia. Older generations include chlorpropamide and tolbutamide; newer drugs include glibenclamide (glyburide), glipizide and glimepiride. May enhance, or be enhanced by, aspirin, anticoagulants, monoamine oxidase inhibitors (MAOIs), beta-blockers or clofibrate
Meglitinides		Meglitinides – repaglinide and nateglinide – promote pancreatic insulin secretion via a cell-surface potassium-based channel. Like sulphonylureas, they cause hypoglycaemia but are very short-acting, with peak effects within 1 h. Preprandial glucose regulators
Biguanides		Metformin is unique in its ability to decrease liver glucose production. It does not increase insulin levels and therefore rarely causes hypoglycaemia. In addition, it suppresses appetite, which may be beneficial in overweight diabetics. Biguanides decrease target tissue insulin resistance, affect the absorption and metabolism of glucose, and reduce appetite, but can induce lactic acidosis. Metformin may be used alone or together with other oral drugs or insulin. It should not be used in renal disease and must be used with caution in liver disease. Metformin should be discontinued for 24 h before surgery or any procedure involving the intravenous injection of dyes (such as for some renal radiographic studies), as the dyes may impair kidney function and cause metformin accumulation
Thiazolidinediones (glitazones)	Help overcome insulin resistance by binding to the adipocyte receptor to increase the response of cells to insulin	Lower blood glucose by increasing cell sensitivity to insulin. Troglitazone has been withdrawn because it causes severe hepatotoxicity. Pioglitazone and rosiglitazone are safer, and effective in lowering blood glucose within 1 h of administration. Rosiglitazone, however, has been associated with an increased risk of cardiovascular events and with fractures of distal long bones of limbs. Glitazones mainly used in addition to metformin/sulphonylurea. Contraindicated in heart failure, ischaemic heart disease or peripheral vascular disease
Alpha-glucosidase inhibitors	Slightly delay intestinal breakdown of oligosaccharides to glucose and monosaccharides, and decrease carbohydrate absorption from the intestine	Carbohydrates are broken down by small-intestine enzymes, such as alpha-glucosidase, into sugars, such as glucose. Acarbose is an alpha-glucosidase inhibitor, whose use results in less efficient breakdown of carbohydrates and thus delay in glucose absorption. It has significant gastrointestinal side-effects, at least for a few weeks, although some patients report persistent problems
Dipeptidyl peptidase-4 inhibitors (DPP-IV; incretins)	Impede breakdown of endogenous incretin glucagon-like peptide 1 (GLP-1), thus stimulating insulin secretion but rarely causing hypoglycaemia	Sitagliptin and saxagliptin have a similar adverse effect profile to exenatide but are in pill form. Linagliptin increases the level of hormones that stimulate the release of insulin after a meal
Exenatide		Exenatide is an incretin mimetic, similar to the gut glucagon-like peptide-1 (GLP-1) hormone, which is broken down in the body by DPP-IV. Incretins, such as GLP-1, enhance glucose-dependent insulin secretion. GLP-1, produced in the small intestine, and amylin, produced by the pancreas, also have glucose-lowering effects. GLP-1, also released in a postprandial manner, promotes insulin production and secretion, reduces glucagon secretion, delays gastric emptying and induces a feeling of fullness. GLP-1 mimetics may produce nausea but have the advantage over other drugs of not leading to weight gain. Exenatide promotes insulin release from beta-cells, mimics certain antihyperglycaemic actions of GLP-1, is not a substitute for insulin, and is used with a thiazolidinedione with or without metformin. Exenatide is injected subcutaneously, twice a day. It may interact with paracetamol (acetaminophen), antibiotics, contraceptive pills, digoxin, lovastatin, sulphonylureas and warfarin
Liraglutide		A GLP-1 receptor agonist, which helps the pancreas make more insulin after a meal. As an injectable medicine, it improves blood glucose in adults with type 2 diabetes when used with a diet and exercise programme
Pramlintide	Affects glycaemic control	The first new injectable, antihyperglycaemic, a synthetic analogue of human amylin, a naturally occurring hormone synthesized by pancreatic beta-cells. Amylin helps control glucose after meals, and is absent or deficient in patients with diabetes

Type 2 diabetes

Medications for type 2 diabetes are designed to:

- increase the pancreatic output of insulin
- increase the response of cells to insulin
- decrease carbohydrate absorption from the intestine
- affect glycaemic control.

When selecting therapy, consideration should be given to:

- the magnitude of change in blood glucose control
- co-morbidities (high cholesterol, hypertension, etc.)
- medication:
 - adverse effects
 - contraindications
 - compliance
 - cost.

Some people with type 2 diabetes find that, despite having their diabetes medication adjusted, their blood glucose levels remain too high and insulin treatment is needed. Combination drugs, such as glibenclamide (glyburide)/metformin, rosiglitazone/metformin, glipizide/metformin, pioglitazone/metformin and metformin/sitagliptin, are available (Table 6.13).

Emerging treatments

Phlorizin, a naturally occurring product found in the bark of pear (*Pyrus communis*), apple, cherry and other fruit trees, is a competitive inhibitor of sodium–glucose co-transporters SGLT1 and SGLT2; it reduces renal glucose transport and lowers blood glucose. Although it is a potential treatment for type 2 diabetes, it has been superseded by more selective and more promising synthetic analogues, dapagliflozin and canagliflozin. Dapagliflozin is a selective and reversible inhibitor

of SGLT2 and has European regulatory approval for treatment of type 2 diabetes.

Combined kidney and pancreas transplantation is used for renal failure from type 1 diabetes in persons who are otherwise in acceptable health. Most people who receive a donor pancreas fall into this group. Approximately 85% of those who receive a combined kidney and pancreas transplant no longer require insulin a year after surgery. Pancreatic transplantation can be associated with all the problems that accompany immunosuppression (Ch. 35).

Islet cell transplantation offers a less invasive, expensive and risky option than a pancreas transplant. In islet cell transplantation, insulin-producing beta-cells are taken from a donor pancreas and transferred into a person with diabetes. Once transplanted, the donor islets begin to make and release insulin, actively regulating the level of blood glucose.

Dental aspects

There are no specific oral manifestations of diabetes mellitus but, even if it is well controlled, diabetic patients are predisposed to infections and have more severe periodontal disease than controls. Severe periodontitis may also upset glycaemic control. If diabetic control is poor, oral candidosis can develop and cause, for example, angular stomatitis. Severe diabetes with ketoacidosis predisposes to and is the main cause of mucormycosis originating in the paranasal sinuses and nose (Ch. 21). Severe dentoalveolar abscesses with fascial space involvement in seemingly healthy individuals may indicate diabetes. Any such patients should be investigated to exclude it and other immune defects.

In patients with insulin-treated diabetes, circumoral paraesthesia is a common and important sign of impending hypoglycaemia. Neuropathy may occasionally cause cranial nerve deficits and occasionally there is swelling of the salivary glands (sialosis; Fig. 6.11) due to autonomic neuropathy. Temporary lingual and labial paraesthesia may follow the removal of mandibular third molar teeth. A burning mouth sensation in the absence of physical changes may be possible. A dry mouth may result from dehydration. The 'Grinspan syndrome' (diabetes, lichen planus and hypertension) may be the result of purely coincidental associations of common disorders probably related to drug use.

Diabetes may have significant complications, such as hypoglycaemia, visual impairment, renal failure, gangrene, stroke or myocardial infarction, which can profoundly influence oral health care. The main hazard is hypoglycaemia, as dental disease and treatment may disrupt the normal pattern of food intake. This should be prevented by planning ahead, such as by administering oral glucose just before the appointment if a patient has taken their medication but has not had the appropriate meal. Furthermore, the patient's blood glucose level may be tested using a point-of-care device prior to treatment, particularly before surgical procedures, and oral glucose given if the level is too low – less than about 5 mmol/L (180 mg/dL). If normal eating will not be resumed at lunchtime, a postoperative blood glucose level may be taken and further glucose given.

Drugs used should be sugar-free, avoiding those that can disturb diabetic control: corticosteroids, which increase blood glucose; and doxycycline, tetracyclines and ciprofloxacin, which enhance insulin hypoglycaemia. Paracetamol (acetaminophen) or codeine is the analgesic of choice. NSAIDs should be used with caution in view of renal damage and risk of gastrointestinal bleeding, especially as many diabetics are already on low-dose aspirin for prophylaxis of ischaemic heart disease. The dentist should manage infections aggressively, as people with diabetes may be immunocompromised (Ch. 20); amoxicillin is the antibiotic of choice.

Fig. 6.11 Sialosis in diabetes.

LA can usually be safely used in diabetics; the dose of adrenaline (epinephrine) is unlikely to increase blood glucose levels significantly. CS with benzodiazepines can usually be safely used. Autonomic neuropathy in diabetes can cause orthostatic hypotension; therefore the supine patient should be slowly raised upright in the dental chair. Routine non-surgical procedures or short minor surgical procedures under LA can be carried out with no special precautions, apart from ensuring that treatment does not interfere with eating.

In a well-controlled diabetic patient, providing that normal diet has been, and can be, taken, it is feasible to carry out even minor surgical procedures, such as simple single extractions under LA, as long as the procedure is carried out within 2 hours of breakfast and the morning insulin injection, with no change in the insulin regimen. More protracted procedures, such as multiple extractions, must only be carried out in hospital. Poorly controlled diabetics (whether type 1 or 2) should also be referred for improved control of their blood glucose before non-emergency treatment is performed.

Diabetics on insulin

In a well-controlled insulin-dependent diabetic, providing that a normal diet can be taken and that the procedure is carried out within 2 hours of breakfast and the morning insulin injection, with no change in the insulin regimen, it is feasible to carry out minor surgical procedures (e.g. simple single extractions under LA, or minor operations under GA in hospital) by operating early in the morning and withholding both food and insulin from the previous midnight, until after the procedure.

The management of diabetes requiring GA is shown in Table 6.14.

Some medications can hide the warning symptoms of hypoglycaemia. These include:

- beta-blockers
- clonidine
- guanethidine
- reserpine.

Other drugs can cause hypoglycaemia (Box 6.3).

Perioperative management

The following section has been adapted from the UK National Health Service's guidelines on emergency and inpatient perioperative management in diabetic patients and from the *Tayside Area Formulary: Guidelines for the perioperative management of patients with diabetes* (www.nhstaysideadtc.scot.nhs.uk; accessed 30 September 2013).

Table 6.14 Management of diabetes requiring general anaesthesia^a

	Type 2 diabetes ^b	Type 1 diabetes
Preoperative	Stop biguanides	Stabilize on at least twice-daily insulin for 2–3 days preoperatively. One day preoperatively, use only short-acting insulin (Actrapid soluble or neutral)
Perioperative	Omit oral hypoglycaemic. Estimate blood glucose level	Do not give sulphonylurea or subcutaneous insulin on day of operation. Estimate blood glucose level. Set up intravenous infusion of 10% glucose 500mL containing Actrapid or Leo neutral insulin 10 units plus potassium chloride 1g at 8.00 am. Infuse over 4h. Estimate blood glucose and potassium levels 2-hourly. Adjust insulin and potassium to keep glucose at 5–10 mmol/L and normokalaemic
Postoperative	Estimate blood glucose 4h postoperatively	Continue infusion 4-hourly. Estimate blood glucose 4-hourly. Estimate potassium 8-hourly
On resuming normal diet	Start sulphonylurea or other usual regimen	Stop infusion. Start Actrapid or Leo neutral insulin and continue over the next 2 days. Start sulphonylurea. Start normal insulin regimen

^aCheck for local guidance protocols, and with anaesthetist.^bIf well controlled, otherwise treat as type 1.**Box 6.3** Drugs that may change blood glucose

- Adrenaline (epinephrine)
- Alcohol
- Anabolic steroids
- Angiotensin-converting enzyme inhibitors
- Antiretroviral protease inhibitors
- Appetite suppressants
- Aspirin and aspirin-like drugs
- Beta-blockers
- Certain medicines used for depression and emotional or psychotic disturbances
- Chromium
- Ciclosporin
- Cisapride
- Clonidine
- Corticosteroids
- Diazoxide
- Diuretics
- Female hormones
- Glucagon
- Growth hormone (somatotropin)
- Guanethidine
- Lithium
- Male hormones
- Medicines for allergies, asthma, cold or cough
- Metoclopramide
- Pentamidine
- Pentoxifylline
- Phenytoin
- Propoxyphene
- Quinolone antibiotics
- Some herbal dietary supplements
- Sulphonamides
- Tacrolimus
- Thyroid hormones

Careful planning is required at all stages of the patient pathway from GP referral to postoperative discharge. The patient should be involved in planning for all stages. Hospital patient administration systems should be able to identify all patients with diabetes so that they can be prioritized on the operating list. High-risk patients (poor glycaemic control/complications of diabetes) should be identified in surgical outpatients or at preoperative assessment, and plans should be put in place to manage their risk.

Early preoperative assessment should be arranged to determine a perioperative diabetes management strategy and to identify and optimize other co-morbidities.

Routine overnight admission for preoperative management of diabetes should not be necessary.

Starvation time should be minimized by prioritizing patients on the operating list.

The aim should be earlier mobilization with resumption of normal diet and return to usual diabetes management. Multimodal analgesia should be combined with appropriate antiemetics to enable an early return to normal diet and the usual diabetes regimen.

The term ‘variable rate intravenous insulin infusion’ (VRIII) should replace the ambiguous ‘sliding scale’. Patients with a planned short starvation period (no more than one missed meal in total) should be managed by modification of their usual diabetes medication, avoiding a VRIII wherever possible. Those expected to miss more than one meal should have a VRIII. The recommended first-choice substrate solution for a VRIII is 0.45% sodium chloride with 5% glucose and either 0.15% potassium chloride (KCl) or 0.3% KCl.

Insulin should be prescribed according to National Patient Safety Agency (NPSA) recommendations for its safe use. Capillary blood glucose (CBG) levels should be monitored and recorded at least hourly during the procedure and in the immediate postoperative period.

The World Health Organization (WHO) surgical safety checklist bundle should be implemented. The target blood glucose should be 6–10 mmol/L (acceptable range 4–12 mmol/L).

The above also applies to patients presenting for emergency surgery, with the proviso that many such patients are high-risk and are likely to require an intravenous insulin infusion and level 1 care (acute ward with input from critical care team) as a minimum.

General assessment

Exclude cardiac, renal and neurological issues that may complicate perioperative management and increase patient risk. Ensure that no other diabetes-related problems (e.g. retinopathy) need attention.

Assessment of glycaemic control

HbA_{1c} is an indicator of recent control (the previous 3 months). If it is above 9%, control is poor; if above 12%, control must be improved before elective surgery.

Perioperative blood glucose control**Patients on diet alone or oral hypoglycaemic agents**

Minor operations (dental, body surface or endoscopic procedures).

- Omit oral hypoglycaemic therapy on the day of the operation and avoid glucose infusions.
- Check fingerprick blood glucose on the morning of the operation and regularly thereafter.
- Operate on these patients early in the morning.
- Note that there is no need to stop metformin any sooner than on the day of surgery. Oral medication, *except for metformin*, should be restarted as normally prescribed with the first meal. Lactic acidosis is more likely if renal impairment is present and so metformin should not be restarted postoperatively unless renal function is known to be satisfactory. Metformin should not be used if the estimated glomerular filtration rate (eGFR) is below 30, and doses not higher than 500 mg b.d. are advised for patients with an eGFR of 30–49. If metformin is contraindicated, then additional hypoglycaemic therapy may be required. If in doubt, contact the diabetes team for advice.

Major operations

- Patients undergoing major operations will require intravenous insulin therapy after fasting.
- Patients on oral therapy who are inadequately controlled (i.e. random venous blood glucose >15.0 mmol/L or HbA_{1c} >9%) should be stabilized on insulin preoperatively and managed in the same way as insulin-treated patients (see below).

Management of patients (type 1 and type 2) on insulin

For surgical procedures, the essential requirement is to avoid hypoglycaemia but to keep hyperglycaemia below levels that may be harmful because of delayed wound healing or phagocyte dysfunction. The desired whole-blood glucose level is therefore 3–5 mmol/L. For major surgery, intermediate insulins are usually omitted and an intravenous infusion is given that contains glucose, to which, according to the level of plasma glucose, regularly measured, soluble (regular) insulin can be added as required. The effects of stress and trauma may raise insulin requirements and precipitate ketosis.

More protracted procedures, such as multiple extractions, must only be carried out in hospital, with the precautions described below.

Preoperatively

- All patients on insulin should be adequately controlled preoperatively and stabilized over 48 hours:
For patients using twice-daily insulin, this may be possible with their usual regime but may involve switching them to a multiple injection regimen.
For people with type 1 diabetes on multiple daily insulin regimens, it is advisable to continue their ‘usual’ daily long-acting analogue insulin, as this will reduce the risk of diabetic ketoacidosis if intravenous insulin is interrupted, and will facilitate a smooth transition to subcutaneous insulin at a suitable mealtime postoperatively.
- Remember that *some patients with type 2 diabetes may be treated with both insulin and metformin* – see above before restarting metformin.
- On the day prior to operation, check random venous blood glucose and urea and electrolytes.

Day-case surgery

- Aim for ‘first on list’.
- For those on a multiple injection regimen, continue the usual basal (long-acting) insulin on the evening prior to the procedure.
- For patients on twice-daily insulin, continue the usual evening insulin prior to the procedure.

- Fast the patient from midnight and omit the morning insulin.
- Check a fingerprick blood glucose before and after the procedure.
- Resume the usual insulin and diet after the procedure. If a b.d. insulin regimen is restarted at lunchtime, it is recommended that half of the normal ‘breakfast’ insulin dose should be prescribed with lunch after the procedure.
- The above applies if rapid recovery is expected, i.e. the patient is expected to be eating within 2 hours of the procedure.
- If the patient is unable to tolerate the diet or the blood glucose is >14 mmol/L, then a glucose, potassium and insulin (GKI) infusion or alternative will be required.

Major surgery

On the morning of the operation:

- check blood glucose and commence an intravenous GKI infusion
- *ensure that the patient does not receive subcutaneous rapid-acting or premixed insulin on the day of surgery.* The last dose of either type of insulin should have been given on the previous evening
- continue checking blood glucose hourly – before, during and after the operation.

Postoperatively

- Change to subcutaneous insulin postoperatively when the patient is eating normally.
- *Continue the intravenous insulin infusion for 60 minutes after the first subcutaneous insulin injection.*
- If the patient has previously been poorly controlled (HbA_{1c} >9%), refer to the diabetes team for advice before discharge.

ADRENAL CORTEX

The hypothalamus is in overall control of adrenocortical function by producing factors that stimulate the pituitary to release adrenocorticotrophic hormone (Fig. 6.12). ACTH arises from a precursor, pro-opiomelanocortin, and is released in response to hypothalamic corticotropin-releasing hormone (CRH), with a diurnal rhythm (peak early morning, nadir on retiring). Circulating corticosteroids have a negative feedback control on hypothalamic activity and ACTH production. There is thus a hypothalamic–pituitary–adrenocortical (HPA) axis. Glucocorticoid production is stimulated by ACTH (corticotropin) from the anterior pituitary gland, and cortisol exerts a negative feedback on the pituitary and hypothalamus. The adrenal cortex produces a series of corticosteroids, mainly cortisol (hydrocortisone) and corticosterone (the glucocorticoids), and aldosterone (the mineralocorticoid).

Corticosteroids are an essential part of the body’s response to stresses such as trauma, infection, GA or operation, pain, stress, fever, burns and hypoglycaemia. At such times, there is normally raised adrenal corticosteroid production and the size of the response is proportional to the degree of stress.

Mineralocorticoid (aldosterone) production is regulated mainly by the renin–angiotensin system, renal blood pressure, and sodium and potassium levels. Renin, an enzyme that converts angiotensinogen to angiotensin 1, is produced by the renal juxtaglomerular apparatus in response to low sodium or renal perfusion (Fig. 6.13). Angiotensin 1 is converted by angiotensin-converting enzyme in the lung parenchyma, to the active angiotensin 2, which stimulates aldosterone release. Aldosterone acts on the kidney to promote sodium retention, potassium excretion and fluid retention, and causes vasoconstriction and thirst.

Fig. 6.12 Adrenal control homeostasis. ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

Fig. 6.13 Blood pressure regulation via aldosterone production.

Atrial natriuretic peptide, synthesized by myocytes in the right atrium and ventricles, causes sodium loss and thus counters the effect of aldosterone.

ADRENOCORTICAL HYPOFUNCTION

Adrenocortical hypofunction can lead to hypotension, shock and death if the individual is stressed – for example, by operation, infection or trauma.

Adrenocortical hypofunction is due most commonly to ACTH (corticotropin) deficiency caused by the suppression of adrenocortical function following the use of systemic corticosteroids (secondary hypoadrenocorticism); occasionally by acquired adrenal disease (primary hypoadrenocorticism); and rarely, by a congenital defect in corticosteroid biosynthesis (congenital adrenal hyperplasia; [Table 6.15](#)).

Primary hypoadrenocorticism (Addison disease)

Primary hypoadrenocorticism is rare; it is caused by autoantibodies to the adrenal cortex, leading to adrenocortical atrophy and

Table 6.15 Causes of adrenal insufficiency

Patient on systemic corticosteroids	Adrenal disorders	Hypopituitarism
Trauma	Addison disease	
Operation	Post-adrenalectomy	
General anaesthesia	Waterhouse–Friderichsen syndrome (adrenal haemorrhage caused by septicaemia, anticoagulants or epilepsy)	
Infection	Congenital adrenal hyperplasia	

Fig. 6.14 Hypoadrenocorticism.

failed hormone secretion – cortisol (hydrocortisone) and aldosterone. Patients also have a higher incidence of other endocrine deficiencies (see later), vitiligo and, occasionally, chronic mucocutaneous candidosis.

Primary hypoadrenocorticism occasionally has other adrenal causes (though the term *primary* is then really a misnomer), such as tuberculosis, histoplasmosis (particularly secondary to human immunodeficiency virus [HIV] infection), malignancy, haemorrhage, sarcoidosis, amyloidosis, or adrenalectomy for metastatic breast cancer.

Clinical features

Lack of cortisol predisposes to hypotension and hypoglycaemia but stimulates the HPA, causing release of pro-opiomelanocortin, which has ACTH and melanocyte-stimulating hormone (MSH) activity and can cause hyperpigmentation. Lack of aldosterone leads to sodium depletion, reduced extracellular fluid volume and hypotension ([Fig. 6.14](#)).

Box 6.4 Hypoadrenocorticism: clinical features

- Anorexia, nausea and vomiting
- Hypotension
- Skin and mucosal pigmentation
- Weakness
- Weight loss

The lack of adrenocortical reserve makes patients vulnerable to any stress such as infection, trauma, surgery or anaesthesia, though they may be asymptomatic otherwise. An acute adrenal crisis (Addisonian crisis or shock) is thus characterized by collapse, bradycardia, hypotension, profound weakness, hypoglycaemia, vomiting and dehydration.

Patients with hypoadrenocorticism also suffer from fatigue and weakness, lethargy, weight loss, anorexia, nausea, vomiting, diarrhoea, hyperpigmentation, dizziness and postural hypotension (Box 6.4).

General management

Diagnosis of hypoadrenocorticism is confirmed by: hypotension; sometimes, low plasma sodium and raised potassium; plasma glucose assay (hypoglycaemia is common); and low plasma cortisol levels and depressed cortisol responses to ACTH stimulation. Blood for plasma cortisol estimation (10mL in a lithium heparin tube, or plain tube) should be taken at 8.00 or 9.00 a.m. In hypoadrenocorticism, the basal plasma cortisol level is usually lower than 6mg/100mL (170nmol/L), often lower than 100nmol/L. In early hypoadrenocorticism, the cortisol levels may still be in the low normal range and therefore a short ACTH stimulation test is indicated. Plasma is collected before and 30min after 250mg of tetracosactrin (synthetic ACTH; Synacthen) is injected intramuscularly or intravenously. In health, the plasma cortisol level normally doubles from at least 200nmol/L to more than 500nmol/L after tetracosactrin. In hypoadrenocorticism, the basal cortisol level is low and does not rise by more than 200nmol/L after tetracosactrin is given.

Estimation of serum ACTH levels differentiates primary (ACTH raised, usually above 200 ng/L) from secondary (ACTH low or normal) hypoadrenocorticism.

Serum should be tested for autoantibodies to various tissues, especially endocrine glands, and other investigations may be needed, including radiography or CT or MRI scans of the skull (for pituitary abnormalities), chest (for tuberculosis) or abdomen (for adrenal calcification suggestive of tuberculosis or a mycosis).

A warning card should be carried (Fig. 6.15) and most patients are treated with oral hydrocortisone and fludrocortisone.

Dental aspects

Adrenal crisis is rare in dentistry; a recent publication identified only six reports in the past 65 years or so. Risks included unrecognized adrenal insufficiency, poor health status and stability at the time of treatment, pain, infection, having undergone an invasive procedure and receipt of a barbiturate GA. Drugs such as barbiturates can accelerate cortisol metabolism and can exacerbate the situation, as can aminoglutethimide, azole antifungals, etomidate, metyrapone, phenytoin and rifampicin.

Nevertheless, despite the low risk, the danger of precipitating hypotensive collapse is such that corticosteroids must be given

practitioners shown overleaf

STC1

INSTRUCTIONS

- 1** **DO NOT STOP** taking the steroid drug except on medical advice. Always have a supply in reserve.
- 2** In case of feverish illness, accident, operation (emergency or otherwise), diarrhoea or vomiting the steroid treatment **MUST** be continued. Your doctor may wish you to have a **LARGER DOSE** or an **INJECTION** at such times.
- 3** If the tablets cause indigestion consult your doctor **AT ONCE**. Always carry this card while receiving steroid treatment and show it to any doctor, dentist, nurse or midwife whom you may consult.
- 4** After your treatment has finished you must still tell any new doctor, dentist, nurse or midwife that you have had steroid treatment.
- 5**

Fig. 6.15 Steroid warning card. This is a blue card that should be carried at all times by patients with hypoadrenocorticism or on systemic corticosteroids in view of the danger of an adrenocortical crisis and collapse if the patient is subject to trauma, stress or anaesthesia. (By permission of the Controller of Her Majesty's Stationery Office).

preoperatively. CS should generally be avoided unless the patient has had corticosteroid cover. GA is obviously a matter for the expert anaesthetist in hospital.

For dental surgery under LA, the glucocorticoid dose should be doubled (up to 20mg hydrocortisone) 1 hour before surgery. After the procedure, the dose of oral medication is doubled for 24 hours, and then the normal dose is reinstated (<http://cks.nice.org.uk/addisons-disease>; accessed 30 September 2013).

Brown or black pigmentation of the mucosa is seen in over 75% of patients with Addison disease, but is not a feature of corticosteroid-induced hypoadrenocorticism or of hypoadrenocorticism secondary to hypothalamopituitary disease. Hyperpigmentation is related to high levels of MSH and affects particularly those areas normally pigmented or exposed to trauma (e.g. in the buccal mucosa at the occlusal line, or the tongue, but also the gingivae). Other causes of oral pigmentation (Ch. 11; especially racial pigmentation) are far more common and need to be differentiated. Addison disease is a rare cause but must be considered, particularly if there is hypotension, weakness, weight loss, anorexia, nausea, vomiting or abdominal pain.

Acute adrenal insufficiency has several causes (see Table 6.15) and is managed as described in Chapter 1.

Secondary adrenocortical insufficiency

Secondary adrenocortical insufficiency can be caused by corticosteroid therapy and ACTH deficiency as a result of hypothalamic or pituitary disease. It is then associated with other endocrine defects but *no* hyperpigmentation (ACTH levels are low) and blood pressure is virtually normal (aldosterone secretion is normal).

Congenital adrenal hyperplasia

Congenital adrenal hyperplasia is the term given to a group of rare autosomal recessive inborn errors of corticosteroid metabolism characterized by defects in 21-hydroxylase or 11-hydroxylase, resulting in lack of cortisol (adrenal insufficiency) and androgen excess. Male precocious puberty or female ambiguous genitalia can result.

Box 6.5 Hyperadrenocorticism: clinical features

- Weakness
- Weight gain
- Truncal obesity
- Hypertension
- Hirsutism
- Amenorrhoea
- Cutaneous striae
- Personality changes

ADRENOCORTICAL HYPERFUNCTION

Adrenocortical hyperfunction may lead to release of excessive:

- glucocorticoids (Cushing disease)
- mineralocorticoids (Conn syndrome or hyperaldosteronism)
- androgens (congenital adrenal hyperplasia).

Cushing disease**General aspects**

Cushing disease is caused by excess glucocorticoid production by adrenal hyperplasia secondary to excess ACTH production by pituitary basophil adenomas. It is occasionally caused by ectopic ACTH from adrenal or other tumours, such as small-cell lung carcinomas or carcinoid tumours. A similar clinical picture results where there is ectopic production by a tumour (usually a bronchial carcinoid tumour) of CRH.

Cushing syndrome is clinically similar but is caused by primary adrenal disease (adenoma or rarely carcinoma or micronodular bilateral hyperplasia). However, most cases of Cushing syndrome have been found to be due to microadenomas of the pituitary, so that the terms Cushing disease and Cushing syndrome are in effect synonymous.

A similar clinical picture is produced by corticosteroid therapy or rarely by the multiple endocrine adenoma syndromes (see later).

Clinical features

These are listed in [Box 6.5](#). The most obvious feature is central obesity, affecting the abdomen and also the face (moon face; [Fig. 6.16](#)). Facial photographs from the past and more recently may show the development of moon face, interscapular region (buffalo hump) and trunk, but with relative sparing of the limbs. Hypertension is common. Breakdown of proteins with conversion to glucose (gluconeogenesis) leads to hyperglycaemia and possibly diabetes mellitus, osteoporosis, muscle weakness, thinning of the skin, purpura and purplish skin striae ([Figs. 6.17 and 6.18](#)). Other features may include hirsutism and acne, oligomenorrhoea, infections and psychoses ([Fig. 6.19](#)).

General management

The main differential diagnoses are severe depression and alcoholism.

The diagnosis is confirmed by a raised plasma cortisol level and absence of the normal diurnal variation in cortisol levels, normally highest in the morning around 8.00 a.m. and lowest at midnight. Another useful screening test is to measure plasma cortisol at 8.00–9.00 a.m. after giving 1 mg dexamethasone orally at midnight to suppress the adrenal glands temporarily; in health, cortisol levels fall but in Cushing syndrome there is no such fall (low-dose overnight dexamethasone suppression test).

Fig. 6.16 Moon face in a patient with Cushing syndrome.

Fig. 6.17 Steroid purpura.

Localization of the cause as adrenal, pituitary or ectopic tumour relies on the CRH stimulation test, which in turn depends on the fact that the pituitary responds to CRH, whereas adrenal and other tumours producing ectopic ACTH do not. Baseline plasma ACTH and cortisol levels are first obtained, CRH is then given, and an exaggerated rise in ACTH and cortisol levels is demonstrated by patients with pituitary Cushing but not by patients with other types of Cushing syndrome. Other special dexamethasone tests or sampling from the inferior petrosal sinus are needed to distinguish pituitary from adrenal causes of Cushing syndrome. Other diagnostic aids include pituitary MRI, tomography of the sella turcica, abdominal CT and adrenal ultrasound scans.

Fig. 6.18 Systemic corticosteroid therapy causes several complications, including cutaneous striae as shown here.

In Cushing disease, the pituitary tumour is treated by trans-sphenoidal microadenectomy and then, for those not cured, by pituitary irradiation or an yttrium implant. Cyproheptadine or sodium valproate is sometimes used where surgery is inappropriate.

In Cushing syndrome, the adrenal gland is usually irradiated or excised (adrenalectomy), though ketoconazole, mitotane, aminoglutethimide or metyrapone can also be effective. Some patients subjected to bilateral adrenalectomy develop pituitary ACTH-producing adenomas with hyperpigmentation and symptoms related to the pituitary tumour (Nelson syndrome). Cushing syndrome secondary to carcinoma of the bronchus is not controllable by surgery but metyrapone, an inhibitor of hydroxylation in the adrenal cortex, can relieve symptoms.

Steroid replacement is subsequently necessary in treated Cushing disease/syndrome. Subacute adrenal insufficiency develops if corticosteroid dosage is reduced too quickly after replacement therapy in post-surgical patients with Cushing syndrome. Features include lethargy, abdominal pain, hypotension and psychological disturbances, and a characteristic sign is scaly desquamation of the facial skin, particularly of the forehead.

Dental aspects

LA is preferred for pain control. CS can be given, preferably with nitrous oxide and oxygen. GA must be carried out in hospital.

Management complications may include:

- the need for corticosteroid cover; patients, once treated, are maintained on corticosteroid replacement therapy and then are at risk from an adrenal crisis if subjected to operation, anaesthesia or trauma
- hypertension
- cardiovascular disease
- diabetes mellitus
- psychosis

Fig. 6.19 Cushing syndrome.

- vertebral collapse or myopathy causing limited mobility
- multiple endocrine adenomatosis (MEA I; see later).

There are no specific oral manifestations of Cushing disease, but patients have been referred for a suspected dental cause of the swollen face.

Hyperaldosteronism

General aspects

Primary hyperaldosteronism (Conn syndrome) arises from an adrenal cortex benign tumour or hyperplasia. Secondary hyperaldosteronism arises from activation of the renin–angiotensin system in cirrhosis, nephrotic syndrome, severe cardiac failure or renal artery stenosis.

Clinical features

High aldosterone secretion leads to potassium loss (hypokalaemia) – causing muscle weakness and cramps, paraesthesia, polyuria and polydipsia, and, since it is associated with a metabolic alkalosis, possibly tetany – and sodium retention (causing hypertension but rarely oedema).

General management

Amiloride, or the aldosterone antagonist spironolactone, is given until the affected adrenal gland can be excised.

Dental aspects

LA is used for pain control. CS may be helpful, especially if there is hypertension. GA must, as always, be carried out in hospital. In the

untreated patient, hypertension and muscle weakness are the main complications. Competitive muscle relaxants may be dangerous, as they can cause profound paralysis.

If bilateral adrenalectomy has been carried out, the patient is at risk from collapse during dental treatment and therefore requires corticosteroid cover.

Autoimmune polyendocrinopathy syndrome

See later.

SYSTEMIC CORTICOSTEROID THERAPY

General aspects

Corticosteroids are frequently used to suppress inflammation and to suppress graft rejection, and occasionally to replace missing hormones (in Addison disease or after adrenalectomy; Table 6.16). Steroids have different potencies (Table 6.17).

Corticosteroids are an essential part of the body's response to stresses such as trauma, infection, GA or operation. At such times there is normally an enhanced adrenal corticosteroid response related to the degree of stress. In patients given exogenous steroids, the enhanced adrenal corticosteroid response may not follow.

Corticosteroids have a negative feedback control on hypothalamic activity and ACTH production; there is thus suppression of the HPA axis and the adrenals may become unable to produce a steroid response to stress. When the adrenal cortex is unable to produce the necessary steroid response to stress, acute adrenal insufficiency (adrenal crisis) can result, with rapidly developing hypotension, collapse and possibly death.

Suppression of the HPA axis becomes profound if corticosteroid treatment has been prolonged and/or the dose of steroids exceeds physiological levels (more than about 7.5 mg/day of prednisolone [prednisone]). Adrenal suppression is less when the exogenous steroid is given on alternate days or as a single morning dose (rather than as divided doses through the day). ACTH (corticotropin) has been used in the hope of reducing adrenal suppression but the response is variable and unpredictable, and wanes with time.

However, adrenal function may even be suppressed for up to a week after cessation of steroid treatment lasting only 5 days. If steroid treatment is for longer periods, adrenal function may be suppressed for at least 30 days and perhaps for 2–24 months after the cessation of treatment. Patients who are on corticosteroid therapy, or have been on it within the past 30 days, may be at risk from adrenal crisis; those who have been on corticosteroids during the previous 24 months may also be at risk, if they are not given supplementary corticosteroids before and during periods of stress such as operation, GA, infection or trauma. Patients who have used systemic corticosteroids should be warned of the danger and should carry a steroid card indicating the dosage and the responsible physician (see Fig. 6.15). Metal bracelets or necklaces with the diagnosis engraved on them are available: for example, from MedicAlert Foundation (<http://www.medicalert.org.uk>).

However, the frequency and extent of the adrenocortical suppression (and the need for supplementary corticosteroids before and during periods of stress) are unclear and have been questioned. Although the evidence for the need for steroid cover may be questionable, medico-legal and other considerations suggest that one should err on the side of caution and fully inform and discuss with the patient, take medical advice in any case of doubt, and give steroid cover unless confident that collapse is unlikely.

Clinical features

Long-term systemic use of corticosteroids can cause many other adverse effects, often beginning soon after the start of treatment, and can lead to significant morbidity or mortality (Table 6.18). Complications includes immediately obvious effects such as Cushingoid weight gain around the face (moon face) and upper back (buffalo hump), and hirsutism. Other possible complications are shown in Table 6.18.

General management

Complications may be reduced but not abolished if steroids are given on alternate days. In order listed above, patients on systemic steroids are usually monitored and given drugs prophylactically:

- There should be no contraindications such as hypertension (Ch. 5), diabetes or latent tuberculosis.
- The smallest effective steroid dose should be given, ideally in the morning on alternate days.
- Systemic corticosteroids cause the greatest risk of adrenocortical suppression, so topical steroids should always be used in preference, provided that the desired therapeutic effect is achievable. However, there can even be adrenocortical suppression from extensive application of steroid skin preparations, particularly if occlusive dressings are used, or from some use in the mouth if ulceration is extensive and potent steroids are used.
- The patient must be given a warning card and told about the dangers of withdrawal and about side-effects. There should never be abrupt withdrawal of the steroid. The dose should be raised if there is illness, infection, trauma or operation.

Table 6.18 *Complications of systemic corticosteroid therapy*

Cardiovascular	Cerebrovascular accidents Hypertension Myocardial infarction
Dermatological	Acne Bruising Hirsutism Striae
Gastrointestinal	Peptic ulcer
Immunosuppressive	Increased susceptibility to infections Neoplasms in the long term
Neurological	Cataracts Mood changes Psychosis
Metabolic	Fat redistribution (moon face and buffalo hump) Growth retardation Hypothalamic–pituitary–adrenal suppression Impaired glucose tolerance or diabetes mellitus Loss of sodium and potassium Muscle weakness Osteoporosis Weight gain

- Weight, chest radiography, bone mineral density, blood pressure and blood glucose baseline measures should be taken and these parameters monitored.
- Ranitidine and calcitriol or disodium etidronate are often given.

Dental aspects

Cortisol is the major glucocorticoid in humans and is involved in metabolic processes, vascular tonicity, inflammatory responses and the control of response to stresses such as trauma, infection, GA or surgery. Secretion from the adrenals is regulated via the HPA axis by involving ACTH. In patients given exogenous corticosteroids (steroids), this feedback response may not occur and acute adrenal insufficiency (adrenal crisis) may result, as the adrenal cortex is unable to produce the necessary steroid response to stress.

Suppression of the HPA axis becomes deeper if treatment with exogenous steroids is prolonged and the dose exceeds physiological levels (over 7.5 mg/day of prednisolone [prednisone]).

Adrenal suppression is likely if the patient is currently on daily systemic corticosteroids at doses of 10 mg prednisolone or above, or has been in the last 3 months.

Adrenocortical function may be suppressed if:

- the patient is currently on daily systemic corticosteroids at doses above 5 mg prednisolone
- corticosteroids have been taken regularly during the previous 30 days
- corticosteroids have been taken for more than 1 month during the past year.

During intercurrent illness or infection, after trauma, or before operation or anaesthesia, these patients may require a higher steroid dosage. Steroid supplementation should be considered before stressful procedures. It is recognized that dentoalveolar or maxillofacial surgery may result in stress, but most other forms of dental treatment cause little response.

Table 6.19 *Suggested management of patients with a history of systemic corticosteroid therapy*

Procedure	No steroids for previous 12 months	Steroids taken during previous 12 months	Steroids currently taken
Conservative dentistry or dentoalveolar surgery (e.g. single extraction under LA)	No cover required	Give usual oral steroid dose in morning or hydrocortisone ^a 25–50 mg i.v. preoperatively	Double oral steroid dose in morning or give hydrocortisone ^a 25–50 mg i.v. preoperatively Continue normal steroid medication postoperatively
Intermediate surgery (e.g. multiple extractions, or surgery under GA)	Consider cover if large doses of steroid were given. Test adrenocortical function (ACTH stimulation test)	Give usual oral steroid dose in morning plus hydrocortisone ^a 25–50 mg i.v. preoperatively and i.m. 6-hourly for 24 h	Double oral steroid dose in morning plus give hydrocortisone ^a 25–50 mg i.v. preoperatively and i.m. 6-hourly for 24 h. Then continue normal medication
Maxillofacial surgery or trauma	Consider cover if large doses of steroid were given. Test adrenocortical function (ACTH stimulation test)	Give usual oral steroid dose in morning plus hydrocortisone ^a 25–50 mg i.v. preoperatively and i.m. 6-hourly for 72 h	Double oral steroid dose in morning plus give hydrocortisone ^a 25–50 mg i.v. preoperatively and i.m. 6-hourly for 72 h. Then continue normal medication

^aHydrocortisone sodium succinate (e.g. Efcortelan soluble) or phosphate given immediately preoperatively and blood pressure monitored.

Patients on long-term systemic steroid medication have been recommended to receive supplementary glucocorticoids or ‘steroid cover’ when undergoing certain types of stressful treatment, including dentistry. Several studies, however, confirm the low likelihood of significant adrenal insufficiency, even following major surgical procedures.

Patients on long-term steroid medication may therefore not require supplementary ‘steroid cover’ for routine dentistry, including minor surgical procedures, under LA. Those with adrenal hypofunction or those undergoing GA for surgical procedures may require supplementary steroids, depending on the dose of steroid and duration of treatment. Individuals who have taken steroids in excess of 10 mg prednisolone, or equivalent, within the last 3 months, should be considered for supplementation. Patients who have not received steroids for more than 3 months are considered to have full recovery of the HPA axis and require no supplementation. Traditionally, minor operations under LA were covered by giving the usual oral steroid dose in the morning and oral steroids 2–4 hours pre- and postoperatively (25–50 mg hydrocortisone or 20 mg prednisolone or 4 mg dexamethasone) or by giving intravenous 25–50 mg hydrocortisone immediately before operation (Table 6.19). These Nicholson’s guidelines are not universally accepted, as they require intravenous administration of steroids. For this reason, regimens such as doubling the normal daily oral steroid dose on the day of procedure (Gibson & Ferguson, 2004) are now more commonly used.

The blood pressure must be carefully watched during surgery and especially during recovery, and steroid supplementation given immediately if it starts to fall. Intravenous hydrocortisone must be immediately available for use if the blood pressure falls or the patient collapses.

Cover for major operations can be provided by giving at least 25–50 mg hydrocortisone sodium succinate intramuscularly or intravenously (with the pre-medication) and then 6-hourly for a further 24–72 hours (see Table 6.19). Corticosteroids given by intramuscular injection are more slowly absorbed and reach lower plasma levels than when given intravenously or orally.

Drugs, especially sedatives and general anaesthetics, are a hazard and it is extremely important to avoid hypoxia, hypotension or haemorrhage. Patients may also require special management as a result of diabetes, hypertension, poor wound healing or infections. Aspirin and other NSAIDs should be avoided, as they may increase the risk of peptic ulceration. Osteoporosis introduces the danger of fractures when handling the patient.

Topical corticosteroids for use in the mouth are unlikely to have any systemic effect but predispose to oral candidosis. Susceptibility to infection is increased by systemic steroid use (see later) and there is a predisposition to herpes virus infections (particularly herpes simplex). Chickenpox is an especial hazard to those who are not immune and fulminant disease can result. Passive immunization with varicella zoster immunoglobulin is indicated for non-immune patients who are on systemic corticosteroids (or who have been on them within the previous 3 months), if exposed to chickenpox or zoster. Immunization should be given within 3 days of exposure.

Wound healing is impaired and wound infections are more frequent. In addition to careful aseptic surgery, prophylactic antimicrobials may be indicated.

Long-term and profound immunosuppression may lead to the appearance of hairy leukoplakia, Kaposi sarcoma, lymphomas, lip cancer, oral keratosis or other oral complications (Ch. 20).

Corticosteroids can also mask the presence of many serious diseases that may influence dental care, as well as causing suppression of the adrenocortical response to stress (see Table 6.19 for management).

POLYCYSTIC OVARY SYNDROME (PCOS)

Polycystic ovary syndrome (PCOS) presents with hirsutism, acne, oligomenorrhoea and subfertility. Other features include obesity, acanthosis nigricans and hypertension (and premature balding in male relatives).

ADRENAL MEDULLA

The adrenal medulla secretes the catecholamines noradrenaline (nor-epinephrine) and adrenaline (epinephrine) in response to hypotension, hypoglycaemia and other stress, their release being regulated by the central nervous system.

PHAEOCHROMOCYTOMA

General aspects

Phaeochromocytomas are rare, usually benign tumours; they are most commonly found in the adrenal medulla (producing adrenaline [epinephrine]) but others arise in other neuroectodermal tissues such as paraganglia or the sympathetic chain and produce noradrenaline (norepinephrine) or dopamine. Ten per cent of phaeochromocytomas are familial, 10% are bilateral, 10% are outside the adrenals and 10% are malignant. Phaeochromocytomas may occasionally be associated with other tumours – neurofibromatosis; endocrine tumours, particularly medullary carcinoma of the thyroid and hyperparathyroidism (multiple endocrine adenomatosis: MEA II or III [see later]); von Hippel–Lindau disease (cerebelloretinal haemangioblastomatosis); and

gastric leiomyosarcoma, pulmonary chondroma and testicular tumours (Carney triad).

Clinical features

Typical features are episodes of anxiety, headache, epigastric discomfort, palpitations, tachycardia, arrhythmias, hypertension, sweating, pyrexia, flushing and glycosuria.

General management

Plasma catecholamines (collected at rest in the supine position) may be raised but are less reliable than urinary assays. Diagnosis is supported by finding excessive urinary catecholamines and their metabolites, such as vanillylmandelic acid (VMA) or metanephrines. The tumour is located by CT, MRI, venous catheterization, arteriography, ultrasonography and radionuclide scanning, such as iodine-131–meta-iodobenzylguanidine (MIBG). The tumour is excised after the blood pressure has been controlled with an alpha-blocking agent (e.g. phenoxybenzamine) and a beta-blocker.

Dental aspects

Acute hypertension and arrhythmias may complicate dental treatment. Elective treatment should therefore be deferred until after surgical treatment of the phaeochromocytoma. If emergency care is required, the blood pressure should first be controlled with alpha-blockers (such as phenoxybenzamine or prazosin) and then beta-adrenergic blockers (such as propranolol).

Patients who have had adrenal surgery may suffer from hypoadrenocorticism, since the adrenal cortex is inevitably damaged at operation. These patients therefore require steroid cover at operation. Local analgesia is then generally safe and adrenaline (epinephrine) in modest amounts is unlikely to have any significant adverse effect. CS may be desirable to control anxiety and endogenous adrenaline production.

GA must only be given in hospital; neuroleptanalgesia, using a combination such as droperidol, fentanyl and midazolam, may be the most satisfactory choice.

Phaeochromocytoma is occasionally associated with oral mucosal neuromas (MEA III syndrome; see later).

THYROID GLAND

The thyroid gland is under the influence of thyroid-stimulating hormone (TSH or thyrotropin) from the pituitary gland, which is itself regulated by thyrotropin-releasing hormone (TRH) from the hypothalamus. Thyroid hormones stored as iodide-rich ‘thyroid colloid’ are thyroxine (T₄; tetra-iodothyronine), which has a half-life of 1 week, and is converted to tri-iodothyronine (T₃), the active form, which has a half-life of 1 day. Thyroid hormones feed back to the hypothalamus and pituitary to regulate TSH release.

Thyroid hormones act on metabolism by regulating protein synthesis via effects on gene transcription and messenger RNA stabilization, and have profound effects on the sensitivity of tissues to catecholamines, as well as on mitochondrial oxidative activity, synthesis and degradation of proteins, differentiation of muscle fibres, capillary growth and levels of antioxidant compounds.

Thyroid function tests (Table 6.20) include serum levels of T₄ and T₃. Free T₄ and free T₃ provide a better assessment of the thyroid status than do total T₄ and T₃ since about 95% of thyroid hormones is

Table 6.20 Tests of thyroid function

Test	Hyperthyroidism	Hypothyroidism

LATS = long-acting thyroid stimulator; ND = not done; T3 = tri-iodothyronine;

T4 = thyroxine (tetraiodothyronine).

^aDepressed in pituitary hypofunction.

^bNot suppressed by administration of T3.

bound to plasma proteins, especially thyroid-binding globulin (TBG) and thyroid-binding pre-albumin (TBPA). TSH levels can be assayed. Thyroid antibody tests, ultrasound and radio-iodine uptake using iodine-131 or 123 are the other common thyroid function tests.

LINGUAL THYROID

The thyroid normally develops as a downgrowth from the foramen caecum at the junction of the posterior third with the anterior two-thirds of the tongue. Rarely, ectopic thyroid tissue remains in this tract and may be seen as a lump in the midline between the foramen caecum and epiglottis, but has also been recorded in the oropharynx, infra-hyoid region, larynx, oesophagus, heart and mediastinum. A lingual thyroid is seen mainly in females and is often asymptomatic, but it may cause dysphagia, airway obstruction or even haemorrhage. Hypothyroidism may be associated in about one-third of cases and, occasionally, the lingual thyroid becomes malignant. There is a raised incidence of thyroid disease in relatives.

A lingual thyroid may not be suspected until the lump in the tongue has been biopsied or excised and examined histologically. The diagnosis can be confirmed by iodine-123, iodine-131 or technetium-99 uptake in the tongue, by biopsy, by CT scanning without contrast or by MRI.

Treatment depends on the size of the lingual thyroid but thyroxine may be needed and, if the lump does not regress sufficiently, the lingual thyroid can be ablated; this is best done by surgery, or, if the patient is unfit, by iodine-131, if normal functioning thyroid tissue is identified in the neck.

GOITRE

A goitre is an enlarged thyroid gland (Fig. 6.20). Most goitres are acquired and seen in Graves disease or thyroiditis (Box 6.6).

The cause of the goitre should be sought. One rare cause is a medullary carcinoma of the thyroid, which can be part of a multiple endocrine adenomatosis syndrome (MEA II and MEA III).

Thyroid function is assessed to determine whether it is normal (euthyroid), hyperactive (hyperthyroid) or hypoactive (hypothyroid).

Most goitres do not require surgery but this is indicated if there is a danger of airways obstruction (cough, voice changes, dyspnoea, tracheal deviation or dysphagia) or for cosmetic reasons.

Dental management in goitre may be influenced by abnormal thyroid function, by the underlying cause of the goitre or by complications such as respiratory obstruction.

**Fig. 6.20** Goitre.

 - Dyshormonogenesis
 - Carcinoma
 - Hashimoto thyroiditis

THYROID NODULES

A nodule in the thyroid gland may represent a neoplasm (Fig. 6.21). Thyroid function tests and ultrasound-guided needle biopsy are indicated. Radio-iodine thyroid scans (nuclear medicine thyroid scanning) does not conclusively determine whether thyroid nodules are benign or malignant but are useful to evaluate the functional status of thyroid nodules in patients who are hyperthyroid. A nodule that takes up radio-iodine is termed a hot nodule and is unlikely to be malignant – more usually it is an adenoma. A nodule that fails to take up the radio-iodine is termed a cold nodule, and may be malignant – usually a papillary, follicular or medullary cell carcinoma; needle biopsy is indicated. Treatment may be surgical, irradiation or sorafenib – now approved to treat differentiated thyroid carcinoma (DTC).

HYPOTHYROIDISM

General aspects

Hypothyroidism may be primary (due to thyroid disease) or secondary (due to hypothalamic or pituitary dysfunction). The common causes are thyroid loss from surgery or destruction by irradiation of the neck or thyroid gland. Autoimmune disease (Hashimoto thyroiditis), associated with autoantibodies to thyroglobulin and thyroid microsomes, and drugs such as amiodarone, carbimazole, lithium or radio-iodine may be implicated. Rare cases in the developed world are caused by iodine deficiency.

Fig. 6.21 Thyroid nodule.

Box 6.7 Hypothyroidism: typical clinical features

- Angina
- Bradycardia
- Cold intolerance
- Constipation
- Decreased appetite
- Decreased sweating
- Dry cold skin
- Hair loss
- Hoarseness
- Ischaemic heart disease
- Menorrhagia
- Periorbital oedema
- Psychosis
- Serous effusions
- Slow cerebration, poor memory
- Slow reactions
- Weight gain

Clinical features

Hypothyroidism is often unrecognized. Subclinical hypothyroidism, with raised TSH but normal T4 levels, may be found in up to 10% of postmenopausal females. However, hypothyroidism can cause weight gain, lassitude, dry skin, myxoedema, loss of hair, cardiac failure, ischaemic heart disease, bradycardia, anaemia, neurological or psychiatric changes, hypotonia, cerebellar signs of ataxia, tremor, dysmetria, polyneuropathy, cranial nerve deficits, entrapment neuropathy (e.g. carpal tunnel syndrome), myopathic weakness, dementia, apathy, mental dullness, irritability and sleepiness (Box 6.7; Fig. 6.22).

Hoarseness and hypothermia and may be complicated by coma. Sjögren syndrome (Ch. 16) may be associated. Congenital hypothyroidism (cretinism) has similar features, together with an enlarged tongue and learning impairment.

General management

The diagnosis is confirmed by demonstrating low serum T4 and T3 levels. TSH levels are raised in primary hypothyroidism and depressed in secondary hypothyroidism. Serum antibodies are detectable in Hashimoto thyroiditis – thyroid microsomal antibodies (TMABs) in 95%, thyroglobulin antibodies (TGABs) in 60%.

Fig. 6.22 Hypothyroidism.

Symptomatic patients are managed with daily oral thyroxine sodium. Treatment is started slowly but angina, myocardial infarction or sudden death may be precipitated, especially if there is evidence of ischaemic heart disease.

Dental aspects

The main danger is precipitation of myxoedema coma by the use of sedatives (including diazepam or midazolam), opioid analgesics (including codeine) or tranquillizers. These should therefore be either avoided or given in a low dose. LA is satisfactory for pain control. CS can be carried out with nitrous oxide and oxygen. Diazepam or midazolam may precipitate coma.

GA may be complicated because of possible ischaemic heart disease and the danger of coma, and the respiratory centre is also hypersensitive to drugs such as opioids or sedatives. GA, if unavoidable, should be delayed if possible until thyroxine has been started.

Associated problems may include hypoadrenocorticism, anaemia, hypotension, diminished cardiac output and bradycardia. Occasional associations include hypopituitarism and other autoimmune disorders such as Sjögren syndrome.

Povidone-iodine and similar compounds are best avoided.

HYPERTHYROIDISM

General aspects

Hyperthyroidism is usually associated with a diffuse goitre due to autoimmune disease (Graves disease, primary hyperthyroidism) when there are thyroid-stimulating autoantibodies against TSH receptor antibodies (TRABs) and TMABs. Sometimes, a hyperfunctioning

Box 6.8 Hyperthyroidism: typical clinical features

- Amenorrhoea
- Atrial fibrillation
- Diarrhoea
- Excess sweating
- Exophthalmos in some
- Gynaecomastia
- Heart failure
- Heat intolerance
- Increased appetite
- Irritability
- No hair loss
- No voice change
- Psychosis
- Tachycardia
- Tremor
- Warm moist skin
- Weight loss

(toxic) multinodular goitre or nodule due to one or more thyroid adenomas produces excess thyroxine. Ninety per cent of the swellings are benign. Rarely, thyroiditis, thyroid hormone overdosage or ectopic thyroid tissue causes a goitre.

Clinical features

Hyperthyroidism may cause exophthalmos, eyelid lag and eyelid retraction (Box 6.8, Figs. 6.23 and 6.24); it mimics the effects of adrenaline (epinephrine), and can cause anorexia, vomiting or diarrhoea, weight loss, anxiety and tremor, sweating and heat intolerance. Cardiac disturbances, particularly in older patients, include tachycardia, arrhythmias (especially atrial fibrillation) or cardiac failure.

Thyrotoxic periodic paralysis comprises attacks of mild to severe weakness, during which serum potassium levels are generally low.

Myasthenia gravis may occasionally be associated.

General management

The diagnosis is confirmed by raised serum levels of T3 and T4. Circulating TMABs and TRABs are found in 55% of patients with Graves disease. A scan or radioactive iodine uptake can differentiate causes of hyperthyroidism: subacute thyroiditis (low uptake) versus Graves disease (high uptake).

Hyperthyroidism can be treated with beta-blockers (which achieve rapid control of many of the signs and symptoms by moderating sympathetic overactivity, but suddenly stopping beta-blocker treatment can precipitate a thyroid crisis within 4 hours). Carbimazole, the usual antithyroid drug, can suppress the bone marrow and cause rashes. Iodine-131 is effective but can result in hypothyroidism. There appears to be no risk of neoplastic change. Surgery is effective but leads to hypothyroidism in about 30%. Hypoparathyroidism and recurrent laryngeal nerve palsy are rare complications.

In untreated patients with hyperthyroidism, pain, anxiety, trauma, GA or premature cessation of antithyroid treatment may precipitate a thyroid (thyrotoxic) crisis, characterized by anxiety, tremor and dyspnoea, which can progress to ventricular fibrillation. Medical assistance is essential, as treatment requires the use of potassium iodide and propylthiouracil, and propranolol or chlorpromazine.

Fig. 6.23 Hyperthyroidism.

Fig. 6.24 Exophthalmos.

Dental aspects

Patients with sympathetic overactivity in untreated hyperthyroidism can be anxious and irritable, and may faint. LA is the main means of pain control; any risk of adrenaline (epinephrine) exacerbating sympathetic overactivity is only theoretical and prilocaine with felypressin is not known to be safer than lidocaine. CS is frequently desirable to control excessive anxiety. Benzodiazepines may potentiate antithyroid drugs, and therefore nitrous oxide, which is more rapidly controllable, is probably safer.

Povidone-iodine and similar compounds are best avoided. Carbimazole occasionally causes agranulocytosis, which may cause oral or oropharyngeal ulceration. Otherwise, the treated thyrotoxic

patient presents no special problems in dental treatment. However, after treatment of hyperthyroidism, the patient is at risk from hypothyroidism, which may pass unrecognized. This point must be borne in mind especially if a GA is required.

PARATHYROID GLANDS

The parathyroids are four pea-sized glands located on the back of the thyroid gland in the neck, which produce parathyroid hormone (PTH). Occasionally, congenitally ectopic parathyroid glands are embedded in

the thyroid, the thymus or the chest. In most such cases, ectopic glands function normally.

PTH and vitamin D both act to control plasma calcium levels. PTH secretion is stimulated by a fall in the level of the plasma ionized calcium. PTH acts on the kidneys to increase renal reabsorption of calcium and impair phosphate reabsorption (Fig. 6.25). PTH enhances gastrointestinal absorption of calcium and promotes osteoclastic bone resorption, causing a rise in the plasma level of calcium and of the osteoblastic enzyme alkaline phosphatase (Table 6.21). Both bone mineral and matrix are degraded, and the amino acids, such as hydroxyproline, thus released are not reused but are excreted in the urine.

^a Only in some types of congenital hypoparathyroidism.

HYPOPARATHYROIDISM

General aspects

The most frequent cause of hypoparathyroidism is thyroidectomy, but it is relatively transient and typically resolves when the remaining parathyroid tissue undergoes compensatory hyperplasia. Rare cases of idiopathic hypoparathyroidism are congenital.

Clinical features

Low plasma calcium leads to muscle irritability and tetany, with facial twitching (Chvostek's sign; contracture of the facial muscles upon tapping over the facial nerve); carpopedal spasms (Trousseau's sign; contracture of the hand and fingers (*main d'accoucheur* – obstetrician's hand) on occluding the arm with a cuff); numbness and tingling of arms and legs; and even laryngeal stridor (Box 6.9 and Fig. 6.26).

Rare cases of idiopathic hypoparathyroidism may be associated with CATCH 22 (Ch. 37), or other endocrine defects – especially hypoadrenocorticism – associated with multiple autoantibodies (see Table 6.22) and cataracts, calcification of the basal ganglia, defects of the teeth and, sometimes, chronic mucocutaneous candidosis.

Pseudohypoparathyroidism is characterized by normal or raised PTH secretion but unresponsive tissue receptors, and has clinical features similar to idiopathic hypoparathyroidism, but there is short stature and small fingers and toes, with a liability to develop cataracts, and no dental defects. Similar appearance in patients with normal biochemistry is termed pseudo-pseudohypoparathyroidism.

General management

Diagnosis is from low plasma calcium; phosphate is often raised (see Table 6.21). Replacement therapy includes vitamin D and calcium supplements.

Dental aspects

There may be facial paraesthesia and facial twitching caused by tetany (Chvostek's sign). Idiopathic (congenital) hypoparathyroidism may feature enamel hypoplasia, shortened roots with osteodentine formation, delayed eruption and sometimes chronic mucocutaneous candidosis (see Box 6.9).

Fig. 6.26 Hypoparathyroidism.

LA is satisfactory. CS can be given, preferably after replacement therapy. Dental management may be complicated by tetany, seizures, psychiatric problems or learning disability, hypoadrenocorticism, diabetes mellitus or other endocrinopathies or arrhythmias.

HYPERPARATHYROIDISM

General aspects

Primary hyperparathyroidism is usually caused by a parathyroid adenoma and is seen in postmenopausal women. Rare causes include carcinoma of the parathyroids.

Secondary hyperparathyroidism is a response to low plasma calcium caused by chronic renal failure or prolonged dialysis, or by severe malabsorption, and is rising in frequency.

Tertiary hyperparathyroidism follows prolonged secondary hyperparathyroidism, which has become autonomous.

Clinical features

The main features (Box 6.10) include hypercalcaemia and renal disease (most patients have renal calcifications), skeletal disease (bone pain, pathological fractures, giant cell tumours, bone rarefaction), peptic ulceration, pancreatitis, hypertension and arrhythmias (Fig. 6.27). Therefore, the expression 'stones, bones and abdominal groans' sometimes applies.

Hyperparathyroidism may occasionally be familial and associated with tumours of other endocrine glands (MEA I, II and III).

Box 6.10 Hyperparathyroidism: clinical features

- Bone resorption
- Nephrocalcinosis
- Peptic ulcer: pain
- Polyuria
- Psychiatric disorders
- Renal stones

Fig. 6.27 Hyperparathyroidism ('stones, bones and abdominal groans').

General management

The diagnosis in primary hyperparathyroidism is confirmed by raised PTH levels, raised serum calcium, low or normal phosphate level, and normal or raised alkaline phosphatase. *Primary hyperparathyroidism* is treated by parathyroidectomy, but medical treatment such as active vitamin D hormone (1,25-dihydroxycholecalciferol; 1,25-DHCC) is useful in those with severe bone disease. *Secondary hyperparathyroidism* often responds to 1,25-DHCC but not to dietary vitamin D (cholecalciferol). Parathyroidectomy may be needed. *Tertiary hyperparathyroidism* requires parathyroidectomy.

Calcimimetics, drugs which bind to the calcium-sensing receptors of the parathyroid glands and lower the sensitivity for receptor activation by extracellular calcium, diminish PTH release, and may become useful for the treatment of primary and secondary hyperparathyroidism.

Dental aspects

Dental changes in hyperparathyroidism include loss of the lamina dura and generalized bone rarefaction, but giant cell lesions are late

Table 6.22 Multiple endocrine adenoma (MEA) syndromes

	MEA type I	MEA type II (IIa)	MEA type III (IIb)
	Werner syndrome	Sipple syndrome	Schmidt syndrome

Pituitary	Adenoma (usually prolactinoma)	–	–
Thyroid	±	Medullary cell carcinoma in 75–100% ^a (calcitonin-secreting)	Medullary cell carcinoma in up to 80–100% (calcitonin-secreting)
Others	Carcinoid, lipomas, gastrinoma	Dermal neuroma	Oral mucosal neuromas, Marfanoid skeletal anomalies, visual disturbances

^aCauses raised serum calcitonin levels and low serum calcium levels.

and uncommon. Giant cell lesions of hyperparathyroidism (brown tumours) are rare but histologically indistinguishable from central giant cell granulomas of the jaws. If, therefore, a giant cell lesion is found, particularly in a middle-aged patient or in a patient with renal failure, parathyroid function should be investigated.

LA is the main means of pain control, especially if hypertension and arrhythmias are present. CS is preferably carried out with nitrous oxide and oxygen. GA may be challenging because of cardiovascular complications and sensitivity to muscle relaxants. Dental treatment in hyperparathyroidism may be complicated by renal disease, peptic ulceration, bone fragility or pluriglandular disease.

MULTIPLE ENDOCRINE ADENOMA SYNDROMES

Multiple endocrine adenoma (MEA) syndromes, also known as the multiple endocrine neoplasia (MEN) syndromes, are rare autosomal dominant diseases affecting several endocrine glands, often with *hyperfunction* (Table 6.22); they are distinct from polyglandular autoimmune syndromes (see below). All MEA syndromes feature parathyroid hyperplasia and hypercalcaemia. Type III is most relevant to dentistry. In the latter, numerous small plexiform neuromas form in the oral mucosa, lips, eyelids and skin. The patient may also have a Marfanoid habitus and diarrhoea.

POLYGLANDULAR AUTOIMMUNE SYNDROMES

Polyglandular autoimmune syndromes feature multiple endocrine *deficiencies*, due to autoantibodies to the glands, most commonly Addison disease and hypoparathyroidism.

As shown in Table 6.23, chronic mucocutaneous candidosis is a very frequent feature in type 1. Its onset is frequently in infancy and it can precede any glandular deficiencies by 10 or more years. Occasionally this sequence is reversed but, in either case, treatment of the glandular deficiency has no effect on the candidosis and vice versa.

Treatment of the hormone deficiencies is as described earlier.

Table 6.23 Polyglandular autoimmune disease, type I and type II

	Type I	Type II
Female:male ratio	1.5:1	1.8:1
Human leukocyte antigen (HLA) associations	Not constant	B8 (A1)
Addison disease	100%	100%
Hypoparathyroidism	76%	–
Chronic mucocutaneous candidosis	73%	–
Alopecia	32%	0.5%
Malabsorption syndromes	22%	–
Gonadal failure	17%	3.6%
Pernicious anaemia	13%	0.5%
Chronic active hepatitis	13%	–
Autoimmune thyroiditis	11%	69%
Type 1 diabetes	4%	52%

HORMONE PRODUCTION BY TUMOURS

Tumours, especially bronchogenic carcinoma, can occasionally produce polypeptide hormones or other biologically active substances ectopically (Appendix 6.1: see also ch. 22).

APPENDIX 6.1 ENDOCRINE AND METABOLIC EFFECTS OF SOME CANCERS

Substance released	Tumours most commonly responsible ^a	Disease resulting	Features
Adrenocorticotrophic hormone (ACTH)	Bronchial, carcinoid, pancreatic, parotid, phaeochromocytoma	Cushing syndrome	See text
Antidiuretic hormone (ADH)	Bronchial, Hodgkin disease, pancreatic	Syndrome of inappropriate ADH secretion (SIADH)	See text
Catecholamines	Adrenal medulla	Phaeochromocytoma	Facial flushing
Erythropoietin	Adrenal, breast, bronchial, fibroids, hepatoma, phaeochromocytoma	Polycythaemia	See Ch. 12
Gastrin	Pancreatic	Zollinger–Ellison syndrome	Diarrhoea, multiple small intestinal ulcers
Human chorionic gonadotropin (HCG)	Breast, hepatoblastoma, pancreatic	Precocious puberty	–
Oestrogens	Adrenal, lung, testicular	Gynaecomastia	Gynaecomastia
Parathyroid hormone (PTH) and prostaglandins	Renal, almost any squamous cell carcinoma	Hypercalcaemia	Polyuria, polydipsia, psychosis, constipation, abdominal pain
Serotonin (5-hydroxytryptamine) and other vasoactive substances	Bronchial, ileocaecal	Carcinoid syndrome	Symptoms mainly if there are hepatic metastases, facial flushing, bronchospasm, diarrhoea. Right-sided valvular heart lesions (especially pulmonary stenosis)
Testosterone	Adrenal, ovarian	–	Hirsutism
Thyroid-stimulating hormone (TSH)	Trophoblastic	Hyperthyroidism	See text
Transforming growth factor (TGF)	Abdominal, breast	Acanthosis nigricans	See text

^aCarcinomas unless otherwise stated.

KEY POINTS

- Dysphagia can signify serious disease
- Coeliac disease is common and often unrecognized
- Inflammatory bowel diseases are serious and may lead to cancer
- Stomach cancer and colonic cancer are common

THE OESOPHAGUS

The oesophagus has the single important function of carrying food, liquids and saliva from the mouth to the stomach, achieved by an automatic process of coordinated contractions of its muscular lining (peristalsis), termed deglutition (swallowing). Deglutition involves a complex and coordinated process initiated by sensory impulses from stimulation of receptors on the fauces, tonsils, soft palate, base of the tongue and posterior pharyngeal wall to the brainstem primarily through cranial nerves VII, IX and X. Cricopharyngeal sphincter opening is reflexive and starts when the bolus reaches the posterior pharyngeal wall before reaching this sphincter. The efferent (motor) function of swallowing is mediated by cranial nerves IX, X and XII. Swallowing has three phases; the first is voluntary, the others are involuntary:

- *Phase one* is collection and swallowing of the masticated food bolus.
- *Phase two* is passage of food through the pharynx into the oesophagus.
- *Phase three* is the passage of food down into the stomach.

Swallowing and respiration are inextricably linked. Neurological damage, such as from a stroke, can lead to disturbed swallowing (dysphagia) and the risk of aspiration into the lungs.

The oesophagus is generally examined by endoscopy. The current 'gold standard' examination of swallowing is videofluoroscopy but this is time-consuming and carries a small radiation risk.

REFLUX OESOPHAGITIS (GASTRO-OESOPHAGEAL REFLUX DISEASE)

General aspects

Gastro-oesophageal reflux disease (GORD) is the term used to describe a backflow of acid from the stomach into the oesophagus. One of the most common kinds of dyspepsia, GORD is predisposed to by gastrointestinal disorders (e.g. high acidity of gastric contents; impaired gastro-oesophageal motility) or extragastrointestinal conditions (obesity, stooping, large meals, smoking, alcohol). Although it was at one time considered to be a result of hiatus hernia (diaphragmatic hernia), the relationship between the symptoms and appearances on barium swallow is inconsistent. Hiatal hernias are found in about 25% of all people over age 50 – particularly in women and those who are overweight. They form at the opening (hiatus) in the diaphragm where the oesophagus joins the stomach. The muscle tissue around the hiatus weakens, allowing the upper stomach to herniate through the diaphragm into the chest cavity. Most hernias cause no symptoms but

larger ones may allow food and acid to regurgitate into the oesophagus, which can cause chest pain ('heartburn').

Clinical features

The usual symptom is an uncomfortable burning sensation behind the sternum, most commonly felt after a meal ('heartburn'). Acid taste is common. Rare complications may include stricture and iron-deficiency anaemia.

General management

Diagnosis can be confirmed by oesophageal pH monitoring. Conditions to differentiate include candidal oesophagitis, or chemical burns from acids or alkalis, non-steroidal anti-inflammatory drugs (NSAIDs), potassium chloride or tetracyclines. Symptoms can often be effectively relieved by losing weight, raising the head of the bed by at least 10cm at night and taking frequent small meals with antacids. Proton-pump inhibitors such as omeprazole or lansoprazole are effective but H₂-blockers (cimetidine, ranitidine) are often used.

Dental aspects

Gastric contents can have a pH as low as 1 and regurgitation, if chronic, can thus cause dental erosion, typically of the palatal aspects of the upper anterior teeth and premolars; this may be worse if there is impaired salivation. Some patients are convinced that other oral symptoms or diseases are caused by 'acid' but, apart from the few genuine cases with persistent regurgitation of gastric contents, this is no more than a folk myth, probably fostered by advertisements for antacids. Other causes of erosion include anorexia nervosa, bulimia (Ch. 27) and alcoholism (Ch. 34).

POST-CRICOID WEB

The association of post-cricoid dysphagia, upper oesophageal webs and iron-deficiency anaemia is known as the Paterson–Brown–Kelly syndrome in the UK and the Plummer–Vinson syndrome (PVS) in the USA. The term sideropenic dysphagia has also been used, since the syndrome can feature iron deficiency (sideropenia) but no anaemia. Postulated aetiopathogenic mechanisms include iron and nutritional deficiencies, genetic predisposition and autoimmune factors. The improvement in dysphagia after iron therapy provides evidence for an association between iron deficiency and post-cricoid dysphagia. Moreover, the decline in Paterson–Brown–Kelly syndrome seems to parallel an improvement in nutritional status, including iron supplementation. However, population-based studies have shown no relationship between post-cricoid dysphagia and anaemia or sideropenia.

If a web is suspected, endoscopy should be carried out carefully under direct vision through the upper oesophageal sphincter. The web typically appears as a thin mucosal membrane covered by normal squamous epithelium. Although reports are inconsistent, patients with Paterson–Brown–Kelly syndrome seem to be at greater risk for hypopharyngeal, oesophageal and oral cancers. Patients with

Box 7.1 Risk factors for oesophageal cancer

- Achalasia – failure of normal peristalsis and relaxation of oesophagogastric sphincter
- Alcohol use
- Barrett oesophagus – this pre-malignant condition may develop into adenocarcinoma
- Burns (e.g. from swallowing lye or other caustic substances)
- Ethnicity – Chinese and Russians predisposed
- Systemic sclerosis
- Tobacco use
- Tylosis (autosomal dominant palmar–plantar hyperkeratosis)

Paterson–Brown–Kelly syndrome usually respond well to iron therapy, diet modification and, if necessary, oesophageal dilatation.

CANCER OF THE OESOPHAGUS

General aspects

Oesophageal cancer is usually squamous cell carcinoma in the upper and middle part of the oesophagus, or adenocarcinoma in the lower third. It is more frequent in older people and in men. Risk factors are shown in Box 7.1.

Clinical features

Early oesophageal cancer usually causes few or no symptoms but later features may include dysphagia, weight loss, pain (in the throat or back, behind the sternum or between the shoulder blades), hoarseness, chronic cough, vomiting or haemoptysis (coughing up blood).

Metastases are typically in the lymph nodes, liver, lungs, brain and bones.

General management

Diagnosis is confirmed by chest radiography, barium swallow (Fig. 7.1), oesophagoscopy (endoscopy), computed tomography (CT), magnetic resonance imaging (MRI) and biopsy. Bone scan and bronchoscopy may be needed.

Surgery is the most common treatment (oesophagectomy). Laser therapy or photodynamic therapy is sometimes used. A stent may be used for palliation; alternatively, a plastic tube or part of the intestine is used to reconnect with the stomach. Radiation therapy may be used alone or with chemotherapy as primary treatment or to shrink the tumour before surgery.

Dental aspects

Patients who have had oesophageal cancer have a greater chance of developing a second cancer in the head and neck area. Paterson–Brown–Kelly syndrome may be associated with a high risk of oral cancer. Rare patients have tylosis and oral leukoplakia.

THE STOMACH AND INTESTINES

Common features of gastrointestinal disorders include nausea and vomiting, diarrhoea and constipation, though none of these is specific and all have a wide range of causes (Ch. 4).

Fig. 7.1 Barium swallow radiography showing oesophageal carcinoma.

THE STOMACH

Gastric products include hydrochloric acid (secreted by parietal cells), pepsin (secreted by chief or peptic cells) and intrinsic factor (secreted by parietal cells). Gastric mucus contains several glycoproteins, which, with bicarbonate, are produced by surface cells and protect the mucosa against erosion.

Hydrochloric acid secretion is stimulated by: hypoglycaemia and mediators including acetylcholine (muscarinic-type receptor); gastrin (from G cells) and synthetic analogues of gastrin (pentagastrin); and histamine (from histaminocytes). Hydrochloric acid secretion is inhibited from higher centres and by low gastric pH and hormones – cholecystokinin, gastric inhibitory peptide (GIP) and secretin (Table 7.1).

Gastric acid secretion in response to various stimuli can be assessed by passing a nasogastric tube and measuring the volume, pH and acid concentration of the aspirate. The response to a meal is regulated by complex hormonal and neural (vagal) mechanisms (see Table 7.1).

Peptic ulcer

General aspects

An ulcer is a break in the continuity of an epithelial surface. Peptic ulcer disease (PUD) develops in or close to acid-secreting areas in the stomach (gastric ulcer) or proximal duodenum (duodenal ulcer). It affects up to 15% of the population, mostly men over the age of 45 years.

Helicobacter pylori, a spiral bacterium that lives in the stomach and duodenum, is the most common contributory cause to peptic ulcers. In the developed world, some 20–50% of normal adults are infected, but the figure is much higher in poor socioeconomic circumstances. Few carriers have disease, but *H. pylori* can cause increased gastric acid secretion, loss of the mucous protective layer, increased secretion of pepsinogen and increased gastrin release. *H. pylori* survives in the mucous lining, and resists gastric acid via the enzyme urease, which converts urea (abundant in the stomach from saliva and gastric juices) into bicarbonate and ammonia – both strong bases. This reaction of urea hydrolysis is important for the diagnosis of *H. pylori* by the ‘breath test’. *H. pylori* has another defence, in that the immune response cannot reach it, and the polymorphs may release their destructive superoxide radicals on to the stomach-lining cells, causing

Table 7.1 Gastrointestinal hormones

Part of gastrointestinal tract	Source	Hormones	Stimulus	Effects
Stomach	G cells	Gastrin	Gastric distension, amino acids	Secretion of gastric acid, pepsin, intrinsic factor
Small intestine	Duodenum and jejunum	Cholecystokinin (pancreozymin)	Fats, amino acids, peptides	Pancreatic secretion, gallbladder contraction, delay in gastric emptying
	Duodenum and jejunum	Gastric inhibitory peptide (GIP)	Glucose, fats, amino acids	Inhibition of gastric acid secretion, release of insulin, reduction of gut motility
	Duodenum and jejunum	Motilin	Acid	Increase in gut motility
	Duodenum and jejunum	Secretin	Acid	Pancreatic bicarbonate secretion, delay in gastric emptying

gastritis and perhaps eventually a peptic ulcer. *H. pylori* is found in the mouth, especially the gingival sulcus, and believed to be transmitted orofaecally. It is possible that *H. pylori* could be transmitted from the stomach to the mouth through gastro-oesophageal reflux and then be transmitted through oral contact.

PUD is also associated with raised gastrin levels, as in Zollinger–Ellison syndrome (a gastrin-producing tumour; high serum calcium provokes gastrin release) and chronic renal failure (poor gastrin metabolism). Other factors that predispose to peptic ulceration include NSAIDs, corticosteroids, smoking, alcohol, diet and stress. There are genetic influences: first-degree relatives have a threefold risk and there is an association with blood group O.

Clinical features

The main feature of PUD is epigastric pain, often relieved by antacids. Many of those affected have no symptoms and the first sign may be one of the complications – haemorrhage, perforation or pyloric obstruction (stenosis) with vomiting.

General management

Patients less than 45 years old who present with typical ulcer symptoms should be screened for *H. pylori*. Four tests are used to detect the bacterium:

- Blood test for antibodies to *H. pylori* – shows past or present infection
- Urea breath test – shows *H. pylori* infection
- Stool antigen test – tests for the presence of *H. pylori* antigens in faeces (stool)
- Stomach biopsy.

Studies of gastric acid or serum gastrin levels may be helpful and, if gastric outlet obstruction is suspected, a barium meal may be diagnostically useful (Fig. 7.2). Management of PUD involves conservative measures: dietary modification (frequent small meals with no fried foods); smoking cessation; alcohol moderation; and treatment of any *H. pylori*. Individuals who are *H. pylori*-positive should be given ‘triple therapy’, usually for 7 days, to eradicate infection. This normally is effective in over 90% with little risk of relapse and consists of a proton-pump inhibitor (esomeprazole, lansoprazole, omeprazole, pantoprazole or rabeprazole) and antibiotics (amoxicillin, clarithromycin and metronidazole). An additional reason to treat *H. pylori* infection is that it may lead to gastric cancer or mucosa-associated lymphoid tissue (MALT) lymphomas.

Fig. 7.2 Barium meal radiography showing gastric ulcer.

PUD that is *H. pylori*-negative is usually associated with NSAID use. Drugs that block histamine (H₂) receptors, such as cimetidine and ranitidine, are therefore used to reduce gastric acid secretion. Prostaglandin analogues such as misoprostol promote healing in PUD and are indicated in patients from whom NSAIDs cannot be withdrawn. Surgery is usually reserved for those with complications; gastric ulcers may be managed by antrectomy with gastroduodenal anastomosis or partial gastrectomy, while duodenal ulcers are managed with vagotomy and pyloroplasty (rarely).

Dental aspects

Gastric acid regurgitation can cause severe dental erosion (perimylolysis), typically of the palatal aspects of the upper anterior teeth and premolars. *H. pylori* may be transmitted in saliva but dental health-care professionals do not appear to be at particular risk from infection. There are conflicting findings as to whether dental plaque or dentures

Box 7.2 Risk factors for stomach cancer

- Achlorhydria
- Atrophic gastritis
- Blood group A
- Diet (smoked foods, salted fish and meat, and pickled vegetables; nitrates and nitrites are substances commonly found in cured meats)
- Genetic influences (carcinoma is common in Japanese and where there is a positive history in first-degree relatives). The E-cadherin/*CDH1* gene is responsible. Hereditary non-polyposis colorectal cancer (HNPCC; Lynch syndrome) and familial adenomatous polyposis (FAP) are genetic disorders with a greatly increased risk of colorectal cancer and a slightly increased risk of stomach cancer. People with mutations of the inherited breast cancer genes *BRCA1* and *BRCA2* may also have a higher rate of stomach cancer
- *Helicobacter pylori*
- Male gender
- Ménétrier disease (hypertrophic gastropathy)
- Obesity
- Occupations – workers in coal, metal and rubber industries
- Older age
- Pernicious anaemia
- Previous stomach surgery
- Tobacco

are an important reservoir for *H. pylori* and significant in transmission of the organism. There may be an association with halitosis.

Gastric surgery may result in attacks of hypoglycaemia. After resection, deficiencies of vitamin B₁₂, folate or iron may cause ulcers, sore tongue or angular stomatitis. Drugs such as aspirin and other NSAIDs and corticosteroids that cause gastric irritation, or promote bleeding, and should not be given to patients with peptic ulcers.

Labial vascular anomalies may be associated with PUD.

Oral adverse effects from medications may include:

- dry mouth from proton-pump inhibitors, pirenzepine and sucralfate
- erythema multiforme from ranitidine
- loss of taste or erythema multiforme from omeprazole.

Antacids impede absorption of ciprofloxacin, erythromycin, metronidazole and tetracyclines. Cimetidine and omeprazole may delay clearance of lidocaine and benzodiazepines but the effect is rarely clinically significant.

Cancer of the stomach

General aspects

Stomach cancer, usually adenocarcinoma, is common. Men are affected nearly twice as often as women. The aetiology of gastric cancer is unclear (Box 7.2).

Clinical features

Early symptoms of gastric cancer may closely mimic those of peptic ulcer – indigestion or vague upper abdominal pain. Later, there may be anorexia, loss of weight, nausea, vomiting, haematemesis or melaena (black and tarry stools with blood). Anaemia may develop. The tumour spreads locally later and leads to pain, and may obstruct the intestine to cause vomiting, or the bile duct to cause jaundice. Metastases are mainly to liver, peritoneum (causing ascites), lungs, bones or brain.

General management

The lesion may show on barium imaging and the diagnosis is usually confirmed by gastroscopy and biopsy, but is often delayed by the lack of early symptoms.

Most patients are treated by surgery but frequently this is only palliative. The prognosis is poor, with about a 7% 5-year survival rate (Ch. 22).

Dental aspects

Anaemia or obstructive jaundice may complicate dental treatment. Oral effects of anaemia (glossitis, ulcers, angular stomatitis) can be an initial sign. It is important to remember that iron deficiency usually results from chronic haemorrhage, in a male often from the gastro-intestinal tract, and then sometimes due to an ulcer or neoplasm in the stomach or large bowel.

Orofacial metastases from gastric carcinoma are rare, usually in the body of the mandible, and may cause swelling, pain, paraesthesia, loosening of teeth or sockets that fail to heal; they may be found as ragged radiolucent areas, sometimes with tooth root resorption. Occasionally, metastases may be first detected in a lower cervical (supraclavicular, or Virchow) lymph node, usually on the left side (Troisier sign).

THE SMALL INTESTINE

The small intestine is the main site of food digestion, which depends on intestinal and pancreatic enzymes acting on food previously exposed to salivary amylase, gastric acid and pepsin. This is where food absorption chiefly occurs.

Iron and folate are absorbed in the duodenum, most other substances in the jejunum. Bile salts facilitate the absorption of fats and the fat-soluble vitamins (A, D, E and K). Gastric intrinsic factor from the stomach parietal cells is needed for vitamin B₁₂ absorption, which occurs in the terminal ileum.

Small intestine disease causes malabsorption, with diarrhoea or steatorrhoea (fatty stools), sometimes abdominal discomfort, and deficiency states leading to lassitude, weakness, loss of weight or failure to thrive, and anaemia.

Diseases of the small intestine of most significance include coeliac disease and Crohn disease. Other causes of problems include surgery, infestations and drugs. For example, olmesartan can cause a sprue-like disease (diarrhoea, weight loss and villous atrophy, which resolves after discontinuation of the drug).

Coeliac disease

Coeliac disease (CD; gluten-sensitive enteropathy; coeliac sprue, non-tropical sprue) is the most common genetic disease in Europe, where up to 1 in 250 people have it. It is rare in Africans, Chinese or Japanese. CD is strongly associated with genes on chromosome 6, on a genetic background of HLA-DQw2 or DRw3, and may have a familial tendency.

CD is a hypersensitivity or toxic reaction of the small intestine mucosa to the gliadin component of gluten (prolamine), a group of proteins found in all forms of wheat (including durum, semolina, spelt, kamut, einkorn and faro), related grains (rye, barley, triticale) and possibly oats. Ingestion of gluten causes destruction of jejunal villi (villous atrophy) and inflammation, leading to malabsorption. Coeliac disease may be associated with autoimmune disorders (Box 7.3). Other food sensitivities or lactose intolerance may also be associated.

Clinical features

CD is one of the great mimics in medicine. It may present at any age and many affected individuals are asymptomatic, but CD can result

Box 7.3 Autoimmune disorders that may be associated with coeliac disease

- Dermatitis herpetiformis
- Diabetes mellitus type 1
- Immunoglobulin A (IgA) deficiency
- IgA nephropathy
- Primary biliary cirrhosis
- Systemic lupus erythematosus
- Thyroid disease

**Fig. 7.3** Coeliac disease.

in malabsorption (leading to growth retardation, vitamin and mineral deficiencies, which may in turn lead to anaemia, osteomalacia, bleeding tendencies and neurological disorders), abdominal pain, steatorrhoea and behavioural changes (Fig. 7.3). Intestinal lymphomas arise in about 6% of individuals.

General management

It is important to diagnose CD and to institute a gluten-free diet as early as possible, even in those with minimal symptoms, in order to prevent long-term complications (especially intestinal lymphoma). Investigations needed to establish the diagnosis include full blood count (anaemia is present in 50%); haematinics (ferritin, vitamin B₁₂ and folate levels may be low secondary to malabsorption); stool examination (24-hour weight of stool – abnormal if greater than 300 g – and the presence of excess fat – more than 6% of the fat consumed). Tolerance or measure-of-digestion/absorption investigations include lactose tolerance and D-xylose tests. Serum antibody screening is indicated (Table 7.2). Endoscopic biopsy of jejunal mucosa shows

Table 7.2 Serum antibodies, and antigens, in coeliac disease

	Antigens	Antibodies
Endomysium	Connective tissue stroma covering muscle fibres	Immunoglobulin (Ig) A class antibodies present in those with severe mucosal damage
Gliadin (gliaden)	Prolamins (glycoproteins) in wheat and several other cereals in the grass genus <i>Triticum</i>	ELISA test for gliadin antibodies is a reliable screening tool. IgG antibody detection is more sensitive but less specific than IgA antibodies. Antigliadin antibodies lose specificity with age
Reticulin	Fibres composed of type III collagen	IgA class reticulin antibodies found in 60% of patients. IgG class reticulin antibodies occasionally also found in bullous dermatoses and in some normal subjects
Transglutaminase	Tissue transglutaminase – the protein cross-linking enzyme – is the endomysial antigen	IgA anti-tissue transglutaminase is 85% sensitive and 97% specific – and the diagnostic gold standard

villous atrophy if positive, and is repeated after a gluten-free diet has been maintained for 3 months. In children the same procedure is used, except that an additional biopsy is carried out after a test challenge of gluten, as it is essential to establish the diagnosis with certainty from the outset, in order to encourage normal growth and to eliminate such conditions as post-infectious gastroenteritis, which can cause a histologically similar lesion. Similar jejunal changes are also seen in dermatitis herpetiformis.

Treatment of CD includes rectifying nutritional deficiencies, and adhering to a gluten-free diet for life. Instead of wheat flour, potato, rice, soy or bean flour and gluten-free bread, pasta and other products are used. Patients require continued supervision, as it is often difficult to comply with such a diet, especially if eating away from home.

Dental aspects

Short stature, associated with diarrhoea and enamel defects, is particularly suggestive of early-onset CD. Anaemia may predispose to oral lesions, notably glossitis, burning mouth, angular stomatitis and ulcers. CD may be found in up to 5% of patients with aphthous-like ulcers and should be suspected if there are any other symptoms suggesting small intestine disease.

Some untreated patients may have a bleeding tendency. Anaemia may complicate general anaesthesia (GA).

Inflammatory bowel disease

Inflammatory bowel disease (IBD) is a collective term for diseases that cause inflammation in the intestines and encompasses the spectrum of disease seen in Crohn disease and ulcerative colitis (UC; Table 7.3). The differential diagnosis includes infectious colitis, microscopic colitis, segmental colitis associated with diverticula, ischaemic colitis, and even cancers. These diseases are seen mainly in northern Europe and USA and in Caucasians.

Genetic factors appear to influence disease susceptibility and patterns but environmental, dietary, and infective factors may be at play. In Crohn disease, all layers of the intestine may be involved and there can be normal healthy bowel between patches of diseased bowel. The

Table 7.3 Crohn disease and ulcerative colitis compared

	Crohn disease	Ulcerative colitis
Main site affected	Ileum	Colorectum
Other sites affected	Any part of the gastrointestinal tract, including the mouth	Terminal ileum
Pathology	Transmural granulomatous inflammation	Superficial inflammation
Abdominal pain	Prominent	Less prominent
Bloody diarrhoea	Less common	Prominent
Fistulae and abscesses	Possible	Rare
Colonic carcinoma risk	Increased	High
Iron deficiency	Common	Common
Folate deficiency	Common	Common
Other deficiencies	Vitamin B ₁₂ deficiency	Rare

aetiology is unknown but available evidence suggests that a deregulated immune response towards commensal bacterial flora is responsible for intestinal inflammation in genetically predisposed individuals. Antigens from commensal microorganisms appear to trigger and maintain inflammation in a number of ways, with effector T cells (Th1, Th2, Th17) predominating and releasing interferon-gamma and interleukin-12 (IL-12); other cytokines, such as tumour necrosis factor alpha (TNF α), IL-1 and IL-6, are produced in response, by macrophages. IL-23 promotes expansion and maintenance of Th17 cells, which secrete the proinflammatory cytokine IL-17. IL-23 also acts on cells of the innate immune system that can contribute to inflammatory cytokine production and tissue inflammation. Natural killer (NK) cells also contribute directly and via IL-13. Chemoattractants, such as IL-8, macrophage inhibitory protein 1 (MIP1) and RANTES (regulated on activation normal T cells as secreted), recruit immunocytes to the area. Interactions between the nervous and immune systems may also play a role: activation of the enteric nervous system may reduce intestinal epithelial permeability, via several mediators including substance P, histamine, neurokinin, serotonin, vanilloids, S-nitrosoglutathione and vasoactive intestinal peptide (VIP).

Emerging biological therapies are thus aimed at cytokines (e.g. adalimumab, certolizumab, infliximab), T-cell activation receptors (abatacept, visilizumab) or adhesion molecules (alicaforfen, MLN-02, natalizumab).

Crohn disease (regional enteritis or ileitis)

General aspects

Crohn disease appears to be a heterogeneous group of chronic inflammatory disorders seen mainly in Caucasians. About 20% of people with Crohn disease have a blood relative with some form of IBD, most often a brother or sister and sometimes a parent or child.

Microscopically, there is submucosal chronic inflammation with many mononuclear, IL-1-producing cells and non-caseating granulomas in the submucosa and lymph nodes. The inflammatory response is probably mediated by factors such as TNF α . Susceptibility appears to be related in 15% to the *CARD15* gene with a locus on chromosome 16, and it has been hypothesized that Crohn disease involves augmentation of the Th1 response in inflammation. The microorganisms involved are unknown but many have been implicated. *Mycobacterium avium* subspecies *paratuberculosis* has been incriminated, but is probably one of a variety of microorganisms simply taking advantage of the damaged mucosa and inability to clear bacteria from the intestinal walls. Other workers have suggested that a lack of *Faecalibacterium*

**Fig. 7.4** Crohn disease.**Fig. 7.5** Perianal tags in Crohn disease.

prausnitzii might be responsible. Diet, oral contraceptives, NSAIDs, isotretinoin and smoking have also been incriminated.

Clinical features

Crohn disease can affect any part of the gastrointestinal tract from mouth to anus (top to tail) but affects especially the ileocaecal region, typically with ulceration, fissuring and fibrosis of the wall. The manifestations depend on its severity and the site affected. Small-intestinal Crohn disease may cause abdominal pain that often mimics appendicitis, with malabsorption or abnormal bowel habits (Fig. 7.4). Features include persistent diarrhoea (loose, watery or frequent bowel movements), cramping abdominal pain, fever and, at times, rectal bleeding. Sometimes deep ulcers turn into tracts – fistulae with tags (Fig. 7.5). Patients may also malabsorb and develop a shortage of proteins, calories or vitamins. Loss of appetite and weight loss may also occur.

Fatigue is another common complaint. The most common complication of Crohn disease is intestinal blockage due to swelling and scar tissue, presenting with cramping pain, vomiting and bloating. Patients have an increased risk of colon cancer, and Crohn disease can also affect the joints, eyes, skin, liver and mouth.

General management

The major differential diagnoses include ulcerative colitis, tuberculosis, ischaemic colitis, infections, infestations such as giardiasis, and lymphoma. There are no specific diagnostic tests for Crohn disease. Investigations may include: faecal calprotectin – now used as a diagnostic marker indicator for IBD (replacing isotope leukocyte intestinal scans); blood count (anaemia is common); serum potassium, zinc and albumin (usually depressed); erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and seromucoid (often raised); small bowel MRI; plain-film and contrast radiography (barium enemas of large and small bowel, or barium meal and follow-through); ultrasound and CT; and endoscopy (sigmoidoscopy, colonoscopy) with mucosal biopsy (often shows typical granulomas).

A high-fibre diet is indicated and anaemia needs treatment. Treatment of Crohn disease includes:

- aminosalicylates (5-ASA) or newer 5-aminosalicylates (mesalazine or olsalazine)
- antibiotics (metronidazole, ampicillin, ciprofloxacin, others)
- immune modifiers (local [prednisolone/prednisone, budesonide] or systemic corticosteroids, azathioprine, 6-mercaptopurine [6-MP] or methotrexate; everolimus in unresponsive patients; biological therapy [monoclonal antibodies directed against TNF α – adalimumab, certolizumab pegol or infliximab]); thiopurines (such as 6-MP and azathioprine) unfortunately can increase a patient's risk of non-Hodgkin lymphoma
- surgery when medications can no longer control the symptoms – two-thirds to three-quarters of patients will require surgery at some point during their lives.

Dental aspects

Dental management may be complicated by any of the problems associated with malabsorption or by corticosteroid or other immunosuppressive treatment. NSAIDs should be avoided. Antibiotics that could aggravate diarrhoea should not be used; these include amoxicillin–clavulanic acid (co-amoxiclav) erythromycin and clindamycin.

Oral lesions may be caused by Crohn disease itself or by associated nutritional defects, and may include ulcers, facial or labial swelling (Fig. 7.6), mucosal tags or 'cobblestone' proliferation of the mucosa, and angular stomatitis. Patients with atypical ulcers, especially when they are large, linear and ragged, or those with recurrent facial swellings, should have biopsy of the mucosa. Melkersson–Rosenthal syndrome (facial swelling, facial palsy and fissured tongue), cheilitis granulomatosa and orofacial granulomatosis may also be incomplete manifestations of Crohn disease, and some of these patients may have asymptomatic intestinal disease or develop intestinal disease later.

A high prevalence of caries and periodontitis in Crohn disease has also been reported.

Orofacial granulomatosis

Orofacial granulomatosis (OFG) is the term given to granulomatous lesions similar to those of Crohn disease and found on oral biopsy but without detectable systemic Crohn disease, though this may be detected later. Th1 immunocytes produce IL-12 and RANTES/MIP1 α , and the granulomas. HLA typing may show HLA-A2 or HLA-A11.

Fig. 7.6 Facial and labial swelling in Crohn disease.

Table 7.4 Factors that have been implicated in orofacial granulomatosis

Foods/additives	Chemicals/metals	Microorganisms
Benzoic acid	Cobalt	<i>Borrelia burgdorferi</i>
Butylated hydroxyanisole	Colophony	<i>Mycobacterium paratuberculosis</i>
Carbone piperitone	Eugenol	<i>Saccharomyces cerevisiae</i>
Carvone	Formaldehyde	<i>Spirochaetes</i>
Chocolate	Isoeugenol	
Cinnamaldehyde or cinnamyl alcohol	Nickel	
Cocoa	Oak moss absolute	
Dairy products	Sodium metabisulfite	
Eggs		
Monosodium glutamate or glutamic acid		
Peanuts		
Piperitone		
Sorbic acid		
Sun yellow		
Tartrazine		
Wheat		

OFG may sometimes result from reactions to some foods or medications, such as cinnamaldehyde and benzoates; up to 40% of patients may be positive to patch tests and half of these may respond to exclusion of dietary antigens (Table 7.4).

Oral lesions of OFG include ulcers, facial or labial swelling, mucosal tags or 'cobblestone' proliferation of the mucosa. Gut Crohn disease and reactions to foods should be excluded by gastrointestinal investigations, and allergy tests are often indicated. If systemic Crohn disease can be excluded, patients still need to be kept under observation for its possible development later.

Exclusion of offending substances can be difficult but may help facial swelling resolve. Clofazimine, dapsone, thalidomide, anti-TNF biological therapies or intralesional injection of corticosteroids may also be needed.

Short bowel syndrome

Short bowel syndrome, in which the small intestine is short, may be congenital or caused by surgery. Numerous metabolic defects, particularly vitamin and mineral deficiencies leading to osteomalacia and

fractures, may result. Patients on home parenteral nutrition due to short bowel syndrome seem to have a high risk of developing systemic osteoporosis, including the jaws, but do not have a higher risk for deterioration of the dental or periodontal state.

THE LARGE INTESTINE

The large intestine has two main functions: recovery of water and electrolytes (sodium and chloride), and the formation, storage and expulsion of faeces (stools). The large intestine lies between the terminal ileum and anus, and consists of the caecum – a blind-ended pouch that carries a worm-like extension (the appendix) in humans; the colon, which forms most of the length of the large intestine and comprises ascending, transverse and descending segments; and the rectum – the short, terminal segment continuous with the anal canal.

Appendicitis

General aspects

Appendicitis is inflammation of the appendix, the cause of which is usually unknown; it may follow a viral infection or obstruction. Appendicitis is most common in people aged 10–30.

Clinical features

Not all appendicitis causes symptoms but features may include pain in the right abdomen, nausea, vomiting, constipation, diarrhoea, abdominal swelling, anorexia and low fever that begins later. The pain usually begins near the umbilicus and moves down and into the right iliac fossa. The pain becomes worse when moving, taking deep breaths, coughing, sneezing and being touched (McBurney point).

General management

Diagnosis is based upon symptoms, examination, blood tests, such as a leukocyte count to check for infection, and urine tests to rule out a urinary tract infection. If untreated, an inflamed appendix can burst, causing peritonitis and even death, and is thus considered an emergency.

If a diagnosis of appendicitis is definite, surgery (appendicectomy) is indicated, sometimes via laparoscopic surgery. If the diagnosis of appendicitis is not certain, the patient may be watched and sometimes treated with antibiotics.

Irritable bowel syndrome

Irritable bowel syndrome (IBS; spastic colon; mucous colitis) may affect up to 30% of the population and is the most common cause of referrals to gastroenterologists. IBS causes recurrent abdominal pain together with increased tone and activity of the colon, abnormal bowel habits and other symptoms. It may occur at any age and has a slight female predominance.

The cause of IBS is unclear but it may begin after an infection or stressful life event; there is often a positive family history, anxious personality type and history of migraine or psychogenic symptoms (Ch. 10). The protozoan *Dientamoeba fragilis* has been implicated by some researchers. Cytokines (IL-1, IL-6 and TNF) and serotonin have also been cited as causes.

Clinical features

IBS leads to crampy abdominal pain, flatulence, bloating and changes in bowel habit – constipation or diarrhoea, often with urgency (tenesmus). Additional gynaecological and urinary symptoms may be reported. Episodes may be precipitated by stressful life events or foods such as chocolate, caffeine, milk products or large amounts of alcohol.

Examination may reveal some abdominal distension and tenderness. However, guarding or rebound tenderness of the abdomen, along with blood or mucus per rectum, suggests other organic disease.

General management

IBS is a diagnosis of exclusion. Investigations are tailored to rule out coeliac disease, IBD or colonic cancer (full blood count and haematinics; inflammatory markers (ESR); contrast radiography; endoscopy and mucosal biopsy).

Stress reduction and a high-fibre diet may control symptoms. Antispasmodics (mebeverine, loperamide or an antimuscarinic such as dicycloverine, or peppermint oil) may help. Probiotics may have a role. Cognitive behavioural therapy or antidepressants may be of benefit for patients with IBS who are clinically depressed. For severe cases that fail to respond to the above measures, it is important to reconsider the diagnosis and re-evaluate the patient's history and presentation; coeliac disease or IBD can easily be missed.

Dental aspects

Local anaesthesia (LA) is satisfactory for pain control. Conscious sedation (CS) may be needed because of these patients' anxious personalities. Orofacial manifestations may include psychogenic oral symptoms such as pain dysfunction syndrome, sore tongue or atypical facial pain.

Loperamide or dicycloverine may cause dry mouth.

Diverticular disease

General aspects

Diverticular disease includes both diverticulosis (small colonic pouches – diverticula – that bulge out through weak spots of the large intestine wall) and diverticulitis (inflammation of these diverticula). Diverticular disease is most common in developed or industrialized countries, where it affects over 50% of those over 60 years. It may result from a low-fibre diet.

Clinical features

Left-sided diverticular disease (involving the sigmoid colon) is most common in the West, while right-sided diverticular disease is more prevalent in Africa and Asia. It may be asymptomatic but is often accompanied by dyspepsia, abdominal pain, constipation and flatulence. Complications include pericolic abscess, perforation and peritonitis, or fistula.

General management

Conditions to be excluded include IBD, IBS, cancer, and urological and gynaecological disorders. Management includes a high-fibre diet and reassurance. Antibiotics and surgery may be needed.

Dental aspects

There are no specific management problems in dentistry, although codeine should be avoided as it worsens constipation.

Fig. 7.7 Ulcerative colitis.

Ulcerative colitis

General aspects

Ulcerative colitis (UC) is an IBD affecting part or the whole of the large intestine – most frequently the lower colon and rectum. It causes inflammation and ulcers in the superficial layers of the mucosa, followed by formation of pseudopolyps, which may be pre-malignant. It most often affects people between the ages of 15 and 40 years.

The aetiology is unknown but autoimmunity, diet, sulphate-reducing bacteria, drugs such as isotretinoin and a genetic basis have been suggested. A role for the *RUNX3* gene on chromosome 1 has been suggested but chromosomes 6, 16, 12, 14, 5, 19 and 3 have also been implicated. Psychosomatic symptoms are often associated.

Clinical features

Typical features are pain and diarrhoea with stools containing intermixed mucus, blood and pus, sometimes with systemic toxicity (fever, anorexia, weight loss, anaemia and raised ESR and CRP; Fig. 7.7). Disease with less than six bloody stools daily but no systemic toxicity is termed 'mild'; if there is toxicity, disease is termed 'moderate'; and the term 'severe ulcerative colitis' is applied when there are more than six bloody stools daily plus toxicity. Disease extension through the muscular layers may result in life-threatening toxic megacolon (the colon dilates and can perforate). The most serious complication is carcinoma of the colon, which is up to 30 times more frequent than in the general population and most likely to develop in patients with early-onset colitis or with disease persisting for more than 10 years.

Non-gastrointestinal features include arthralgia, conjunctivitis, uveitis, iritis, finger-clubbing, sacroiliitis, skin disease (erythema nodosum

Box 7.4 Management of ulcerative colitis

- Local corticosteroids (prednisolone [prednisone]) – often by enema
- Sulfasalazine or 5-aminosalicylates (balsalazide, mesalazine, olsalazine) to induce and maintain remission
- Tacrolimus, ciclosporin, infliximab or vedolizumab
- Systemic corticosteroids or azathioprine in acute exacerbations
- Surgery for failed medical therapy or to treat complications

and pyoderma gangrenosum), liver disease (especially primary sclerosing cholangitis), gallstones and renal calculi. Overproduction of platelets and some clotting factors may lead to thromboembolism.

General management

There are no specific diagnostic tests. Investigations include full blood count and haematinics; inflammatory markers (ESR); contrast radiography (barium studies); endoscopy and mucosal biopsy.

A high-fibre diet is indicated and any anaemia needs treatment. Medical therapy includes conservative measures (nutritional support) and drug therapy (Box 7.4). Vedolizumab is a humanized monoclonal antibody to $\alpha 4 \beta 7$ integrin that appears beneficial.

The surgical options in UC depend on the extent of disease but generally consist of colectomy (excision of diseased bowel with either re-anastomosis or ileostomy construction) if symptoms are severe, the response to medical treatment is poor, complications such as pyoderma gangrenosum or haemorrhage develop, or there is a risk of malignant change. Unlike in Crohn disease, surgery can be curative.

Dental aspects

Drugs that should be avoided include NSAIDs and antibiotics including amoxicillin–clavulanic acid (co-amoxiclav), erythromycin and clindamycin, which could aggravate diarrhoea.

LA is satisfactory and there are no objections to CS if needed. Management complications may include anaemia and those associated with corticosteroid therapy.

Oral manifestations in UC are rare but include pyostomatitis gangrenosum (chronic ulceration), pyostomatitis vegetans (multiple intraepithelial microabscesses), discrete haemorrhagic ulcers or lesions related to anaemia. Since uveitis, skin lesions and mouth ulcers can be found in UC, it is important to differentiate it from Behçet disease (Ch. 11).

Familial polyposis coli

Familial polyposis coli (FPC) is an autosomal dominant disease in which multiple adenomatous polyps affect the rectum and colon; carcinomatous change usually supervenes. FPC is a feature of Gardner syndrome, along with multiple exostoses and osteomas of the jaws. These bone lesions also appear to be more common in patients with non-familial colorectal cancer than in the general population. Colectomy is indicated.

Carcinoma of the colon

General aspects

Carcinoma of the colon (colorectal cancer) is common. The peak incidence is in the sixth or seventh decade and the tumour usually forms in the

Box 7.5 Risk factors for colonic carcinoma

- Cholecystectomy
- Diet low in fibre, fruit and vegetables, and high in red meat and fat
- Heredity; familial polyposis coli
- Inflammatory bowel disease
- Tobacco

Fig. 7.8 Barium enema radiography showing colorectal carcinoma.

rectum or pelvic (sigmoid) colon. A series of gene alterations can lead to adenomas and eventually, in some patients, to carcinoma. Risk factors are shown in [Box 7.5](#). Long-term aspirin use lowers the risk of colonic cancer.

Clinical features

Carcinoma of the colon may cause abdominal pain, change in bowel habit, melaena, weight loss or complications such as anaemia, intestinal obstruction or perforation.

General management

Abdominal examination may reveal a mass. Sigmoidoscopy and sometimes faecal occult blood testing (stool guaiac), MRI, ultrasound, barium enema ([Fig. 7.8](#)) and colonoscopy may be required. Methylated septin 9 (SEPT9), a plasma test to screen for colorectal cancer, has a sensitivity and specificity similar to those of stool guaiac or faecal immune tests (immunochemical faecal occult blood test).

Surgical resection is the usual treatment. Spread is frequently to the liver. The 5-year survival rate is overall about 30% (Ch. 22). Radiotherapy may be useful for dealing with pain from recurrences. Chemotherapy may be used in advanced cancer: capecitabine, irinotecan, oxaliplatin, raltitrexed and possibly cetuximab. Serial monitoring for serum carcino-embryonic antigen or serum or faecal M2-pyruvate kinase (M2-PK) antigen may help detect recurrences (Ch. 22). Metastatic carcinoma may be treated with bevacizumab, cetuximab or antiangiogenesis agents, such as aflibercept, in combination with chemotherapy.

Dental aspects

LA is satisfactory and acceptable. CS can be given if needed. GA must be given by a specialist, particularly if complications have developed.

Anaemia resulting from chronic intestinal haemorrhage can complicate dental management or cause oral signs or symptoms.

Mandibular osteomas may be markers of an enhanced risk of colorectal cancer.

Antibiotic-associated (pseudomembranous) colitis

Most of the orally administered antimicrobials can cause diarrhoea, but clinically significant colitis is rare and is more likely to affect older or debilitated patients. The most severe type of colitis is staphylococcal enterocolitis, usually caused by prolonged heavy doses of tetracyclines, particularly after bowel surgery; now that the cause is recognized, this type of colitis has become rare. Pseudomembranous colitis is caused more frequently by lincomycin and clindamycin than by other antibiotics, as a result of proliferation of toxigenic strains of clostridia, particularly *Clostridium difficile*, which are resistant to low concentrations of these antibiotics.

Clinically, antibiotic-associated colitis is characterized by painful diarrhoea and passage of mucus. In elderly debilitated patients especially, there is passage of blood and pseudomembranous material (necrotic mucosa), occasionally resulting in death. The diagnosis cannot be made from the presence of *C. difficile* in the stool, as 1–9% of hospital patients carry the bacterium, but only from sigmoidoscopy and biopsy. Pseudomembranous colitis usually responds to metronidazole or oral vancomycin, plus cessation of the causal antibiotic.

ANAL DISEASES

Because of the widespread habit of anal intercourse, the anus can show the signs of many sexually shared infections. It is also a particularly important portal of entry for human immunodeficiency virus (HIV) infection because of the delicate lining of the anal canal. Carcinoma of the anus is rare, but more common in patients with HIV/acquired immunodeficiency syndrome (AIDS) and often associated with human papillomavirus infection.

Haemorrhoids

General aspects

Haemorrhoids is a term that refers to a condition in which the veins around the anus or lower rectum are swollen and inflamed. Haemorrhoids may result from straining to pass stool; contributory factors include pregnancy, ageing, chronic constipation or diarrhoea, and anal intercourse.

Clinical features

The most common symptom of internal haemorrhoids is bright red blood covering the stool, on toilet paper, or in the WC pan. Symptoms of external haemorrhoids may include irritation around the anus. Bleeding and/or itching, a painful swelling or hard lumps from thrombosed external haemorrhoids are other effects.

General management

Sigmoidoscopy or colonoscopy may be needed to rule out other causes of gastrointestinal bleeding such as colorectal cancer. A softer stool makes emptying the bowels easier and lessens the pressure on haemorrhoids, as does diltiazem to relieve tension; application of a haemorrhoidal cream or suppository to the affected area relieves symptoms. Surgery may be needed, such as sclerotherapy, rubber band ligation, infrared coagulation or haemorrhoidectomy. Dental care should be deferred until the patient can sit normally.

PERITONITIS

The peritoneal cavity normally holds only 50 mL of fluid, which contains complement factors but few leukocytes, circulates in the peritoneal space and drains via the lymphatics. Acute peritonitis is fairly uncommon but is usually a serious infection with inflammation of the peritoneum that follows rupture of a viscus (e.g. appendix) or trauma. Chronic peritonitis develops in patients on continuous ambulatory peritoneal dialysis and in some intensive care patients.

Spontaneous bacterial peritonitis is an infection of ascites fluid in patients with cirrhosis, in which the source of the infection is not known. Although *Streptococcus pneumoniae* is the most common pathogen, there is rarely any obvious source.

Clinical features

Severe and generalized abdominal pain, vomiting, pyrexia, a rigid/board-like and tender abdomen and no bowel sounds are the main features. Peritonitis can lead rapidly to hypovolaemic shock and death.

General management

Diagnosis is clinical, supported by imaging and culture. Treatment includes urgent fluid administration, antibiotics and laparotomy/surgical debridement/drainage as required.

THE PANCREAS

The pancreas is intimately associated with the common bile duct and performs exocrine and endocrine functions (Fig. 7.9). The exocrine pancreas produces digestive juices and the enzymes trypsinogen, chymotrypsinogen, amylase and lipase, which enter the common bile duct via the pancreatic duct, and then pass from the common bile duct to the small intestine. The endocrine function is performed by the pancreatic islets of Langerhans, which secrete insulin and glucagon—regulating glucose metabolism—along with pancreatic polypeptide and somatostatin, which help control the function of other endocrine hormones (Ch. 6).

ACUTE PANCREATITIS

General aspects

Acute pancreatitis is mainly caused by gallstone disease but may be precipitated by alcoholism, trauma, hypercalcaemia, hyperlipidaemia, viral infections such as mumps, endoscopic retrograde cholangiopancreatography (ERCP) or various drugs such as azathioprine, contraceptive pills, corticosteroids, furosemide or phenothiazines.

Clinical features

Acute pancreatitis causes acinar damage and activation of enzymes, leading to local fat necrosis. Mild pancreatitis usually resolves in a few days but in fulminating pancreatitis the patient is severely ill with retroperitoneal haemorrhage, pleural effusion and paralytic ileus. Systemic effects include severe abdominal pain, nausea, vomiting, hypotension and shock. Possible complications are wide-ranging (Box 7.6). The mortality rate is 15–25%.

Fig. 7.9 Pancreatic anatomy.

Box 7.6 Complications of acute pancreatitis

- Abscess
- Acute renal failure
- Disseminated intravascular coagulopathy
- Metabolic (hypocalcaemia, hyperbilirubinaemia and hyperglycaemia)
- Respiratory distress
- Splenic vein thrombosis

General management

Raised serum levels of alkaline phosphatase, the transaminases, amylase and lipase, and radiology, MRI and ultrasonography aid the diagnosis. Shock, metabolic complications and pain must be urgently treated.

Dental aspects

LA is suitable if emergency treatment is required. CS and GA are not feasible until after resolution.

CHRONIC PANCREATITIS

General aspects

Causes include gallstone disease and alcoholism particularly. Malnutrition, hyperparathyroidism, haemochromatosis, hyperlipidaemia, carcinoma, cystic fibrosis and other factors may sometimes be implicated.

Clinical features

Chronic pancreatitis results in acinar atrophy and deterioration in both exocrine and endocrine function. Exocrine dysfunction causes a decline in the volume, bicarbonate content and enzyme content of pancreatic secretions. Endocrine dysfunction often includes abnormal glucose tolerance or frank diabetes. Chronic dull abdominal pain is punctuated by episodes of acute pancreatitis. Weight loss is common, as are nausea, vomiting and pruritus (from bile salt accumulation).

General management

Diagnosis is assisted by finding raised serum levels of amylase and lipase. Pancreolauryl and para-aminobenzoic acid testing are used to assess exocrine function. Pancreatic steatorrhoea is suggested by high faecal fat and undigested meat fibres. Faecal levels of chymotrypsin

are depressed. CT demonstrates pancreatic calcification, especially in alcoholic pancreatitis. Barium meal, duodenography, cholangiography and endoscopy (ERCP) are diagnostically helpful.

Management includes analgesics, treatment of diabetes and the oral administration of pancreatic enzymes to aid digestion.

Dental aspects

Factors predisposing to or resulting from pancreatitis that might influence dental management include bleeding due to vitamin K malabsorption (Ch. 8), alcoholism (Ch. 34), diabetes mellitus (Ch. 6), hyperparathyroidism (Ch. 6), cystic fibrosis (Ch. 15) or narcotic abuse because of severe pain.

LA is satisfactory for pain relief. CS may be given for control of anxiety. Oral ulceration can result from holding pancreatic enzyme in the mouth.

Pancreatitis has *rarely* arisen from an oral source of infection.

PANCREATIC TUMOURS

General aspects

Most pancreatic tumours originate in the exocrine duct (acinar cells); nearly 95% are adenocarcinomas, usually involving the head of the pancreas. They appear to be rising in incidence and are now one-tenth as common as bronchogenic carcinoma. A minority (less than 10%) of pancreatic cancers result from an inherited tendency; there is a higher incidence of the familial tendencies in people with familial adenomatous polyposis, non-polyposis colonic cancer and familial breast cancer associated with the *BRCA2* gene. Known risk factors are shown in [Box 7.7](#); periodontal inflammatory disease has also been implicated.

Tumours that begin in the islet cells (endocrine tumours) are rare but these and others may release hormones ([Table 7.5](#)).

Clinical features

Pancreatic carcinoma frequently invades to cause biliary obstruction (jaundice), pancreatitis and diabetes mellitus. Extrapancreatic complications, such as peripheral vein thrombosis (thrombophlebitis migrans), pruritus, nausea and vomiting, are common.

General management

Plain radiography, CT, MRI, ultrasound, endoscopy (ERCP) or percutaneous transhepatic cholangiography may be diagnostically helpful.

Pancreatic carcinoma is usually treated surgically, often with a bypass to relieve obstructive jaundice. Stenting may be used to relieve jaundice for as long as possible. Gemcitabine may help delay progress of advanced carcinoma. Pancreatic carcinoma has the worst prognosis of any cancer, with a 1-year survival of 10% and a 5-year survival of 3% (see Ch. 22).

Dental aspects

In many cases the poor prognosis of pancreatic cancer may significantly influence the dental treatment plan. Biliary obstruction may lead to bleeding tendencies, especially if there are hepatic metastases. Diabetes mellitus may be an added complication. Local anaesthesia is satisfactory. Conscious sedation may be given to relieve excessive anxiety. GA should not usually be considered because of the poor overall prognosis.

Box 7.7 Risk factors for pancreatic cancer

- Alcohol abuse
- Betel chewing
- Chronic exposure to petroleum compounds
- Chronic pancreatitis (often alcohol-induced)
- Diets high in animal fat and low in fruits and vegetables
- Heredity
- Obesity and physical inactivity
- Tobacco (responsible for at least 30%)

Table 7.5 Hormone-secreting pancreatic tumours

Tumour	Hormone released	Comments
Glucagonomas	Glucagon	Hyperglycaemia and abnormal glucose tolerance. Tumours are frequently malignant. Estimation of plasma glucagon levels differentiates glucagonomas from diabetes mellitus. Glucagon levels may also be raised in patients taking danazol. A major clinical feature is distinctive bullous or pustular skin and mouth lesions. There is often weight loss, anaemia and hypercholesterolaemia too
Insulinomas	Insulin	Hypoglycaemia – the most common cause in those not taking insulin
Watery diarrhoea, hypokalaemia and achlorhydria (WDHA) syndrome	Vasoactive peptides	Hyperglycaemia accompanies the watery diarrhoea, hypokalaemia and achlorhydria
Zollinger–Ellison syndrome	Gastrin	Diarrhoea and duodenal ulceration. May be part of the multiple endocrine adenoma syndrome (MEA I; Ch. 6).

PANCREATIC TRANSPLANTATION AND SIMULTANEOUS PANCREAS–KIDNEY TRANSPLANTATION

General aspects

Pancreas transplantation is used to ameliorate type 1 diabetes and provide complete insulin independence. The pancreas usually comes from a cadaveric organ donor but living donor pancreas transplants have been carried out. About 85% of pancreatic transplants are performed along with a kidney transplant (both organs from the same donor) in diabetic patients with renal failure; this is called a simultaneous pancreas–kidney transplant. About 10% of cases are performed after a previously successful kidney transplant (called a pancreas-after-kidney transplant); 5% are performed as pancreas transplant alone in non-uraemic patients with very labile and problematic diabetes.

General management

All transplant recipients require lifelong immunosuppression to prevent a T-cell alloimmune rejection response.

Dental aspects

A meticulous oral assessment is required before surgery, and dental treatment should be undertaken with particular attention to establishing optimal oral hygiene and eradicating sources of potential infection.

Dental treatment should be completed before surgery. For 6 months after surgery, elective dental care is best deferred. If surgical treatment is needed during that period, antibiotic prophylaxis is probably warranted. See also Chapter 35.

KEY POINTS

- Postoperative bleeding usually has a local cause
- Von Willebrand disease is the most common inherited bleeding disorder
- Warfarin anticoagulation is common
- Anaemia is common and usually due to chronic blood loss
- Leukaemia presents with bleeding, anaemia and infections

HAEMOSTASIS

Normal haemostasis (bleeding cessation) depends on the interaction of blood vessels, platelets, fibrin coagulation and deposition, and fibrinolytic proteins (Fig. 8.1). Three reactions – primary, secondary and tertiary haemostasis – act simultaneously. Excessive blood clotting is prevented by the endothelium, which provides a physical barrier and secretes products that inhibit platelets (e.g. nitric oxide and prostaglandin I_2 [prostacyclin]). Inhibitors limit haemostasis to the site of injury and prevent overproduction of the clot – which could lead to pathological thrombosis.

PRIMARY HAEMOSTASIS (VASCULAR AND PLATELET ACTIVITY)

Primary haemostasis is by vasoconstriction after injury, which retards blood loss, slows local blood flow, enhances platelet adherence to sub-endothelial surfaces and activates coagulation.

The endothelial lining of the vessel wall is a barrier between the circulating platelets and the prothrombotic subendothelial matrix. Upon vessel injury, the endothelial layer is disrupted and the circulating platelets interact with the subendothelium through adhesive receptors, such as glycoprotein (GP) Ib-IX-V receptors, that mediate rolling and tethering of the platelets to von Willebrand factor (vWF) at the site. Platelet collagen receptors $\alpha_2\beta_1$ and GP VI then mediate more firm adhesion and further platelet activation, causing release of platelet dense granules contents; these contain agonists such as adenosine diphosphate (ADP), and α -granules, which contain fibrinogen, factor V and P-selectin. The platelet generates lipid mediators such as thromboxane A_2 . ADP elicits its effects on the platelet through the $P2Y_1$ and $P2Y_{12}$ receptors, whereas thromboxane A_2 activates the thromboxane-prostanoid (TP) receptor on the platelet surface. The release of the granule contents also triggers the blood coagulation response as a result of the release of clotting factor V, and the inflammatory response through the exposure of P-selectin on the platelet surface. Also, tissue factor is exposed, which initiates the coagulation response that results in formation of thrombin. Thrombin activates platelets via interactions with the proteinase-activated receptor-1 (PAR1) and PAR4 receptors and also cleaves fibrinogen to form fibrin. Fibrin further stabilizes the accumulating platelet plug at the site of injury, resulting in a stable haemostatic plug.

Platelet activation in response to vessel injury is thus important for the arrest of bleeding (Fig. 8.2), but activation during disease states leads to vascular occlusion and ischaemic damage. The $P2Y_{12}$ receptor,

Table 8.1 Blood coagulation factors

Factor	Name
I	Fibrinogen
II	Prothrombin
III	Thromboplastin
IV	Calcium
V	Proaccelerin
VI	–
VII	Proconvertin
VIII	Antihæmophilic factor
IX	Christmas factor (plasma thromboplastin component)
X	Stuart–Prower factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin-stabilizing factor
Fitzgerald factor	High-molecular-weight kininogen
Fletcher factor	Prekallikrein

restricted by blood coagulation. However, if the defect is severe, more pronounced bleeding can result (e.g. intracavity hæmorrhage).

Primary hæmostasis inhibitors are the natural inhibitors of platelet function, such as bradykinin, prostacyclin and nitric oxide, released by endothelial cells. Acquired inhibitors of platelet function are rare, whereas acquired inhibitors of vWF (platelet GP Ib) form in a variety of diseases and result in acquired von Willebrand disease (avWD).

More commonly, platelet function is inhibited intentionally by the administration of agents such as aspirin or clopidogrel for the prevention of thrombosis.

SECONDARY HAEMOSTASIS (BLOOD COAGULATION OR CLOTTING)

Secondary hæmostasis is the formation of fibrin through the coagulation cascade (Table 8.1, Fig. 8.3), which is traditionally separated into three pathways (extrinsic, intrinsic and common) involving blood coagulation factors acting as enzymes, which require activation and cofactors.

The *extrinsic* pathway is the main pathway. It is initiated by the generation/exposure of tissue factor (factor III), with expression being upregulated by cytokines (tumour necrosis factor alpha [TNF α], interleukin [IL]-6), and the tissue factor–factor VII complex, the latter activating factor X.

The *intrinsic* pathway amplifies coagulation, is stimulated by thrombin, through activation of factor XI, and involves high-molecular-weight kininogen, prekallikrein, factors XII, XI and IX, and factor VIII, which acts as a cofactor (with calcium and platelet phospholipid) for the factor IX-mediated activation of factor X. A minor route of stimulation of the intrinsic pathway (the alternative pathway) is the direct activation of factor IX by the tissue factor–factor VII complex.

The *common* pathway involves the factor X-mediated generation of thrombin from prothrombin (facilitated by factor V, calcium and platelet phospholipid [‘prothrombinase complex’]). Thrombin then activates factors XI and VIII, amplifying the coagulation cascade. Activated factor IX, together with activated factor VIII, calcium and phospholipid (‘tenase complex’), amplify the activation of factor X, generating large amounts of thrombin.

Thrombin cleaves fibrinogen to form soluble fibrin monomers, which spontaneously polymerize to soluble fibrin polymer; thrombin also activates factor XIII, which, together with calcium, cross-links

Fig. 8.3 Blood coagulation and assays. APTT = activated partial thromboplastin time; PT = prothrombin time; TT = thrombin time.

and stabilizes the soluble fibrin polymer, resulting in cross-linked (insoluble) fibrin. Thrombin also promotes coagulation by promoting platelet aggregation, and activating factors V and VIII – necessary cofactors for the ‘prothrombinase’ and ‘tenase’ complexes, respectively. Thrombin also activates factor XIII, essential for the cross-linking of the fibrin polymer, and inhibits fibrinolysis by generation of a thrombin-activatable fibrinolytic inhibitor (TAFI).

Drugs that act as anticoagulants include warfarin, new oral anticoagulants (NOACs), heparin and hirudin.

Abnormalities in the coagulation cascade

These cause more serious bleeding than do defects of primary hæmostasis, resulting in bleeding into cavities (chest, joints and cranium) and subcutaneously (hæmatomas). Petechial hæmorrhages are rare. The main *coagulation inhibitor* is antithrombin (AT; also called antithrombin III, or ATIII), a liver α_2 -globulin that inhibits thrombin (factor IIa) and many activated coagulation proteins (including factors II, IX, X, XI and XII). Heparin, produced *in vivo* by degranulated mast cells or basophils, enhances antithrombin binding to thrombin, and this is the basis for its use as an anticoagulant.

Protein C, a vitamin K-dependent protein produced in the liver, inactivates factors V and VIII. Protein S (named after Seattle), another vitamin K-dependent protein synthesized in endothelial cells, megakaryocytes and hepatocytes, facilitates the action of protein C.

TERTIARY HAEMOSTASIS (FIBRINOLYSIS)

Tertiary hæmostasis is the formation of plasmin from plasminogen via tissue-type plasminogen activators (t-PAs); other plasminogen activators include urokinase, factor XII and kallikrein. Plasmin lyses both fibrinogen and fibrin, releasing fibrin(ogen) degradation products (FDPs). Activation of fibrinolysis is triggered by fibrin and t-PA, a process regulated by hæmostasis inhibitors.

Haemostasis inhibitors (inhibitors of fibrinolysis) include TAFI, α_2 -antiplasmin, histidine-rich glycoprotein and plasminogen activator inhibitors. Amplification of the coagulation cascade from thrombin-mediated activation of factor XI leads to large amounts of thrombin and subsequent activation of TAFI, which prevents the binding of plasminogen to fibrin, thus inhibiting its conversion to plasmin. α_2 -antiplasmin binds free plasmin and causes its removal by the monocyte–macrophage system, preventing widespread fibrinolysis. Plasminogen activator inhibitors (PAI-1 and PAI-2) are released by endothelial cells and limit plasmin generation by binding to t-PA.

Drugs that inhibit fibrinolysis (antifibrinolytics) include epsilon aminocaproic acid and tranexamic acid.

HAEMOSTASIS SCREENING TESTS

Screening tests are done to show if there is a bleeding disorder, but further tests needed to define the disorder (Appendix 8.1) must follow consultation with the haematologist to ensure that they are appropriate. All that is needed on the request form is to state: ‘History of prolonged bleeding’ and to ask ‘Would you please investigate haemostatic function?’, giving as much clinical detail as possible. The blood sample should be adequately labelled and sent immediately for testing, together with relevant clinical information. Tests may need to be repeated before an accurate diagnosis can be made because levels of factors vary over time as a result of stress, pregnancy and infections.

Essential tests usually include:

- *full blood count, film*. A routine ‘blood count’ [full blood picture] cannot identify a clotting defect but might show platelet deficiency
- *activated partial thromboplastin time (APTT)*. The APTT measures the intrinsic pathway and factors V, VIII, IX, X and XI (Table 8.2). Normal APTT values range between 25 ± 10 seconds. The APTT was sometimes known as PTT or kaolin cephalin PTT. It is prolonged in heparin treatment, liver disease, haemophilias, disseminated intravascular coagulation (DIC), massive transfusion and some autoimmune disorders
- *prothrombin time (PT) and international normalized ratio (INR)*. The activity of the extrinsic coagulation pathway (factors II, V, VII and X) is measured by the PT, normal values ranging between 12 and 15 seconds. The PT will vary with the type of thromboplastin (e.g. rabbit, human, bovine, etc.) used in the assay, so therefore the INR is used. The INR is the PT ratio of a test sample compared to a normal PT corrected for the sensitivity of the thromboplastin used. Normal INR values are about 1.0. An INR above 1 indicates that clotting will take longer than normal. An INR of 2–3 is the usual therapeutic range for patients on anticoagulants used to treat deep vein thrombosis, and an INR of up to 3.5 is required for patients with prosthetic heart valves. The INR (and PT) is prolonged in warfarin treatment, liver disease, vitamin K deficiency, and DIC (Table 8.3). The INR may be quite stable or erratic in an individual but, in any event, is best assayed less than 24 hours preoperatively, though less than 72 hours may suffice. A normal PT does not necessarily exclude a significant underlying coagulopathy; for example, the PT is normal in severe haemophilias A and B and in factor XI deficiency
- *thrombin time (TT)* (citrated sample)
- *platelet count*. In the tourniquet test (Hess test), the appearance of more than a few petechiae on the forearm when a

Table 8.2 Interpretation of activated partial thromboplastin time (APTT) results

APTT	Interpretation
Isolated prolonged	Acquired clotting factor inhibitors – usually directed against factor VIII (e.g. acquired haemophilia A) Congenital deficiencies of factor XII, XI, IX or VIII (in general, the factor has to be lower than 20–40% of normal before APTT is prolonged) Lupus anticoagulant (LA) – targets phospholipid
Prolonged + prolonged PT	Combined clotting factors deficiency Disseminated intravascular coagulation (DIC) Liver disease Massive blood transfusion – dilutional coagulopathy Thrombin inhibitors (hirudin, argatroban and dabigatran) Thrombolytic therapy Vitamin K deficiency
Increased $\pm$ prolonged PT	Unfractionated heparin [UFH] significantly prolongs APTT but PT usually shows little prolongation Antiphospholipid antibodies Acquired clotting factor inhibitors, e.g. factors V, X
Prolonged $\pm$ prolonged PT	Warfarin overdose
Short	An acute phase response with high factor VIII

Table 8.3 Interpretation of international normalized ratio (INR) and prothrombin time (PT) results

PT or INR	Interpretation
Prolonged alone	Factor VII deficiency
Prolonged, along with other coagulation abnormalities	Afibrinogenaemia and dysfibrinogenaemia Dilutional coagulopathy, e.g. massive blood transfusion Direct thrombin inhibitors, e.g. lepirudin Liver disease Malabsorption (leads to vitamin K deficiency) Multiple clotting factor deficiencies Unfractionated heparin Vitamin K deficiency Vitamin K antagonists (e.g. warfarin, phenindione)
Shortened	Treatment with recombinant factor VIIa

sphygmomanometer cuff is inflated suggests a platelet or vascular defect, but the clinical test is neither sensitive nor specific. The ‘bleeding time’ is also rarely used, as it is not completely reliable. Thus to exclude platelet defects, a platelet count is essential and platelet function assays may be indicated. A normal platelet count should be 100 000–400 000 cells/mm³ (Fig. 8.4); a count of less than 100 000 cells/mm³ (thrombocytopenia) can be associated with major postoperative bleeding

- *serum for blood grouping and cross-matching*. This should be done if an operation is planned.

Fig. 8.4 Protocol for investigation of a bleeding disorder. DIC = disseminated intravascular coagulation.

Once the haemostasis screening tests have indicated that there is a bleeding disorder, other, more specific tests are required, such as:

- *factor VIII clotting activity* – to measure factor VIII amount
- *vWF antigen* – to measure vWF amount
- *ristocetin cofactor activity* – to measure vWF function
- *vWF multimers* – to measure vWF structure
- *platelet aggregation tests* – before assessing platelet function using *in vitro* tests of platelet adhesion and aggregation, aspirin, non-steroidal inflammatory drugs (NSAIDs) and antiplatelet drugs should be avoided for at least 7 days. The average lifespan of a platelet ranges from 7 to 12 days. Platelet aggregation can be measured using aggregating agents such as ristocetin but, unfortunately, such tests are difficult to standardize and do not identify all platelet disorders; the clinical features are often more important.

A practical guide to laboratory haemostasis is provided at: <http://www.practical-haemostasis.com/Screening%20Tests/tt.html> (accessed 30 September 2013).

BLEEDING (HAEMOSTATIC) DISORDERS

General aspects

Bleeding disorders manifest with common bleeding features, including epistaxis and gingival bleeding, and may occur after wounds and surgery; these are often the first indications of a haemostatic defect. Defects in haemostasis can comprise abnormalities in platelet activation and function, contact activation or with clotting proteins, or may signal excess antithrombin function. The more common causes of a bleeding tendency include:

- aspirin (one tablet impairs platelet function for almost 1 week but this rarely causes significant postoperative haemorrhage), NSAIDs and other antiplatelet drugs

- warfarin (the most common anticoagulant, which interferes with clotting factor production via vitamin K blockage)
- von Willebrand disease (the most common inherited bleeding disorder).
- acquired bleeding tendencies, such as:
 - ◆ bone marrow disease
 - ◆ immune disorders
 - ◆ liver disease
 - ◆ renal disease.

Clinical features

Examination may reveal signs of purpura in the skin or mucosae (Fig. 8.5). Signs of underlying disease – such as anaemia and lymphadenopathy in leukaemia, for example – must also be sought. Joint deformities from haemarthroses, characteristic of haemophilia, should also be looked for but are infrequently seen now (Fig. 8.6).

Alternatively, purpura may be localized to the mouth (sometimes grandiloquently termed ‘angina bullosa haemorrhagica’) and not associated with any abnormal bleeding tendencies. People with *senile purpura* (an age-related condition) bruise easily with minimal trauma, often without any other apparent underlying cause, and generally on the forearms and tops of the hands. The resulting dark purplish-red splotches fade gradually, often leaving a yellow/brown stain, which may disappear completely or remain. Such purpura can be caused by excessive sun exposure; drugs, such as aspirin and steroids (*steroid purpura*); diabetes; vascular diseases; thrombocytopenia; scurvy; and connective tissue diseases. There is no treatment available.

General management

Patients may already be aware of having a bleeding disorder and may carry an appropriate warning card, bracelet or wristband. Otherwise,

Fig. 8.5 Purpura in a patient with myeloid leukaemia.

Fig. 8.6 Haemarthrosis in an older haemophiliac has caused crippling arthritis. His five brothers all succumbed to haemophilia at a time when factor VIII was unknown.

Table 8.4 Comparative features of bleeding disorders

	Platelet defects ^a	Coagulation defects
Gender affected	Females mainly	Males
Family history	Rarely	Usually positive
Nature of bleeding after trauma	Immediate	Delayed
Effect when locally applied pressure removed	May stop bleeding	Bleeding recurs
Spontaneous bleeding into skin or mucosa, or from mucosa or gingivae	Common	Uncommon
Bleeding from minor superficial injuries (e.g. needle prick)	Common	Uncommon
Deep haemorrhages or haemarthroses	Rare	Common
Bleeding time	Prolonged	Normal
Tourniquet (Hess) test	Positive	Negative
Platelet count	Often low	Normal
Clotting function	Normal	Abnormal

^aPurpura is rarely vascular.

Table 8.5 Typical laboratory findings in platelet disorders

Thrombocythaemia	↑	↑	N or ↓	N or ↓	N or ↓

N = normal.

an adequate history is the single most important part of evaluation; physical examination is necessary and laboratory tests are needed to confirm the diagnosis. Table 8.4 shows comparative features of coagulation defects and platelet defects, and Table 8.5 lists typical laboratory findings in platelet disorders.

A history with any suggestion of a haemorrhagic tendency must be taken seriously. Nevertheless, patients can be remarkably capricious as to the information they provide and, in any case, cannot always be expected to know when bleeding can legitimately be regarded as ‘abnormal’. Previous dental extractions provide a useful guide, but

Fig. 8.7 Oral purpura.

prolonged bleeding (up to 24–48 hours) as an isolated episode is usually the result of local factors, especially excessive trauma. It should be stressed again that a history of previous haemorrhagic episodes is the most important feature since screening tests of haemostasis do not always detect mild defects.

Special emphasis must be placed on the following, which are suggestive of a bleeding disorder:

- Deep haemorrhage into muscles, joints or skin – suggests a clotting defect
- Bleeding from and into mucosae – suggests purpura (Fig. 8.7).

Females often ‘bruise easily’ but any such bruises are usually insignificant and small. Excessive menstrual bleeding is also rarely due to a bleeding disorder.

Most significant congenital bleeding disorders become apparent in childhood and patients may carry a warning card. However, people with mild bleeding tendencies can escape recognition until adult life if they manage to avoid injury or surgery, but can then present with oozing from an extraction socket for 2–3 weeks despite local haemostatic measures such as suturing. Patients who have had tonsillectomy or dental extractions without trouble, or previous dental bleeding that was controlled by local measures, are unlikely to have a serious congenital haemorrhagic disease. On the other hand, admission to hospital and blood transfusion or comparable measures have obvious implications. Haemorrhagic disease in a blood relative is also strongly suggestive of a clotting defect. Many drugs, such as anticoagulants (Fig. 8.8), NSAIDs and antiplatelet drugs, may cause bleeding tendencies, as may hepatic, renal, human immunodeficiency (HIV) and other disease. Some herbal products may also impair platelet aggregation and prolong bleeding (Ch. 26).

Precise characterization of a congenital clotting defect depends on assay of the individual factors, and a wide range of other investigations may be indicated according to the type of case. For example, the assays usually used in the diagnosis of haemophilia A are the APTT and the factor VIII coagulant (FVIIIIC) activity. The bleeding time and whole-blood clotting time are uninformative and obsolete.

It is important also to investigate patients with a suspected bleeding tendency for anaemia. This is because:

- anaemia is an expected consequence of repeated haemorrhages
- any further bleeding as a result of surgery will worsen the anaemia, or the anaemia may need to be treated before surgery can be carried out
- anaemia may be an essential concomitant of the haemorrhagic tendency – as in leukaemia.

Anticoagulant Alert Card

This patient is taking anticoagulant therapy
This card should be carried at all times and shown to healthcare professionals

Name of patient:

Address:

Postcode: Telephone:

Name of next of kin:

Hospital number: NHS Number:

Fig. 8.8 Oral anticoagulant therapy warning card.

Patients may also need to be screened for liver disease and for blood-borne infections, particularly HIV and hepatitis viruses.

Individuals with bleeding disorders may need to be treated with replacement of the missing factor. Earlier, use of blood or blood fractions sometimes resulted in the transmission of blood-borne viruses and other infections. In many countries, blood is now collected from donors under careful precautions, and screened to exclude antibodies to infections such as HIV, hepatitis B, hepatitis C, syphilis or cytomegalovirus. In developed countries, all cellular blood products are leukodepleted to limit the risk of transmission of prions and some other infections. Leukocytes in erythrocyte and platelet concentrates are now considered as a contaminant since they can cause many other adverse effects, such as the transmission of other cell-associated infectious agents (e.g. herpesviruses and *Toxoplasma*), febrile non-haemolytic reactions, graft-versus-host disease and immunosuppression. Recombinant factors are thus preferred for factor replacement.

Dental aspects

Prolonged post-operative bleeding is defined if any of the following appertains:

- Bleeding continues for 12 hours.
- Bleeding causes the patient to return for attention.
- Bleeding causes a large haematoma/ecchymosis.
- The patient needs a transfusion.

All dental professionals encounter patients who experience prolonged bleeding following operative procedures, often a dental extraction. Saliva contains fibrinolytic agents that may aggravate the situation. In most cases, the cause is local, and bleeding can be managed using simple local haemostatic measures such as applying pressure to the wound with sterile pads (moistened with water, normal saline or 5% tranexamic acid solution), using absorbable oxidized cellulose sponges, and suturing, as well as giving postoperative instructions verbally and in writing.

A bleeding tendency can be encountered in patients with congenital haemostatic defects such as haemophilias or some rare platelet defects; or acquired disorders such as may arise in liver disease, renal disease, bone marrow disease, immune disorders or with some drugs. In vascular or platelet disorders, postoperative problems following an extraction usually present as prolonged bleeding *immediately* after the event; in coagulation defects, the bleeding typically begins *after some delay*. Patients with a bleeding tendency may require prophylactic measures preoperatively, special precautions perioperatively and careful management postoperatively. Patients with hereditary bleeding disorders

are often registered with a haemophilia reference centre. Care is as follows:

- Those with a mild to moderate bleeding disorder might be appropriately shared between specialist hospital care and community and/or primary care dental services for different procedures.
- Those with a severe bleeding disorder managed from home with appropriate medication may possibly be treated in primary care under the direction of the haemophilia reference centre.
- Those with a severe bleeding condition with associated complications such as HIV, hepatitis C or inhibitors, or those requiring surgery, are often more appropriately cared for in a hospital care setting.

Some known haemophiliacs have neglected oral health because of barriers to accessing care, including travel to specialist centres, waiting times, increased treatment needs and cost, or fear of bleeding from dental procedures. They may require more complex treatment and management by the time that they present.

Surgery should ideally be planned and done where appropriate after suitable measures to correct the bleeding tendency, such as blood clotting factor or platelet replacement or, where drugs are responsible, by modifying drug doses provided that the risk of subsequent thromboembolism is not a contra-indication:

- at the beginning of the day – this allows more time to deal with immediate rebleeding problems
- early in the week – this allows for delayed rebleeding episodes occurring after 24–48 hours to be dealt with during the working week.

VASCULAR DISORDERS

Vascular purpura rarely causes serious bleeding; any bleeding into mucous membranes or skin starts immediately after trauma but stops within 24–48 hours. Vascular disorders are a rare cause of bleeding problems; they include Marfan, Ehlers–Danlos (Ch. 16) and Osler–Rendu–Weber syndromes.

OSLER–WEBER–RENDU SYNDROME (HEREDITARY HAEMORRHAGIC TELANGIECTASIA [HHT/HHT1])

General aspects

Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant condition with a high penetrance, as 97% of people affected exhibit symptoms. There is vascular dysplasia leading to telangiectasia and arteriovenous malformations in the skin, mucosa and viscera. There may be associated immunoglobulin A (IgA) deficiency or, rarely, vWD (see below).

Clinical features

Interestingly, HHT usually presents in adolescence. Telangiectasia on the skin or any part of the oral, nasal, conjunctival, respiratory, gastrointestinal or urogenital mucosa, or brain and liver (Fig. 8.9), leads to bleeding. Most people (62%) are diagnosed by the age of 16, with over 90% of cases presenting with recurrent epistaxis, not present until adult life. Other associated features include:

- haemorrhage of the gastrointestinal tract, which can result in iron deficiency anaemia

Fig. 8.9 Hereditary haemorrhagic telangiectasia.

- respiratory arteriovenous malformations, which can present as dyspnoea, cyanosis or finger-clubbing. Paradoxical cerebral emboli can cause stroke or cerebral abscess. Care must be taken when prescribing midazolam sedation or general anaesthesia for these patients
- liver arteriovenous malformations that can cause cirrhosis, which can further exacerbate the bleeding tendency, and high-output cardiac failure.

General management

Investigations include capillary microscopy, computed tomography (CT), magnetic resonance imaging (MRI) and angiography. Treatment is by cryosurgery or argon laser treatment, if the telangiectases have bled significantly or are cosmetically unacceptable.

Dental aspects

Telangiectases may be seen in any part of the mouth and may be conspicuous on the lips and tongue. Bleeding from oral surgery is unlikely to be troublesome. Rarely, brain abscesses or other infections have followed oral procedures that cause bacteraemias but there is no consensus as to the need for antibacterial prophylaxis.

Regional local anaesthesia (LA) should be avoided because of the risk of deep bleeding. Conscious sedation (CS) can be given if required. In general anaesthesia (GA), nasal intubation is best avoided and close postoperative observation is advisable.

LOCALIZED ORAL PURPURA ('ANGINA BULLOSA HAEMORRHAGICA')

Blood blisters are occasionally seen, typically in older persons, in the absence of obvious trauma, generalized purpura, any other bleeding tendency or evidence of any systemic disease. These blood blisters are often in the palate and may sometimes be a centimetre or more in diameter; after rupture, they may leave a sore area for a few days. When a large blood blister of this type is in the pharynx, it can cause an alarming choking sensation and was therefore originally termed 'angina bullosa haemorrhagica'. However, almost any site in the mouth can be affected.

Before the diagnosis of localized oral purpura can be made confidently and the patient reassured, other causes of blood blisters in the mouth must be excluded. These include: platelet disorders, amyloidosis (causing factor X deficiency), leukaemia, infectious mononucleosis, HIV or rubella; trauma; corticosteroid inhalers; or bleeding into sub-epithelial blisters, such as in mucous membrane pemphigoid (Ch. 11).

Table 8.6 Platelet defects

	Defect	Manifestations	Management
Thrombasthenia (Glanzmann syndrome)	Defective platelet aggregation due to defective membrane protein	Severe bleeding tendency	Platelet infusions needed preoperatively
Bernard–Soulier syndrome	Giant platelets with defect in platelet glycoprotein which acts as receptor for von Willebrand factor	Heritable disorder resembling von Willebrand disease but considerably more rare	Platelet infusions needed preoperatively
Storage pool deficiency	Platelets lack capacity to store serotonin and adenine nucleotides, and consequently fail to aggregate	Usually congenital with autosomal inheritance. If associated with albinism, is termed Hermansky–Pudlak syndrome	Platelet infusion or cryoprecipitate corrects the bleeding tendency
HIV infection	Purpura is a relatively common feature of HIV infection. May be autoimmune but there appears also to be a platelet defect resulting from the infection; drugs such as zidovudine or some protease inhibitors and bone marrow disease may also contribute	Oral purpura in HIV infection may closely mimic oral lesions of Kaposi sarcoma (Ch. 20)	See Ch. 20
Chronic renal failure	Ch. 12		
Drugs: heparin, dextrans	See later in this chapter		
Dysproteinaemias	See later in this chapter		
Myelodysplastic syndrome	See later in this chapter		

PLATELET DISORDERS

Platelets originate from bone marrow megakaryocytes and have a life span of about 1 week, before they are destroyed in the spleen. Thrombopoietin, the megakaryocyte-stimulating hormone is produced in the liver and kidneys, so liver, kidney or bone marrow disease can each cause thrombocytopenia. Platelet numbers or function, if impaired, can cause a bleeding tendency, purpura and abnormal laboratory investigation results (Tables 8.5 and 8.6). Drugs, bone marrow invasion, autoimmune diseases and other disorders can reduce platelet numbers (if the platelet count falls below $100 \times 10^9/L$, a patient has thrombocytopenia). Thrombocytopenia may arise from (Fig. 8.10):

- *decreased megakaryocyte production/maturation.* Most thrombocytopenia is idiopathic (autoimmune thrombocytopenia), but can be caused by viruses such as human parvovirus B19, rubella, Epstein–Barr, cytomegalovirus and HIV, as well as drugs such as cytotoxics. Infiltration of the bone marrow by leukaemia, myeloma or carcinoma leads to bone marrow suppression and thrombocytopenia plus anaemia. Vitamin B₁₂ and folate deficiency leads to inadequate megakaryocyte maturation
- *increased platelet destruction.* This is seen in *idiopathic thrombocytopenic purpura (ITP)*, *haemolytic uraemic syndrome (HUS)* and *thrombotic thrombocytopenic purpura (TTP)* – see below. *DIC* (see later) leads to consumption of platelets and to thrombocytopenia
- *sequestration of platelets.* An enlarged spleen (splenomegaly) is usually responsible for platelet sequestration which may be, therefore, caused by:
 - portal hypertension, e.g. cirrhosis
 - haematological disorders, e.g. myeloproliferative disorders
 - infections, e.g. malaria, leishmaniasis, Epstein–Barr virus
 - storage disorders, e.g. Gaucher disease, Niemann–Pick disease
 - inflammatory disorders, e.g. systemic lupus erythematosus (SLE), Felty syndrome.

Inherited platelet abnormalities tend to affect platelet function rather than number. *Abnormal platelet function* is seen in Glanzmann disease and dysproteinaemias. Platelet function can also be impaired

↓ Platelet production

Bone marrow disease (aplastic anaemia, myelodysplastic syndromes, radiotherapy, chemotherapy drugs, metastatic disease) or transiently after bone marrow transplantation.

Liver disease

Viral infections (HIV, CMV, rubella, parvovirus B19, EBV)

Drugs

↑ Platelet destruction

Immunological (idiopathic thrombocytopenic purpura: ITP)

Pooling in splenomegaly or haemangiomas

Coagulation/thrombosis in disseminated intravascular coagulopathy (DIC), haemolytic–uraemic syndrome (HUS) or vasculitis

Fig. 8.10 Thrombocytopenia. CMV = cytomegalovirus; EBV = Epstein–Barr virus.

due to an increase in numbers (thrombocytosis). *Abnormal platelet distribution* is seen in splenomegaly or transfusion of stored blood.

IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP)

This involves autoantibody-mediated platelet destruction, the most common antibody being directed against the platelet GPIIb–IIIa receptor. Features include petechiae, ecchymoses and postoperative

haemorrhage. Full blood picture and platelet counts are indicated. Corticosteroids or other immunosuppressives are the main treatments. Splenectomy or splenic irradiation, followed by thrombopoietin therapy is sometimes needed. Eltrombopag and romiplostin are thrombopoietin receptor agonists which stimulate platelet production and used to treat ITP. Dental extractions can be covered by these agents.

HAEMOLYTIC URAEMIC SYNDROME (HUS) AND THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

These conditions are caused by small-vessel wall damage, leading to fibrin and platelet deposition and haemolysis. HUS predominantly affects the kidneys and TTP the brain. *Escherichia coli* O157 gastroenteritis may cause HUS in children, but in adults more commonly causes TTP.

GLANZMANN DISEASE (GLANZMANN THROMBASTHENIA)

Glanzmann disease is a rare autosomal recessive disorder caused by either deficient or abnormal glycoprotein platelet receptors. Defects in the GP IIb/IIIa complex lead to defective platelet aggregation and subsequent bleeding, usually presenting in infancy or early childhood, with bruising or petechiae following minimal or unrecognized trauma, or epistaxis. The platelet count is normal but platelet aggregation defective.

Management includes avoiding trauma and avoiding analgesics such as aspirin. Minor bleeding intraorally can be managed with tranexamic acid. Major bleeding may require platelet transfusion. Recombinant human-activated factor VII (rFVII) has been used in patients with antibodies to GP IIb/IIIa and/or human leukocyte antigen (HLA) that render transfusions ineffective.

BERNARD-SOULIER SYNDROME

Bernard-Soulier syndrome is a rare congenital disorder with large platelets that lack platelet membrane glycoproteins – resulting in defective platelet adhesion. Clinical features resemble those of Glanzmann disease. A full blood count reveals giant platelets. Platelets fail to aggregate in response to vWF.

Management is as for Glanzmann disease.

RENAL FAILURE

High serum urea levels directly inhibit platelet function and there may also be thrombocytopenia. Desmopressin (deamino-8-D-arginine vasopressin; DDAVP) may be used to boost vWF levels in order to treat mild bleeding episodes. In severe bleeding, cryoprecipitate or platelet transfusion may be required.

ANTIPLATELET DRUGS

Platelets may pathologically aggregate intravascularly as arterial thrombi in response to haemorrhage into atherosclerotic plaques, and this is potentially lethal. Antiplatelet drugs prevent and/or reverse platelet aggregation in arterial thromboses, and help prevent clotting in patients who have had a myocardial infarct, unstable angina, ischaemic strokes, transient ischaemic attacks (TIAs or 'little strokes') and other forms of cardiovascular disease. In practice, a favourable balance between the beneficial and harmful effects of antiplatelet therapy is achieved by treating patients whose thrombotic risk outweighs their risk of bleeding complications.

Commonly used antiplatelet agents include:

- aspirin
- GP IIb/IIIa inhibitors (abciximab, eptifibatide and tirofiban)
- phosphodiesterase inhibitors (e.g. dipyridamole)
- thienopyridines (e.g. clopidogrel, prasugrel and ticlopidine).

Aspirin

Aspirin is an irreversible inhibitor of platelet cyclo-oxygenase (COX) enzymes, which catalyse the production of thromboxane A₂ (an important platelet aggregator) from arachidonic acid. Low-dose aspirin is the usual first-line treatment for thrombosis and myocardial infarction. The most common adverse effect of aspirin is gastrointestinal bleeding, which can be minimized by using the lowest effective dose (often 75 mg daily), advising patients to take aspirin with food, and, where indicated, co-prescribing a proton pump inhibitor (PPI).

GP IIb/IIIa inhibitors

These drugs prevent cross-linking of platelets. *Abciximab* is a chimeric human-murine GP IIb/IIIa antibody; the peptide derivatives, *eptifibatide* and *tirofiban*, are more selective towards the GP IIb/IIIa receptor and have a shorter effect than abciximab. These agents are used parenterally in acute coronary syndromes, but only by specialists. Serious adverse effects of GP IIb/IIIa antagonists include major bleeding, intracerebral haemorrhage and thrombocytopenia.

Phosphodiesterase inhibitors

Phosphodiesterase inhibitors include *dipyridamole* – a vasodilator and antiplatelet agent that inhibits adenosine uptake and cyclic guanosine monophosphate (cGMP) phosphodiesterase activity, thus decreasing platelet aggregability. Dipyridamole is used with aspirin or warfarin in the prophylaxis of thromboembolic disorders.

Thienopyridines

Thienopyridines act via inhibition of platelet activation by the ADP-dependent pathway without a direct effect on prostaglandin metabolism. *Ticlopidine* is the oldest thienopyridine available and is approved for secondary prevention of thrombotic strokes in aspirin-intolerant patients, and in combination with aspirin for prevention of coronary stent thrombosis. Serious adverse effects are mainly haematological (neutropenia, thrombocytopenia and TTP). *Clopidogrel* has a better safety profile than ticlopidine and is often reserved for those with true aspirin hypersensitivity or intolerance, and for prevention of atherosclerotic events following recent myocardial infarction, stroke or established peripheral arterial disease. It is also approved for use in acute coronary syndromes that are treated with either percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG). Dual therapy with aspirin and clopidogrel increases the risk of gastrointestinal bleeding and is thus usually restricted to patients following PCI or acute coronary syndromes. *Prasugrel* is a more rapid-acting and potent platelet aggregation inhibitor and may be used together with aspirin in the setting of high-risk or urgent PCI.

Dental aspects of platelet disorders

The main danger of platelet disorders is haemorrhage but this is rarely as severe as in clotting disorders. Regional LA block injections can

Table 8.7 Thrombocytopenia: manifestations and management of oral surgery

Platelet count ($\times 10^9/L$)	Severity of thrombocytopenia	Manifestations	Management in relation to type of surgery	
			Dentoalveolar	Maxillofacial
100–150	Mild	Mild purpura sometimes. Slightly prolonged postoperative bleeding	No platelet transfusion. Local haemostatic measures. ^a Observe	Consider platelet transfusion. Local haemostatic measures. ^a Observe
50–100	Moderate	Purpura, postoperative bleeding	Platelets may be needed. Local haemostatic measures. ^a Consider postoperative tranexamic acid mouthwash for 3 days	Platelets needed. Local haemostatic measures. ^a Postoperative tranexamic acid mouthwash for 3 days
30–50	Severe	Purpura, postoperative bleeding, even from venepuncture	Platelets needed. Local haemostatic measures. ^a Postoperative tranexamic acid mouthwash for 3 days	Platelets needed. Local haemostatic measures. ^a Avoid surgery where possible. Postoperative tranexamic acid mouthwash for 3 days
<30	Life-threatening	Purpura, spontaneous bleeding	Platelets needed. Local haemostatic measures. ^a Avoid surgery where possible. Postoperative tranexamic acid mouthwash for 3 days	Platelets needed. Local haemostatic measures. ^a Avoid surgery where possible. Postoperative tranexamic acid mouthwash for 3 days

^aLocal haemostatic measures comprise compressive packing, sutures, and microfibrillar collagen or oxidized cellulose.

be given if the platelet levels are above $30 \times 10^9/L$. Haemostasis after dentoalveolar surgery is usually adequate if platelet levels are above $50 \times 10^9/L$. Major surgery requires platelet levels above $75 \times 10^9/L$. CS can be given but if it is delivered by the intravenous route, care must be taken not to damage the vein. GA can be given in hospital but expert intubation is needed to avoid the risk of submucous bleeding into the airway.

Platelets can be replaced or supplemented by platelet transfusions (1 unit of platelets should raise the count by around 10×10^9 platelets/L), but sequestration of platelets is very rapid. Platelet transfusions are therefore best used for controlling already established thrombocytopenic bleeding. When given prophylactically, platelets should be given in the following way: half just before surgery to control capillary bleeding, and half at the end of the operation to facilitate placement of adequate sutures. Platelets should be used within 6–24 hours of collection. Suitable preparations include platelet-rich plasma (PRP), which contains about 90% of the platelets from a unit of fresh blood in about half this volume, and platelet-rich concentrate (PRC), which contains about 50% of the platelets from a unit of fresh whole blood in a volume of only 25 mL. PRC is thus the best source of platelets. Platelet infusions carry the risk of isoimmunization, infection with blood-borne agents and, rarely, graft-versus-host disease. Where there is immune destruction of platelets (e.g. in ITP), platelet infusions are less effective. The need for platelet transfusions can be reduced by local haemostatic measures and use of desmopressin (DDAVP) or tranexamic acid or topical administration of platelet concentrates. Absorbable haemostatic agents, such as oxidized regenerated cellulose (Surgicel), synthetic collagen (Instat) or microcrystalline collagen (Avitene), may be put in the socket to assist clotting.

Splenectomy predisposes to infections, typically with pneumococci, and especially within the first 2 years. Systemic infection post-splenectomy, involving oral streptococci, is rare and antimicrobial prophylaxis is not therefore generally recommended before invasive dental procedures.

Long-term corticosteroids can cause well-recognized problems (Ch. 6). Perioperative management is summarized in Tables 8.6 and 8.7 and Figure 8.11. Drugs such as aspirin and other NSAIDs that damage platelets should be avoided (Table 8.8). The effects of aspirin are *not* dose-dependent; even a single tablet can affect platelet COX

**Fig. 8.11** Dental management in platelet disorders.

irreversibly for about a week. Other NSAIDs may have a reversible effect and act for up to 48 hours only. COX-2 inhibitors have no such effect on platelets.

When prescribed as primary prevention, *antiplatelet agents* may be safely withdrawn 7 days before surgery, but any decision to stop antiplatelet therapy used for secondary prevention must balance the risk of thrombosis and ischaemia against bleeding. There is no evidence that continuing antiplatelet monotherapy causes major bleeding problems during or after minor surgery such as dental extractions. The risk of bleeding is greater with aspirin–clopidogrel or prasugrel–aspirin combinations, but patients taking these drugs are generally already at a higher risk of thromboembolic events; therefore, advice from a specialist should be sought before withholding treatment, or the patient may need to be referred to a hospital setting for the procedure. There is no suitable test available to assess the increased risk of bleeding in patients taking antiplatelet medications.

Table 8.8 Some drugs that may impair platelets or their function

Class	Examples
Alcohol	
Analgesics and other platelet inhibitors	Aspirin and other NSAIDs Clopidogrel
Antibiotics	Amoxicillin Ampicillin and derivatives Azithromycin Benzylpenicillin (penicillin G) Carbenicillin Cephalosporins Gentamicin Meticillin Rifampicin Sulphonamides Trimethoprim
Antidiabetics	Tolbutamide
Cardiovascular drugs	Digitoxin Heparin Methyldopa Oxprenolol Quinine
Cytotoxic drugs	Many
Diuretics	Acetazolamide Chlorothiazide Furosemide
General anaesthetic agents	Halothane
Psychoactive drugs	Antihistamines (some) Chlorpromazine Diazepam Haloperidol Tricyclic antidepressants Valproate

Patients who should *not* have their medications stopped or altered prior to dental surgical procedures in primary care include those taking:

- low-dose aspirin
- clopidogrel
- dipyridamole.

Patients are more at risk of permanent disability or death from thromboembolic episodes if they stop antiplatelet medications prior to a surgical procedure than if they continue them. Although the risk is low, the outcome is serious, so antiplatelet medications should only be discontinued in the perioperative period when the haemorrhagic risk of continuing them is definitely greater than the cardiovascular risk associated with their discontinuation. Bleeding complications, while inconvenient, do not carry the same risks as thromboembolic complications. Patients taking antiplatelet medications will have a prolonged bleeding time but this may not be clinically relevant and postoperative bleeding after dental procedures can usually be controlled using local haemostatic measures.

Consensus, then, is that for dentoalveolar surgical procedures, antiplatelet medications should not be stopped nor doses altered, but that local haemostatic measures should be used to control bleeding. The following patients taking antiplatelet medication, however, should

Table 8.9 Drug effects on bleeding tendency

Drug	Effect on bleeding
Alcohol	Warfarin enhanced by large amounts of alcohol
Analgesics	Bleeding enhanced by aspirin effect on platelets
Antibacterials	Warfarin enhanced by cephalosporins, erythromycin and metronidazole. Ampicillin and amoxicillin may increase bleeding
Antifungals	Warfarin enhanced by azoles, including miconazole topically
Anti-inflammatories	Bleeding enhanced by antiplatelet activity of NSAIDs; warfarin may also be enhanced. Corticosteroids may alter warfarin activity

Box 8.1 Main coagulation defects

- Anticoagulants and thrombolytic agents
- Chronic renal failure
- Deficiencies of factors XII and XIII and others
- Disseminated intravascular coagulation
- Dysproteinaemias, especially multiple myeloma
- Haemophilia
- Liver disease, including obstructive jaundice
- Lupus erythematosus
- Von Willebrand disease

not be treated in primary care without medical advice – or should be referred to a dental hospital or hospital-based dental clinic:

- Those with liver impairment and/or alcoholism
- Those with renal failure
- Those with thrombocytopenia, haemophilia or other disorder of haemostasis
- Those currently receiving a course of cytotoxic medication.

Dentoalveolar surgical procedures likely to be carried out in primary care will be classified as minor, e.g. simple extraction of up to three teeth, gingival surgery, crown and bridge procedures, dental scaling and the surgical removal of teeth. When more than three teeth need to be extracted, multiple visits will be required. Extractions may be planned to remove two or three teeth at a time, by quadrants, or singly at separate visits. Scaling and gingival surgery should initially be restricted to a limited area to assess whether bleeding is problematic. Patients requiring major surgery should usually be treated in a secondary care setting.

BLOOD COAGULATION DISORDERS

Blood coagulates via a number of liver-synthesized serum proteins (coagulation factors), activated by a cascade of enzymatic reactions. Two pathways of coagulation – the intrinsic and extrinsic – have a common end-point at the formation of thrombin, which then catalyses the formation of fibrin from fibrinogen. Coagulation disorders – typically from drugs (e.g. warfarin), liver failure and renal failure – are the main causes of such a bleeding tendency.

Coagulation disorders are due mainly to genetic defects of clotting factors (vWD but also other haemophilias), to anticoagulant or other drug therapy (Table 8.9), or to a range of diseases, especially those affecting the liver or kidney (Box 8.1). These cause a range of changes in the results of laboratory investigations (Table 8.10).

Table 8.10 Laboratory findings in clotting disorders

Disorder	Prothrombin time (PT)	Activated partial thromboplastin time (APTT)	Thrombin time (TT)	Fibrinogen level	Fibrin(ogen) degradation products (FDP)
Haemophilia A; haemophilia B; von Willebrand disease; deficiency of factors XI and XII	N	↑	N	N	N
Warfarin or other coumarin therapy; obstructive jaundice or other causes of vitamin K deficiency; deficiency of factor V or X	↑	↑	N	N	N
Heparin therapy; disseminated intravascular coagulation	↑	↑	N	N	N
Parenchymal liver disease	↑	↑	↑	↓	↑
Deficiency of factor VII	↑	N	N	N	N

N = normal.

Table 8.11 Blood coagulation factor defects in descending order of frequency

Factor deficient	Inheritance	Incidence (1 in)
VIII	X-linked	10 000
IX	X-linked	60 000
VII	Autosomal recessive	500 000
V	Autosomal recessive	1 million
X	Autosomal recessive	1 million
XI	Autosomal recessive	1 million
XIII	Autosomal recessive	1 million
Fibrinogen	Autosomal recessive	1 million
Prothrombin	Autosomal recessive	2 million

CONGENITAL COAGULATION (CLOTTING) DISORDERS (COAGULOPATHIES)

These are usually due to a deficiency or lack of a specific blood-clotting factor. The vascular and platelet haemostatic responses usually mask any problem initially, and patients usually complain of a delayed blood oozing from the area, such as a tooth extraction socket.

The most important hereditary bleeding disorder in terms of prevalence and severity is von Willebrand disease, but haemophilia A and B (Christmas disease) are the other most common coagulopathies. Haemophilia A and B are hereditary X-linked recessive disorders characterized by deficiencies in blood clotting factors VIII and IX, respectively. Factor XI deficiency is also important. Less common disorders are summarized in Table 8.11 and Appendix 8.2.

HAEMOPHILIA A

Haemophilia A affects approximately 1 in 5000 males.

General aspects

Haemophilia A is an X-linked disorder resulting from a deficiency in blood clotting factor VIII, a key component of the coagulation cascade. Haemophilia A thus affects males. Sons of carriers have a 50:50 chance of developing haemophilia, while daughters of carriers have a 50:50 chance of being carriers. All daughters of an affected male are carriers but sons are normal. Carriers rarely have a clinically manifest bleeding tendency. The female carrier will transmit the disorder to half of her sons and the carrier state to half of her daughters. The affected males will not transmit the disorder to their sons because their Y chromosome cannot carry the haemophilic gene.

**Fig. 8.12** Haemophilia.

Haemophilia A is about ten times as common as haemophilia B, except in some Asians, in whom frequencies are almost equal. Haemophilia A arises from a variety of mutations; some 150 different point mutations have been characterized but a family history can be obtained in only about 65% of cases.

Clinical features

Haemophilia is characterized by excessive bleeding, particularly after trauma and sometimes spontaneously. Haemorrhage appears to stop immediately after the injury (due to normal vascular and platelet haemostatic responses) but intractable oozing with rapid blood loss soon follows. Haemorrhage is dangerous either because of acute blood loss or due to bleeding into tissues, particularly the brain, larynx, pharynx, joints and muscles (Fig. 8.12). Abdominal haemorrhage may simulate

Table 8.12 Severity of haemophilia

	% factor VIII	Clinical features
Severe	<1	Spontaneous bleeding, typically from childhood, with bleeding into muscles or joints (haemarthroses), easy bruising and prolonged bleeding from minor injuries
Moderate	1–5	Comparatively minor trauma may still lead to significant blood loss
Mild	>5–25	Comparatively minor trauma may still lead to significant blood loss. Bleeding after dental extractions is sometimes the first or only sign of mild disease
Very mild	>25	Patient can generally lead a normal life and may remain undiagnosed but there can be prolonged bleeding after trauma or surgery. Some may not bleed excessively even after a simple dental extraction, so that the absence of post-extraction haemorrhage cannot reliably be used to exclude haemophilia. Most will, however, bleed excessively after more traumatic surgery, such as tonsillectomy

an ‘acute abdomen’. Haemarthroses can cause joint damage and cripple the patient.

Dental extractions lead to prolonged bleeding and, in the past, have been fatal. Abnormal bleeding after extractions has sometimes led to recognition of haemophilia. The severity of bleeding in haemophilia A correlates with the level of factor VIII:coagulant (VIII:C) activity and degree of trauma (Table 8.12). Normal plasma contains 1 unit of factor VIII per millilitre, a level defined as 100%.

Haemophilia should be suspected in males presenting with a history of:

- easy bruising in early childhood
- ‘spontaneous’ bleeding (bleeding for no apparent/known reason), particularly into the joints, muscles and soft tissues
- excessive bleeding following trauma or surgery.

Unlike platelet disorders, which present as bleeding into and from mucous membranes, haemophilia presents mainly as bleeding into muscle or joints (haemarthrosis). More seriously, a cerebral bleed can be a fatal complication. Bleeding around the larynx or pharynx after inferior alveolar nerve block administration or floor-of-mouth infiltration can obstruct the airway. While the history of bleeding is usually life-long, some children with severe haemophilia may not have bleeding symptoms until later, when they begin walking or running. Patients with mild haemophilia may not bleed excessively until they experience trauma or surgery. The severity of bleeding in haemophilia is generally correlated with the clotting factor level:

- Severe – spontaneous bleeding into joints or muscles, predominantly in the absence of identifiable haemostatic challenge
- Moderate – occasional spontaneous bleeding; prolonged bleeding with minor trauma or surgery
- Mild – severe bleeding with major trauma or surgery; spontaneous bleeding is rare.

General management

Diagnosis

The diagnosis of haemophilias is based upon the clinical presentation, a positive family history, coagulation studies and clotting factor assays. Typical findings are shown in Box 8.2. In haemophilia, the various factors are:

- factor VIIIc – which participates in the clotting pathway

Box 8.2 Laboratory findings in haemophilias

- Normal prothrombin time (PT and INR)
- Prolonged activated partial thromboplastin time (APTT)
- Reduced factor VIII:C level (haemophilia A)
- Reduced factor IX level (haemophilia B)
- Normal levels of von Willebrand factor (vWF)

- factor VIII:Ag – von Willebrand factor – which binds to platelets and is the carrier for factor VIIIc
- factor VIII:Co – a cofactor which aids platelet aggregation.

Diagnostic laboratory findings can be summarized as:

- a prolonged APTT
- a normal PT
- low factor VIIIc.

Factor VIII assay is generally required, as even the APTT may be normal or mild in some cases. A definitive diagnosis depends on factor assay to demonstrate a deficiency of factor VIII. The severity of haemophilia A is associated with factor VIIIc activity, measured by the factor VIII plasma level. People with factor VIII levels below 25% lead relatively normal lives.

Management

Haemophiliacs should be under the care of recognized haemophilia reference centres, where the primary aim is to prevent and treat bleeding with the missing clotting factor, using a specific factor concentrate. Factor VIII must be replaced to adequate levels during episodes of bleeding and this must be ascertained preoperatively.

To facilitate appropriate management in emergency situations, all patients should carry easily accessible identification, indicating the diagnosis, severity of the bleeding disorder, inhibitor status, type of treatment product used, initial dosage for treatment of severe, moderate and mild bleeding, and contact information for the treating physician/clinic.

Patients usually recognize early symptoms of bleeding, even before the manifestation of physical signs. This is often described as a tingling sensation or ‘aura’. During an episode of acute bleeding, an assessment should be performed to identify the bleeding site (if not clinically obvious) and appropriate clotting factor should be administered. Acute bleeds should be treated as quickly as possible, preferably within 2 hours. In severe bleeding episodes that are potentially life-threatening, especially those in the head, neck, chest and gastrointestinal tract, factor treatment should be initiated immediately, even before diagnostic assessment is complete.

Desmopressin (DDAVP) can raise factor VIII level adequately (3–6 times baseline levels) to control bleeding in patients with mild, and possibly moderate, haemophilia A.

Veins must be treated with care. They are lifelines for a person with haemophilia:

- Use of 23- or 25-gauge butterfly needles is recommended.
- It is advisable never to cut down into a vein, except in an emergency.
- Pressure should be applied for 3–5 minutes after venepuncture.
- Venous access devices should be avoided whenever possible, but may be required in some children.

Adjunctive therapies can be used to control bleeding, particularly in the absence of clotting factor concentrates, and may decrease the need for factor. If bleeding does not resolve despite adequate treatment, clotting factor levels should be measured. Inhibitor testing should be

performed if the level is unexpectedly low. Prevention of bleeding can be achieved by prophylactic factor replacement. Factor levels should be raised to appropriate levels prior to any invasive procedure.

Patients should avoid:

- activities likely to cause trauma
- drugs that affect platelet function, particularly aspirin and NSAIDs, except certain COX-2 inhibitors; paracetamol (acetaminophen) is a safe alternative for analgesia.

For persons with haemophilia, good oral hygiene is essential to prevent periodontal disease and dental caries. Dental examinations should be regular, starting as the primary teeth start to erupt. Teeth should be brushed twice a day with a medium-texture brush. In view of the liability to gingival haemorrhage, careful cleaning with a powered brush that can be positioned to avoid gingival trauma can be helpful. Dental floss or interdental brushes should be used wherever possible. Airfloss or ultrasonic brushes may help. Toothpaste containing fluoride should be used in areas where natural fluoride is not present in the water supply. Fluoride supplements may also be prescribed if appropriate. An orthodontic assessment should be considered for all patients between the ages of 10 and 14. Close liaison between the dental surgeon and the haemophilia team is essential to provide good comprehensive dental care.

Infiltration and intrapapillary and intraligamentary injections are often done under factor cover (20–40%), although it may be possible for those with adequate experience to administer these injections without it. Treatment from the haemophilia unit may be required before an inferior alveolar nerve block or lingual infiltration.

Dental extraction or surgical procedures carried out within the oral cavity should be performed with a plan in place for haemostasis management, in consultation with the haematologist.

Tranexamic acid or epsilon aminocaproic acid (EACA) is often used after dental procedures to reduce the need for replacement therapy.

Oral antibiotics should only be prescribed if clinically necessary.

Local haemostatic measures may also be used whenever possible following a dental extraction. Typical products include oxidized cellulose and fibrin glue.

Following a tooth extraction, the patient should be advised to avoid hot food and drinks until normal feeling has returned. Smoking

should be avoided, as this can cause problems with healing. Regular warm saltwater mouthwashes (1 teaspoon of salt in a glass of warm water [50°C]) should begin the day after treatment and continue for 5–7 days or until the mouth has healed.

Prolonged bleeding and/or difficulty in speaking, swallowing or breathing following dental manipulation should be reported to the haematologist/dental surgeon immediately.

The presence of blood-borne infections should not affect the availability of dental treatment.

Prevention of bleeding at the time of dental procedures in patients with inhibitors to factor VIII requires careful planning.

Synthetic vasopressin (desmopressin, DDAVP) acts to increase factor VIII levels and may be used in very mild haemophilia. ‘Gene therapy’ and ‘gene-delivery systems’ raise the possibility of a potential cure for haemophilia in the future.

Rarely, vWD may mimic haemophilia and, though the history may help to distinguish the two conditions, laboratory testing is essential (see later).

Factor VIII must be replaced to a level adequate to ensure haemostasis if bleeding starts or is expected. The following tests are typically required:

- Full blood count, APTT, PT, factor VIII assay
- Specific factor VIII antibody test
- Hepatitis B, hepatitis C, HIV tests
- Liver function tests
- Blood grouping and cross-matching in case of emergency, when surgery is contemplated.

The main aim of providing coagulant cover is to raise the existing factor VIII levels to normal to achieve adequate haemostasis (Table 8.13). Normal factor VIII levels can be achieved by the following measures:

- Desmopressin (DDAVP) may produce a two- to threefold rise in factor VIII activity after 90 minutes, and has a mean half-life of 9.4 hours. DDAVP can be taken as a nasal spray by some patients; in this case, the intranasal spray is delivered as 1.5 mg desmopressin (DDAVP) per mL. Each 0.1 mL pump spray delivers 100–150 mcg dosage. It can also be given subcutaneously. DDAVP is more appropriate for mild cases and can only be

Table 8.13 Dental care in haemophilias

Severity	Factor VIII levels	Symptoms	Dental treatment	Treatment options
Severe	>1% (1 IU/dL)	Spontaneous bleeding usually in childhood	Scale and polish	DDAVP (desmopressin; subject to response test)
		Bleeding into muscles/joints (haemarthrosis)	Conservation	Factor VIII
		Easy bruising	Inferior dental nerve block injection	Factor VIII and tranexamic acid
		Prolonged bleeding following minor injuries/trauma	Extractions	
Moderate	1–5% (FVIII:C >5 IU/dL)	Prolonged bleeding following mild to moderate trauma/surgery/extractions	Scale and polish	DDAVP (subject to response test)
			Conservation	DDAVP and tranexamic acid
			Inferior dental nerve block injection	
			Extractions	
Mild	>5% (FVIII:C >5 IU/dL)	Prolonged bleeding following mild trauma	Scale and polish	Nil
			Conservation	Nil for buccal infiltrations DDAVP (subject to a response test) DDAVP and postoperative tranexamic acid
			Inferior dental nerve block injections	
			Extractions	

repeated after 48 hours; therefore, factor VIII might be more suitable for the management of postoperative surgical cases. Multiple DDAVP infusions have been associated with a reduced response.

- Antifibrinolytic agents include tranexamic acid (Cyklokapron), a synthetic derivative of the amino acid lysine, which acts by reversibly blocking lysine-binding sites on plasminogen. This can be used systemically in a dose of 1 g (30 mg/kg) orally 4 times daily, starting 1 hour before the procedure, or as an infusion in a dose of 10 mg/kg in 20 mL normal saline over 20 minutes (child's dose is 20 mg/kg). However, nausea is a common adverse effect and antifibrinolytics must not be used systemically where residual clots are present (e.g. in the urinary tract or intracranially). Tranexamic acid significantly reduces blood loss after surgery in patients with haemophilia and can be used topically or systemically. Topical tranexamic acid as a 5% solution is used as a mouthwash in a dose of 10 mL 4 times daily for 1–2 weeks after scaling or dental extractions; it may also be applied on gauze swabs placed over the extraction sockets. Tranexamic acid is not approved for use in the USA by the Food and Drug Administration (FDA), where EACA is an alternative.
- Recombinant factor VIII. Factor VIII levels of 50–75% are required for minor surgery such as dental extractions. Patients can be helped postoperatively with tranexamic acid and local measures. For any persistent bleeding, factor VIII must be administered to manage the problem. For patients having a general anaesthetic, replacement factor VIII must be given to prepare for endotracheal intubation, which is likely to cause bleeding due to nasal trauma. Any major maxillofacial surgery must be carried out in a hospital setting; a bed should be arranged where appropriate in close consultation with the haemophilia reference centre.
- Many haemophiliacs with mild to moderate levels of factor VIII can manage their coagulant cover prior to dental treatment through their haemophilia reference centre. In mild to moderate haemophiliacs, non-surgical dental treatment can usually be carried out by using tranexamic acid and regional LA. Any surgical procedures in patients with mild to moderate haemophilia usually require at least DDAVP and tranexamic acid. Any major procedures must be carried out in a hospital setting in close consultation with the haemophilia reference centre.
- Haemophiliacs who manage their own factor VIII cover may well be able to do so for their dental treatment in a primary care setting. Any dental treatment should still be as atraumatic as possible. Any major procedures must be carried out in a hospital setting in close consultation with the haemophilia reference centre.
- Severe haemophiliacs often self-administer factor VIII prophylactically to prevent joint damage, this needing injections three times weekly. The factor VIII half-life is around 12 hours. This has huge cost implications, as well as presenting the problem of antibody (inhibitor) formation.

In mild haemophilia, desmopressin (DDAVP) and antifibrinolytics such as tranexamic acid may be adequate (see later).

Recombinant factor VIII is used to treat patients acutely for bleeding episodes. (Pooled factor VIII from donor serum, fresh-frozen plasma, cryoprecipitate, or fractionated human factor concentrates from pooled blood sources were used for many years but allowed transmission of blood-borne viral infections, such as hepatitis B virus (HBV), hepatitis C virus (HCV) and HIV.) Many older adult haemophiliacs are HCV-positive; many have been exposed to HBV (a proportion of whom are

carriers); and some are HIV-infected. Replacement of the missing clotting factor is therefore achieved with porcine factor VIII or recombinant factor VIII. Regular prophylactic replacement of factor VIII is used when possible but necessitates daily injections as the half-life is around 12 hours, and its use may be complicated by antibody formation.

Desmopressin (DDAVP) is a synthetic analogue of vasopressin that induces the release of factor VIIIc, vWF and tissue plasminogen activator from storage sites in endothelium. Desmopressin cover just before surgery, repeated 12-hourly if necessary for up to 4 days, is useful to cover minor operations in some very mild haemophiliacs, but factor VIII cover may be needed if there is any doubt about haemostasis. Desmopressin can be given as an intranasal spray of 1.5 mg desmopressin per mL with each 0.1 mL pump spray, or as a slow intravenous infusion over 20 minutes of 0.3–0.5 mcg/kg.

Although females may be carriers of haemophilia only, they may still exhibit symptoms of haemophilia. Depending on their factor VIII levels, they may need haematological management through a haemophilia reference centre prior to any invasive dental procedures requiring surgery or extractions.

Management challenges

- *Impaired mobility and access.* Joint problems are common in severe haemophiliacs.
- *Infections.* The stigma associated with infection by blood-borne viruses may constitute a barrier to care because of infection, increased bleeding due to liver damage or thrombocytopenia, delayed healing, impaired drug metabolism associated with hepatitis or adverse effects of medications. People who received British blood products between 1980 and 2001 may be at risk of variant Creutzfeldt–Jakob disease (vCJD) transmitted in factor VIII concentrates.
- *Inhibitors.* Factor VIII antibodies/inhibitors are autoantibodies to factor VIII that may arise in people with severe haemophilia, and can constitute a major complication. Traumatic procedures must be avoided unless absolutely they are necessary. The haematologist must always be consulted and patients with inhibitors treated with caution when inferior dental nerve block injections are administered or surgery is carried out. In individuals requiring invasive treatment, human factor VIII inhibitor bypassing fractions (FEIBA) can be administered intravenously beforehand; FEIBA are usually either non-activated prothrombin complex concentrates (PCC) or activated prothrombin complex concentrates (APCC) that exert their effect by activating factor X, thus altogether bypassing the intrinsic clotting pathway. PCC contains factors II, IX, VII and X. Unfortunately, these products can cause uncontrolled coagulation and thromboses. An alternative is to administer 1 000 000 units of activated factor VIIa, which directly acts on the surface of platelets. Adjuncts such as Tisseel, a highly concentrated combination of fibrinogen, thrombin and factor XIII, aid cross-linking of the clot and, together with topical tranexamic acid, help to stabilize the clot postoperatively. Platelets may also be given.
- Some people who received British blood products between 1980 and 2001 may be at risk of variant CJD.

Dental aspects of haemophilia A

Many of the coagulation defects present a hazard to surgery and to LA injections, but in general the teeth erupt and exfoliate without problems, and non-invasive dental care is safe. Close cooperation is needed between the physician and dentist to plan safe, comprehensive dental care.

Prevention of dental disease

Haemophiliacs form a priority group in whom the need for dental operative intervention should be minimized, as it can cause severe, or occasionally fatal, complications. Early prevention will reduce the need for future dental treatment and for repeated cover, which is not only uncomfortable but also costly, and can lead to the formation of inhibitors. Education of patients or parents and preventive dentistry should be started as early as possible in the young child, when the teeth begin to erupt. Caries must be minimized or avoided. Prevention of periodontal disease is also imperative. It is important to institute the use of fluorides from childhood, to use fissure sealants/preventive resin restorations, and to emphasize the importance of dietary sugar restriction, good oral hygiene and regular dental check-ups. An orthodontic assessment should also be carried out at an early stage to predict any future problems such as overcrowding, which might be avoided. In adults, long term-prevention and routine care are also essential.

Pain and anxiety control

Anxiety and drug dependence can be barriers to managing patients.

- **LA.** There is an 80% chance of haematomas developing in haemophiliacs not treated with cover prior to mandibular block injection; infiltrations and intraligamentary, intraosseous and pulpal injections are safer. LA as an inferior dental nerve block, posterior superior alveolar nerve block, lingual infiltration or injections in the floor of the mouth must always be appropriately covered prior to dental treatment. Failure to achieve this can result in the life-threatening complication of haemorrhage, which can compromise the airway. Infiltration anaesthesia is safe without factor replacement, except for lingual infiltration where blood can track down into lingual spaces. Alternative methods of achieving LA must be tried, such as intraligamentary anaesthesia, or infiltrations using articaine where appropriate. Buccal infiltration of the mandibular first molar with 4% 1:100 000 adrenaline (epinephrine) has resulted in a higher success rate than 2% lidocaine with 100 000 epinephrine in non-haemophilic patients. It is also more comfortable compared with inferior dental nerve block injection. However, it is less successful with mandibular second and third molar teeth because of the presence of denser cortical bone. Depending on their inhibitor titre, patients who have inhibitors must always be monitored postoperatively despite having cover.
- **CS.** Conscious sedation using inhalation sedation or midazolam is usually safe in selected cases, depending on the American Society of Anesthesiology (ASA) classification, and providing that appropriate cover is given by the haematologist. There should be no problems with haematoma formation at the cannulation site if there is a mild to moderate haemophilia or if the patient has received factor VIII cover.
- **GA.** A thorough preoperative assessment, with the anaesthetist, haematologist and dentist in close consultation, is essential. Nasal intubation should be avoided if possible. Overnight stay and postoperative follow-up should be considered, especially for those patients with added complications who have hepatitis, HIV or inhibitors. Individuals with severe haemophilia may also benefit from an overnight stay, depending on the treatment being carried out and the haematologist's advice.

Conservation and fixed prosthodontics

Careful placement of rubber dams and matrix bands can minimize bleeding. Trauma from high-speed suction or a saliva ejector can be avoided by placing gauze beneath it. Fissure sealants should be considered at an early stage as part of the prevention regime. Use of

atraumatic restorative technique (ART) or air abrasion/Carisolv gel may be appropriate. Any sharp-edged restorations or dentures must be smoothed. Conservative extension of gingival margins and supra-gingival crown preparations should be considered. Tranexamic acid can be used topically to control any local bleeding. Non-metal impression trays can minimize soft-tissue trauma. Endodontic treatment should be appropriately covered, the main concern being to avoid instrumentation through the apex (use an apex locator). Intrapulpal anaesthesia may also reduce the bleeding risk.

Periodontology

In mild haemophiliacs, scaling can usually be carried out using tranexamic acid cover; if in doubt, seek advice from the haematologist. In moderate haemophiliacs, DDAVP as well as tranexamic acid might be required. Severe haemophiliacs may require factor VIII and tranexamic acid cover. Any additional treatment, such as conservation, should also be carried out at the same visit to avoid the need for repeated cover. Periodontal surgery, as any surgery, requires appropriate cover, depending on the severity of the condition – at least to a level of factor VIII at 50–75%.

Orthodontic treatment

There is no contraindication to orthodontic treatment. Care must be taken with any sharp edges to orthodontic appliances or wires.

Exodontia/dentoalveolar surgery/maxillofacial surgery

Tooth extractions must be carefully planned in close communication with the haematologist, weighing up the risk of repeated factor VIII cover and managing bleeding. Factor VIII levels should be between 50 and 75%. When maxillofacial surgery is scheduled, factor VIII replacement is necessary for *all* haemophiliacs at a level of 75–100% and is required 1 hour postoperatively.

Lingual tissues should be left undisturbed when raising mucoperiosteal flaps to prevent blood from tracking down the mediastinum. Local measures must be implemented such as: minimal trauma to both soft tissues and bone, good wound cleaning, and placement of resorbable sutures to reduce the risk of further bleeding on removal. Polyglactin (Vicryl) sutures are preferable to stabilize the gum flap, as they remain in situ for about 4 days. In addition to the application of continuous pressure (i.e. gentle hand pressure, additional stitches), cooling of the site (i.e. with an ice pack) and use of vasoconstrictors, there are usually other materials that could be applied to the site in order to reduce or even stop the bleeding. These include: oxidized cellulose, absorbent gelatin sponge, collagen sponge, resorbable gelatin sponge, topical thrombin, EACA, tranexamic acid, fibrin sealant and many others (Table 8.14). Due to a concern regarding vCJD, recombinant fibrin glues are becoming more easily available.

Table 8.14 Topical haemostatic agents

Agent	Main constituent	Source
Avitene	Collagen	Bovine
Beriplast	Fibrin	Various
CollaCote	Collagen	Bovine
Cyklokapron	Tranexamic acid	Synthetic
Gelfoam	Gelatin	Bovine
Helistat	Collagen	Bovine
Instat	Collagen	Bovine
Surgicel	Cellulose	Synthetic
Thrombinar	Thrombin	Bovine
Thrombogen	Thrombin	Bovine
Thrombostat	Thrombin	Bovine

Patients should be instructed to take a soft diet for a week after surgery. Antimicrobials might be indicated. The patient should be warned to report any swelling, dysphagia or hoarseness, as this may indicate haematoma formation and risk to the airway. For postoperative pain management, paracetamol (acetaminophen) or a combination of codeine/paracetamol may be suitable; NSAIDs and aspirin should be avoided, and care should be taken when prescribing opioids, due to the enhanced sedative effects following sedation or GA on the same day.

LA injections or surgery can be followed by persistent bleeding for days or weeks; the haemorrhage cannot be controlled by pressure alone and the problem may be life-threatening. Management of haemophiliacs should take consideration of the factors listed in [Box 8.3](#).

The bleeding tendency can be aggravated by NSAIDs. It may also be worsened by other factors, such as liver damage after hepatitis, HIV disease, thrombocytopenia and the effects of drugs such as protease inhibitors. Paracetamol (acetaminophen), codeine and COX-2 inhibitors are safer.

An outline of management of haemophiliacs needing surgery is given in [Table 8.15](#).

Local use of fibrin glue and swish-and-swallow rinses of tranexamic acid before and after severe anaemia, neutropenia and thrombocytopenia, which predispose to oral manifestations.

Haemophiliacs with inhibitors

The haematologist must always be consulted. Factor VIII inhibitor levels should be checked preoperatively and, in general, patients with

low-titre inhibitors can have dental treatment in the same way as those who have no antibodies.

Those with high-titre inhibitors need special care. In this group, traumatic procedures must be avoided, unless absolutely essential. Human FEIBA can often be effective; these are usually either non-activated PCC or APCCs, which act by activating factor X, directly bypassing the intrinsic pathway of blood clotting. The danger with these products is that of uncontrolled coagulation with thromboses. The real choice lies between either prothrombin-complex concentrates (e.g. FEIBA) or recombinant factor VIIa. In some cases, desmopressin (DDAVP) is an effective alternative, and antifibrinolytics may help.

CS can be given but, if intravenous, great care must be taken to avoid damaging the vein. If GA is needed, nasal intubation should be avoided.

HAEMOPHILIA B (CHRISTMAS DISEASE)

General and clinical aspects

Haemophilia B (Christmas disease; factor IX deficiency) is clinically identical to haemophilia A and inherited in the same way; it also affects males only but is about one-tenth as common as haemophilia A, except in some Asians, in whom frequencies are almost equal. Female carriers of haemophilia B (unlike haemophilia A) often have a mild bleeding tendency.

General management

The APTT is prolonged with a normal PT, and factor IX levels are low. Treatment is with synthetic factor IX concentrate, which is more stable than factor VIII with a half-life that is usually 18 hours but often up to 2 days, so that replacement therapy can sometimes be given at longer intervals than in haemophilia A. A dose of 20 units of factor IX per kilogram body weight is given intravenously 1 hour preoperatively.

Dental aspects

Comments on dental management in haemophilia A apply to patients with haemophilia B, apart from using factor IX and not using desmopressin (DDAVP).

Box 8.3 Factors to consider in haemophilia management

- Aggravation of bleeding by drugs
- Anxiety
- Dental neglect necessitating frequent dental extractions
- Drug dependence as a result of chronic pain
- Factor VIII inhibitors
- Hazards of anaesthesia, nasal intubation and intramuscular injections
- Hepatitis and liver disease
- HIV infection
- Trauma, surgery and subsequent haemorrhage

Table 8.15 Outline of management of haemophiliacs requiring surgery

Operation	Factor VIII level required	Preoperative regimen	Postoperative schedule
Dental extraction, dentoalveolar or periodontal surgery	Minimum of 50% at operation	Factor VIII i.v. ^a Tranexamic acid 1 g i.v. (or by mouth starting 24 h preoperatively)	Local haemostatic measures ^b
Maxillofacial surgery	75–100% at operation; at least 50% for 7 days postoperatively	Factor VIII i.v. ^c	Local haemostatic measures ^b Rest as inpatient for 7 days unless resident close to centre (then 3 days) Soft diet For 10 days give tranexamic acid 1 g 4 times daily and penicillin V 250 mg 4 times daily If there is bleeding during this period: Give repeat dose of factor VIII ^a Rest inpatient for 10 days Soft diet Twice-daily i.v. factor VIII ^a for 7–10 days

^aFactor VIII dose in units = weight in kilograms × 25 given 1 h preoperatively.

^bSee [Table 8.14](#).

^cFactor VIII dose in units = weight in kilograms × 50 given 1 h preoperatively.

Table 8.16 *Types of von Willebrand disease (vWD)*

Type	Type of vWD defect	Percentage of cases	Comments	Factor VIIIc levels	Benefit from factor VIII replacement	Desmopressin (DDAVP)
1	Partial quantitative	80	Autosomal dominant inheritance. Disease is mild and characterized by bleeding from mucous membranes – nosebleeds, gingival haemorrhage and gastrointestinal blood loss	May be normal	–	Used as nasal spray
2A	Qualitative	15		Reduced	+	Used as nasal spray
2B	Qualitative	Rare		Reduced	+	Contraindicated
2C	Qualitative	Rare		Reduced	+	Used as nasal spray
2M	Qualitative	Rare		Reduced	+	Contraindicated
2N	Qualitative	Rare		Reduced	+	Used as nasal spray
3	Complete lack of vWF	5	Bleeding is more severe than in types 1 and 2 but joint and muscle bleeds characteristic of haemophilia are rare	Reduced	+	Contraindicated

VON WILLEBRAND DISEASE (VWD)

General aspects

vWD is the most common inherited bleeding disorder and is caused by von Willebrand factor (vWF) deficiency. Inheritance is usually autosomal dominant and disease affects males or females. vWF is a protein expressed in both platelets and blood vessel endothelial cells; it is synthesized in the endothelium and megakaryocytes, and has binding sites for collagen and for platelet glycoprotein (GP) receptors. vWF normally acts in two ways:

- It normally binds to GP Ib and acts as a carrier for factor VIII, increasing factor VIII half-life by protecting it from proteolytic degradation; thus a deficiency of vWF also leads to a low factor VIII concentration in the blood.
- vWF also mediates platelet adhesion to damaged vascular endothelium, enhancing platelet aggregation. Thus a deficiency of vWF leads to defective platelet adhesion, which in turn causes a secondary deficiency in factor VIII.

Clinically significant vWD affects approximately 1% of the population and 6% of women with menorrhagia – a frequency at least twice that of haemophilia A. vWD may occasionally be inherited as a sex-linked recessive trait like true haemophilia. Rarely, vWD may be acquired, particularly in patients with autoimmune or lymphoproliferative diseases.

Clinical features

The types of vWD are shown in Table 8.16.

vWD causes bleeding that has features similar to those caused by platelet dysfunction; if severe, however, it can resemble haemophilia (Table 8.17). The common pattern is bleeding from, and purpura of, mucous membranes and the skin. Gingival haemorrhage is more common than in haemophilia. Postoperative haemorrhage can be troublesome; excessive haemorrhage may occur after dental treatment and surgery. Excessive menstrual bleeding is common in females. Haemarthroses are possible but rare.

The severity also varies from patient to patient and from time to time. Some patients have a clinically insignificant disorder, while others have factor VIII levels low enough to cause severe clotting defects as well as a prolonged bleeding time. However, severity does not correlate well with factor VIII level. Pregnancy and the contraceptive pill may cause transient amelioration.

The pattern of clinical features in vWD is distinct from that of haemophilia. Bruising, epistaxis and prolonged bleeding during surgical or dental procedures are the most common features but menorrhagia

Table 8.17 *Differentiation of haemophilia A and von Willebrand disease^a*

	Haemophilia A	Von Willebrand disease
Dominant inheritance	Sex-linked recessive	Autosomal
Haemarthroses/deep haematomas	Common	Rare
Epistaxes	Uncommon	Common
Gastrointestinal bleeding	Uncommon	Common
Haematuria	Common	Uncommon
Menorrhagia	None (males)	Common
Post-extraction bleeding	Starts 1–24 h after trauma, lasts 3–40 days and is not controlled by pressure	Starts immediately, lasts 24–48 h and is often controlled by pressure
Bleeding time	Normal	Prolonged
Factor VIII coagulant activity	Low	Low
Factor VIIIIR:RCo (plasma factor VIII complex; ristocetin cofactor)	Normal	Low

^aSevere von Willebrand disease is occasionally identical to haemophilia.

or gastrointestinal haemorrhage also occur frequently. The amount of bleeding depends on the type and severity of vWD but manifests with:

- frequent or hard-to-stop nosebleeds:
 - ◆ start without injury (spontaneous)
 - ◆ occur often, usually five times or more in a year
 - ◆ last more than 10 minutes
 - ◆ need packing or cautery to stop the bleeding
- easy bruising:
 - ◆ occurs with very little or no trauma or injury
 - ◆ occurs often (1–4 times per month)
 - ◆ is larger than the size of a 10 pence coin (or a US quarter)
 - ◆ is not flat and has a raised lump
- heavy menstrual bleeding:
 - ◆ involves the passing of clots larger than the size of a penny
 - ◆ soaks more than one pad through every 2 hours
 - ◆ is diagnosed as anaemia as a result of bleeding from heavy periods
- longer-than-normal bleeding after injury, surgery, childbirth or dental care:
 - ◆ lasts more than 5 minutes after a cut to the skin

- ◆ involves heavy or longer bleeding after surgery; bleeding sometimes stops but starts up again hours or days later
- ◆ involves heavy bleeding during or after childbirth
- ◆ involves heavy bleeding during or after dental surgery
- ◆ leads to oozing of blood from the surgery site longer than 3 hours after the dental surgery
- ◆ means that the dental surgery site needs packing or cautery to stop the bleeding
- other common bleeding events, including:
 - ◆ blood in the stool (faeces) from bleeding into the stomach or intestines
 - ◆ blood in the urine from bleeding into the kidneys or bladder
 - ◆ bleeding into joints or internal organs in severe cases (type 3).

Expression is variable, with some patients experiencing bleeding only after surgery or major trauma and others suffering from frequent spontaneous bleeding of the mucosal surfaces. Patients also present with deep-seated haemorrhages caused by factor VIII deficiency.

Type 1

This is the most common form of VWD and the mildest. Inherited in autosomal dominant fashion, it is usually confirmed by a combination of:

- abnormal platelet function
- decreased vWF antigen
- proportional decrease in factor VIII.

Type 2

There are normal amounts of vWF but it is dysfunctional. Type 2 contains subtypes 2A, 2B, 2C, 2M and 2N, and treatment is different for each type. Platelet-type vWD, also known as pseudo-vWD, is an autosomal dominant condition inherited by gain-of-function mutations of the vWF receptor on platelets. It is similar to type 2B vWD.

Type 3

This is the most severe form of vWD, in which a person has no vWF and also low levels of factor VIII. The presentation usually resembles haemophilia.

Rarely, aortic stenosis (Heyde syndrome), hereditary haemorrhagic telangiectasia, IgA deficiency, mitral valve prolapse or factor XII deficiency may be associated with vWD.

General management

vWD is characterized by the laboratory findings shown in [Box 8.4](#). The PT is normal and the APTT often normal (factor VIII levels are often adequate for a normal APTT). vWF levels are, however, reduced. Platelet count is usually normal. Factor VIII assay is usually reduced while the tourniquet test may be positive in most cases.

Before surgery, patients with vWD need treatment to reduce the risk of haemorrhage ([Table 8.18](#)). Essentially, management is the same as for haemophilia A. The following should be discussed with the haematologist:

- The severity of the disease
- The procedures planned and the nature of the bleeding risk
- The patient's response to previous treatment, surgery and trauma
- The patient's response to various types of systemic therapy.

Dental aspects

The treatment prescribed for vWD depends on the type and severity of the disease. For minor bleeds, treatment might not be needed. The most commonly used types of treatment are:

Box 8.4 Laboratory findings in von Willebrand disease

- Prolonged activated partial thromboplastin time
- Low levels of von Willebrand factor (factor VIII:Ag)
- Low factor VIII:C levels
- Reduced platelet aggregation in the presence of ristocetin

Table 8.18 von Willebrand disease: haemostatic prophylaxis for surgery^a

von Willebrand disease type	Desmopressin	Factor VIII replacement
1	Nasal spray typically effective	–
2A	Nasal spray may be effective: check response with trial dose	±
2B	Contraindicated	+
2C	Nasal spray useful	±
2M	Contraindicated	+
2N	Unlikely to be of value	±
3	Contraindicated	+

^aPlus local haemostatic measures (see [Table 8.14](#)).

- desmopressin acetate (DDAVP) nasal spray – this acts by boosting levels of vWF and factor VIII and is used to treat people with some milder forms of vWD. DDAVP acts by boosting levels of vWF and factor VIII, and is sometimes injected intravenously to treat some forms of vWD (mainly type 1)
- vWF factor replacement – human plasma rich in vWF and factor VIII is used to treat more severe forms of vWD, or people with milder forms of vWD who do not respond well to nasal DDAVP. Recombinant vWF is unavailable, and recombinant factor VIII has no beneficial effect.
- antifibrinolytic drugs – these are either injected or taken orally to help slow or prevent blood clot breakdown.

In type 1 vWD, desmopressin (DDAVP) may be used to increase vWF levels acutely.

DDAVP may be effective in type 2A and it is often helpful to give patients a trial dose to ascertain the response.

In some type 2B vWD, DDAVP is contraindicated, as it can stimulate release of dysfunctional vWF, which leads in turn to platelet aggregation and severe, though transient, thrombocytopenia.

DDAVP is contraindicated in type 3 vWD, as there is an almost complete lack of vWF; patients are managed as for severe haemophilia A.

Clotting factor replacement is needed. Intermediate-purity factor VIII, cryoprecipitate and fresh-frozen plasma are effective. Human plasma does contain vWF and is usually effective in treating severe vWD. In more severe cases, vWF concentrate may be needed. However, recombinant factor VIII lacks vWF and is thus a non-viable treatment for vWD.

In all types, aspirin and NSAIDs should be avoided. Infiltration or intraligamentary LA should generally be used. CS can be given, but care must be taken not to damage the vein. GA must be given in hospital, where expert attention is available. Intubation is a possible hazard because of the risk of submucosal bleeding in the airway.

All invasive procedures, such as extractions, minor oral/periodontal surgery, implants and deep scaling, require haematological cover, depending on the severity of disease.

Following dental treatment, antiplatelet medications for analgesia, such as aspirin or ibuprofen, are contraindicated. Paracetamol

Table 8.19 *Inherited disorders in fibrinogen*

Condition	Definition	Inheritance	Features
Afibrinogenaemia	Complete lack of fibrinogen	Autosomal recessive	Neonatal umbilical cord haemorrhage, ecchymoses, mucosal haemorrhage, internal haemorrhage and recurrent abortion
Hypofibrinogenaemia	Low levels of fibrinogen below 100mg/dL (normal is 250–350 mg/dL)	Acquired or inherited	Symptoms similar to but less severe than afibrinogenaemia
Dysfibrinogenaemia	Dysfunctional fibrinogen	Inherited	Haemorrhage, spontaneous abortion and thromboembolism
Hypoplasminogenaemia	Plasminogen deficient or defective	Inherited	Fibrin deposits with gingival swelling and sometimes ligneous conjunctivitis

(acetaminophen) is the usual drug of choice, or combination analgesia, such as co-codamol, may be given for further pain relief.

FACTOR XI DEFICIENCY ('HAEMOPHILIA C')

Common in Ashkenazi Jews, factor XI deficiency is inherited as an autosomal disorder with either homozygosity or compound heterozygosity.

Patients with factor XI deficiency cannot activate thrombin-activatable fibrinolytic inhibitor (TAFI); this results in rapid fibrinolysis, which is responsible for the bleeding tendency seen in this disorder. Fresh-frozen plasma or factor XI is required.

FACTOR XII DEFICIENCY

Factor XII (the first component of the intrinsic pathway) is more important for the generation of bradykinin and stimulation of fibrinolysis than for initiation of coagulation. Patients with factor XII deficiency rarely show signs of haemorrhage.

FACTOR XIII DEFICIENCY

Factor XIII, the pro-enzyme of plasma transglutaminase, is normally activated by thrombin in the presence of calcium to catalyse the cross-linking of fibrin monomers.

Factor XIII deficiency leads to neonatal umbilical cord bleeding, intracranial haemorrhage and soft-tissue haematomas. Primary haemostasis is normal but delayed bleeding is seen.

FIBRINOGEN DISORDERS

Inherited disorders in fibrinogen are rare (Table 8.19). In contrast, raised plasma fibrinogen levels are found in coronary artery disease, diabetes, hypertension, peripheral artery disease, hyperlipoproteinaemia, hypertriglyceridaemia, pregnancy, menopause, hypercholesterolaemia, use of oral contraceptives and smoking.

ACQUIRED COAGULATION DEFECTS

Acquired haemorrhagic disorders are far more prevalent than congenital diseases but, except in anticoagulant therapy or liver disease, are usually less severe. Important causes include anticoagulant therapy and liver disease, vitamin K deficiency or malabsorption, disseminated intravascular coagulation, fibrinolytic states, amyloidosis (deficiency of factor X) and autoimmune disorders (e.g. acquired haemophilia). Some patients also have clinical bleeding tendencies but no defect detectable by current laboratory methods.

LIVER FAILURE

Liver failure leads to impaired synthesis of vitamin K-dependent clotting factors, such as factors II, VII, IX, X and fibrinogen – leading to prolonged PT and INR. Patients with liver failure may also have oesophageal varices associated with portal hypertension, and serious bleeding from these is possible. During bleeding, fresh-frozen plasma (contains all clotting factors) may be needed. Treatment with regular high-dose vitamin K increases levels of these clotting factors.

DRUGS

Anticoagulants are given to prevent and treat thromboembolic disease but have many uses. They are used to treat atrial fibrillation, cardiac valvular disease, ischaemic heart disease and post-myocardial infarction (sometimes), deep venous thrombosis (DVT), pulmonary embolism, cerebrovascular accident and many other conditions, and are used when there are heart valve replacements or renal dialysis.

Commonly used anticoagulants are the coumarin warfarin for long-term treatment and heparin for short-term treatment. Because it takes several days for the maximum effect of warfarin to be realized, heparin is normally given first.

Warfarin, a 4-hydroxycoumarin derivative, is the most commonly used oral anticoagulant. It is a vitamin K antagonist, which acts by inhibiting the post-translational glutamate carboxylation of blood coagulation factors II, VII, IX and X. Warfarin also inhibits glutamate carboxylation of the proteins C and S. The anticoagulant effect of warfarin results predominantly from reduction in factor II.

Warfarin is most frequently prescribed to control and prevent thromboembolic disorders in atrial fibrillation, after cardiac surgery or organ transplants, after cerebrovascular accident, or in DVT or pulmonary embolism.

Warfarin effects begin after 8–12 hours, are maximal at 36 hours, and persist for 72 hours, prolonging the INR – the ratio of the patient's prothrombin time to a standardized control. An INR above 1 indicates that clotting will take longer than normal. The management of patients on warfarin should take into consideration the type of dental procedure, the INR value, the underlying condition for which anticoagulation is used and other risk factors (e.g. hepatic disorders or local inflammation). Surgery is the main oral health-care hazard to the patient on warfarin (see below).

The plasminogen activators, such as t-PA (alteplase) or streptokinase, also are useful for controlling coagulation, in particular during the short period after myocardial infarction (Ch. 5). Because t-PA is highly selective for the degradation of fibrin in clots, it is extremely helpful in restoring the patency of the coronary arteries after thrombosis. Streptokinase (an enzyme from streptococci) is another plasminogen activator that is useful from a therapeutic standpoint but it is

less selective than t-PA, being able to activate circulating plasminogen as well as that bound to a fibrin clot.

Aspirin, by virtue of inhibiting the activity of the COX enzyme, depresses the production of thromboxane (TXA₂) and prostacyclin (PGI₂), and inhibits platelet aggregation.

Commonly prescribed anticoagulants include:

- dalteparin (Fragmin)
- danaparoid (Orgaran)
- enoxaparin (Lovenox)
- heparin (various)
- tinzaparin (Innohep)
- warfarin (Coumadin).

Warfarin

Surgery is the main oral health-care hazard to the patient on warfarin and thus the possibility of alternatives, e.g. endodontics, should always be considered. The INR is used as a guideline to care and should be checked on the day of operation or, if that is not possible, within the 24 hours prior to surgery.

Anticoagulant treatment should not be altered without the agreement of the clinician in charge, and stopping it preoperatively is rarely the best policy, since it does not necessarily reduce bleeding significantly; in contrast, it may cause hypercoagulability and rebound thrombosis – which has damaged prosthetic cardiac valves and even caused thrombotic deaths in dental patients. Hospital or specialist referral is indicated in the presence of:

- an INR of more than 4.0
- the need for more than a simple surgical procedure
- the presence of additional bleeding risk factors or logistical difficulties
- drug interactions with warfarin.

LA regional block injections, or those in the floor of the mouth, may be a hazard, since bleeding into the fascial spaces of the neck can threaten airway patency.

If surgery is to be limited, such as the uncomplicated forceps extraction of 1–3 teeth, and the INR is below 4.0, with no other risk factors (additional bleeding risk factors or logistical difficulties; drug interactions with warfarin) present, local haemostatic measures alone should suffice. Postoperative bleeding may be minimized by the use of oxidized cellulose, collagen sponges and sutures. If surgery is not to be simple or minor, the INR is over 4.0 or other risk factors are present, the patient should be treated in a hospital or other specialist centre. Topical antifibrinolytic agents, such as tranexamic acid (10 mL of a 5% w/v solution used as a mouthwash for 2 minutes, four times daily for 7 days), may help. Postoperatively, airway patency must always be ensured.

Warfarin may be enhanced by drugs such as NSAIDs, some antibiotics and azole antifungal agents (Table 8.20). Paracetamol (acetaminophen) is the analgesic of choice since it does not affect platelets. Codeine is a suitable alternative in adults. Penicillin V and clindamycin are the antibiotics of choice.

As we have seen, warfarin is orally administered and acts by inhibiting the vitamin K activation of clotting factors II, VII, IX and X. It prolongs the INR and PT, but it takes 2–3 days for warfarin's full anticoagulant effects to manifest and several days for its effects to abate. INR monitoring must be performed regularly for all patients so that the dose of warfarin may be adjusted appropriately. If more rapid reversal of anticoagulation is needed, protamine or APCC can be used.

Table 8.20 Drug use in patients on warfarin^a

Drug group	Avoid: warfarin effect is enhanced	Alternatives that can probably be used safely ^b
Analgesics	Aspirin and other NSAIDs	Paracetamol (acetaminophen)
	Tramadol	Celecoxib Codeine
Antibacterials	Amoxicillin	Azithromycin
	Amoxicillin plus clavulanic acid	Cephalosporins (others)
	Ampicillin	Clindamycin
	Benzympenicillin	Erythromycin
	Cephalosporins (2nd, 3rd generation)	Penicillins (others)
	Ciprofloxacin	
	Clarithromycin	
	Co-trimoxazole (and other sulphonamides)	
	Doxycycline	
	Isoniazid	
	Metronidazole	
	Neomycin	
	Quinolones	
Antidepressants	Tetracyclines	
	Selective serotonin reuptake inhibitors (Ch. 10)	Tricyclic antidepressants (Ch. 10)
Antifungals	Azoles (fluconazole, itraconazole, ketoconazole, miconazole)	Amphotericin
	Griseofulvin	Nystatin
Antivirals	Ritonavir	
	Saquinavir	

^aWarfarin effect may be enhanced by several drugs but where a single dose of amoxicillin is required there should be no problem. If infection is present, no elective surgery should be done until the patient has been treated with antibiotics and is free from acute infection. In case of emergency, careful haemostatic control should suffice.

^bPatients should still be advised to be vigilant for excessive bleeding.

Medication and dietary interactions with warfarin

Warfarin's effect may be changed by several drugs (see Table 8.20). Even topical miconazole gel has led to bleeding. Aspirin and other NSAIDs can also interfere with platelet function and cause gastric bleeding.

Of greater significance is the increased risk of intracranial haemorrhage from the concurrent administration of warfarin and aspirin.

For postoperative pain management, paracetamol (acetaminophen; an intake of four 500-mg tablets per day for up to 5 days) is recommended as the general analgesic and antipyretic of choice for short-term use in patients on oral anticoagulant therapy. Paracetamol is preferred over NSAIDs because it does not affect platelets, but excessive and prolonged administration can enhance warfarin activity. An intake of fewer than six tablets of 325 mg of paracetamol per week has little effect on INR; however, four tablets a day for a week significantly affects the INR. The concurrent administration of warfarin and paracetamol at a dose of four 325-mg tablets a day for 7 days will raise the INR and risk of haemorrhage because one of the metabolites inhibits a key enzyme in the vitamin K cycle that is required for the liver to produce coagulation factors. Paracetamol will affect the INR within 18–48 hours of administration.

Codeine may be prescribed with the paracetamol to enhance the analgesic effect. COX-2-selective NSAIDs (celecoxib and rofecoxib),

Table 8.21 Novel oral anticoagulants compared with warfarin

	Warfarin	Dabigatran	Rivaroxaban
Targets	Factors II, VII, IX and X Proteins C and S	Thrombin (inhibits)	Factor Xa (inhibits)
Effective half-life	20–60 h (mean ~40 h)	Adult 12–17 h; older people 14–17 h (assuming no renal impairment)	Young people 5–9 h; older people 11–13 h
Food and other effects on absorption	Food may delay rate	Acidic environment needed Absorption may be reduced by drugs such as proton pump inhibitors and antacids	Food increases rate and extent of absorption by 25–35%
Need for routine monitoring of coagulation	Yes (PT/INR)	No	No
Antidote/reversal agent available	Yes (vitamin K)	No	No
Drug and food interactions: increased anticoagulation			
Antifungals	Miconazole, ketoconazole, fluconazole (itraconazole to a lesser degree)	Ketoconazole, itraconazole	Ketoconazole, itraconazole (miconazole if renal function impaired)
Antibiotics	Erythromycin, clarithromycin, (metronidazole possibly), azithromycin, tetracycline, doxycycline, cephalosporins, levofloxacin	Erythromycin, clarithromycin	–
Analgesics	NSAIDs, (antiplatelet agents: aspirin, clopidogrel), ibuprofen, diclofenac, paracetamol (acetaminophen; prolonged regular use)	NSAIDs (antiplatelet agents: aspirin, clopidogrel), ketorolac (diclofenac appears not to interact)	NSAIDs (antiplatelet agents: aspirin, clopidogrel)
Food/herbs:	Cranberry juice, St John's wort, alcohol, many dietary supplements	Alfalfa, anise, bilberry	Grapefruit juice, alfalfa, anise, bilberry
Drug and food interactions: decreased anticoagulation	Green leafy vegetables (Vitamin K), vitamin E	Dexamethasone Carbamazepine Rifampicin St John's wort	Phenytoin Rifampicin St John's wort

which were potential alternatives, are contraindicated because of cardiotoxicity. Tramadol occasionally interferes with warfarin and raises the INR.

When taken over a number of days concurrently with warfarin, certain other medications may increase the patient's INR value and risk of haemorrhage unless the warfarin dosage is adjusted. Warfarin's anticoagulation effect is derived as discussed, from its ability to prevent the metabolism of vitamin K to its active form, which is needed for the liver to synthesize clotting factors II, VII, IX and X. Some antimicrobials (tetracyclines, broad-spectrum penicillins – amoxicillin, ampicillin) further decrease available vitamin K because they destroy some of the normal intestinal bacteria that produce it. The INR and risk of haemorrhage may also be increased by antimicrobials such as metronidazole and the macrolides (erythromycin, azithromycin, clarithromycin) because they inhibit the normal metabolism of warfarin. If a full antimicrobial course is indicated, the narrow-spectrum penicillin V (or clindamycin for those allergic to penicillin) is the preferred medication. Azole antifungals, such as ketoconazole, fluconazole, clotrimazole, itraconazole and miconazole, may also increase the INR by inhibiting the hepatic metabolism of warfarin.

Other medications that may adversely interact include dicloxacillin, nafcillin, phenobarbital and chloral hydrate, which can induce enzyme systems to metabolize warfarin rapidly.

Warfarin's effect can also be influenced by irregular tablet-taking. Diets high in vitamin K (avocado, sugar beet/beetroot, broccoli, Brussels sprouts, cabbage, chick peas, green peas, green tea, kale, lettuce, liver, spinach and turnips) can lower the INR. Alcohol can inhibit warfarin but may have the converse effect if there is liver disease. Disorders such as diarrhoea, liver disease and malignant disease can

raise the INR. Cranberry juice (*Vaccinium macrocarpon*), popularly used to prevent cystitis, may enhance warfarin activity.

Novel oral anticoagulants (NAOCs)

Novel oral anticoagulants (NOACs), such as direct thrombin inhibitors (DTIs; gatrans) and anti-factor Xa (xabans), target the single coagulation enzymes thrombin (dabigatran) or factor Xa (apixaban, rivaroxaban and edoxaban) (Table 8.21). In contrast to warfarin, NOACs have minimal food and drug interactions. Moreover, NOACs do not require monitoring and, compared with warfarin, have fewer thrombotic events and lower rates of major bleeding events. NOACs are thus poised to replace vitamin K antagonists for many patients with atrial fibrillation and may have a role after acute coronary syndromes. It is possible that two anticoagulants will eventually replace warfarin. The National Institute for Health and Care Excellence (NICE) has recommended dabigatran etexilate as a possible treatment to prevent stroke and systemic embolism in people with atrial fibrillation. The FDA has also approved rivaroxaban.

Dabigatran and rivaroxaban are both quickly absorbed (dabigatran action starts within 30 minutes to 2 hours of oral administration) and have short half-lives compared to warfarin, and so, in the event of excessive anticoagulant activity, discontinuing the drug is usually sufficient. They have no antidotes. There is no need for routine coagulation monitoring using the prothrombin time or INR.

Concomitant administration of potent permeability glycoprotein (P-gp) enzyme inducers (such as rifampicin, St John's wort, carbamazepine and phenytoin) can decrease dabigatran plasma concentrations and should be avoided. Co-administration of potent P-gp inhibitors, such as

quinidine, ketoconazole, amiodarone and verapamil, can increase plasma concentrations of dabigatran by enhancing its reabsorption via P-gp into the gastrointestinal tract. The anti-arrhythmic dronedarone should not be co-administered with dabigatran. As rivaroxaban is metabolized via CYP3A4 and CYP2J2, and is a substrate of P-gp, it is not recommended in patients receiving strong inhibitors of both CYP3A4 and P-gp, such as azole antimycotics and HIV protease inhibitors.

The known drug interaction profiles of both dabigatran and rivaroxaban, as regards antimicrobials and analgesics, are less restrictive than those of warfarin. It may be better to confine analgesic use to paracetamol (acetaminophen) since NSAIDs have antiplatelet effects. Table 8.21 shows data relevant to dental health care. Most dental situations, such as removal of a small number of teeth, would be comparable to treating a patient with an INR of 4 or below, relying on local haemostatic measures.

Surgery and oral anticoagulants

Vitamin K antagonists (VKAs), such as warfarin, should be continued in patients undergoing selected minor procedures. In major procedures that necessitate warfarin interruption, however, heparin bridging therapy, either with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), should be considered in patients at high thromboembolic risk and in a minority of those at moderate risk of thromboembolism. The emergence and anticipated routine clinical use of NOACs, such as the direct factor IIa (thrombin) inhibitor dabigatran and the direct factor Xa inhibitors rivaroxaban and apixaban, have the potential to simplify periprocedural anticoagulant management greatly. Minor dental procedures include tooth extractions, endodontic (root canal) and minor reconstructive procedures.

Clinical data support two approaches:

- Continuation of VKA and the use of a prohaemostatic agent (e.g. oral tranexamic acid mouthwash with local application and expectoration)
- Partial interruption of VKA therapy 2–5 days before the procedure.

Both approaches are associated with a low risk of clinically relevant bleeding (<5%) and rare thromboembolic outcomes (<0.1%), although minor bleeding (such as oozing from gingiva) may be common.

In patients on dabigatran who are undergoing relatively minor procedures (dental, skin, cataract; Box 8.5) or coronary angiography, it may be reasonable to continue dabigatran in the same circumstances in which warfarin can be safely continued. However, clinical data to support this approach are lacking, to date.

For major procedures or those involving a high bleed risk that necessitate the interruption of oral anticoagulant therapy, heparin bridging therapy using a standardized protocol should be reserved for patients at high thromboembolic risk and for a minority of patients at intermediate thromboembolic risk. Depending on procedural bleed risk and haemostasis, postprocedure initiation of bridging therapy for most major surgeries should delay resumption of treatment-dose therapy for a full 48–72 hours, using a stepwise approach moving from prophylactic to treatment doses; alternatively, bridging therapy should be avoided altogether during reinitiation of warfarin. For the NOACs, the timing of postprocedural reinitiation should also depend on procedural bleed risk, haemostasis and renal function (especially in the case of dabigatran), with either delayed resumption of full-dose therapy or stepwise resumption moving from prophylactic to full dose in the case of high-bleed-risk procedures. Given the pharmacokinetic profiles of the NOACs, heparin bridging therapy is unlikely to be useful, except in cases where patients cannot tolerate oral medications postoperatively.

Box 8.5 Procedural bleeding risks

High (2-day risk of major bleed 2–4%)

- Heart valve replacement
- Coronary artery bypass
- Abdominal aortic aneurysm repair
- Neurosurgical/urological/head and neck/abdominal/breast cancer surgery
- Bilateral knee replacement
- Laminectomy
- Transurethral prostate resection
- Kidney biopsy
- Polypectomy, variceal treatment, biliary sphincterectomy, pneumatic dilatation
- *Percutaneous endoscopic gastrostomy (PEG) placement*
- Endoscopically guided fine-needle aspiration
- *Multiple tooth extractions*
- Vascular and general surgery
- Any major operation (procedure duration < 45 min)

Low (2-day risk of major bleed 0–2%)

- Cholecystectomy
- Abdominal hysterectomy
- Gastrointestinal endoscopy, biopsy, enteroscopy, biliary/pancreatic stent without sphincterotomy, endosonography without fine-needle aspiration
- Pacemaker and cardiac defibrillator insertion and electrophysiological testing
- *Simple dental extractions*
- Carpal tunnel repair
- Knee/hip replacement and shoulder/foot/hand surgery and arthroscopy
- Dilatation and curettage
- *Skin cancer excision*
- Abdominal hernia repair
- Haemorrhoidal surgery
- Axillary node dissection
- Hydrocoele repair
- Cataract and non-cataract eye surgery
- Non-coronary angiography
- Bronchoscopy/biopsy
- Central venous catheter removal
- Cutaneous and bladder/prostate/thyroid/breast/lymph node biopsies

Adapted from Spyropoulos AC, Douketis JD. How I treat anticoagulated patients undergoing an elective procedure or surgery. *Blood* 2012 11 Oct; 120(15):2954.

^aItalics show the most relevant risks.

Several oral direct thrombin inhibitors (DTIs) and factor Xa (FXa) inhibitors have received recent FDA approval or are under investigation in late-stage clinical trials for the prevention and treatment of thromboembolic events. Rapid reversal of anticoagulation is typically recommended in patients with severe or life-threatening bleeding and in those requiring surgery or invasive procedures. However, no antidote exists for DTIs or FXa inhibitors, though replacement of coagulation factors using clotting factor concentrates is routinely considered in some clinical scenarios. Clotting factor concentrates available in the United States include prothrombin complex concentrate, activated prothrombin complex concentrate, and recombinant factor VII, activated. Coagulation tests to confirm adequate reversal of anticoagulation should be considered and commonly include APTT and TT for DTIs, and chromogenic FXa assay and TT for FXa inhibitors.

Monitoring of coagulation tests should continue for 1–2 days after achievement of haemostasis, since the duration of the clotting factor

Fig. 8.13 Ecchymosis tracking to mediastinum after oral surgery.

concentrate may be shorter than that of the oral anticoagulant, especially in patients with organ dysfunction.

Dental aspects of oral anticoagulants

Some patients on anticoagulant drugs have a tendency to bleed excessively after trauma or surgery. Dental preventive care is especially important in order to minimize the need for surgical intervention. Alternatives, such as endodontics, should always be considered. Patients must be warned of the risk of intra- and postoperative bleeding and intra-/extraoral bruising (Fig. 8.13). Systemic conditions that may aggravate the bleeding tendency include coagulopathies, thrombocytopenias, vascular disorders such as Ehlers–Danlos syndrome, liver disease, renal disease, malignancy and HIV infection. Drugs that might worsen the bleeding tendency (aspirin and other NSAIDs) should be avoided (see later), as should intramuscular injections. Regional block LA injections may also be a hazard. Bleeding into the fascial spaces of the neck can threaten airway patency. Intraligamentary or intrapapillary injections are safer. CS can be given but, if intravenous, care must be taken not to damage the vein. GA requires expert attention in hospital.

In general, anticoagulation should not be stopped, except for very good reasons, because it does not necessarily reduce bleeding significantly; in contrast, stopping anticoagulation may cause hypercoagulability and rebound thrombosis, which has damaged prosthetic cardiac valves and even caused thrombotic deaths in dental patients. Certainly, anticoagulant treatment should not be altered without the agreement of the clinician in charge.

Warfarin does not usually need to be stopped before primary-care dental surgical procedures. *Minor dental procedures*, such as the administration of infiltration LA, restoration placement, fabrication of fixed and removable prosthetic appliances, and supragingival scaling and polishing, do not usually require consideration of the INR, but the prudent dentist will consult with the physician responsible for the patient's warfarin therapy before performing *more invasive procedures*.

Such potentially invasive procedures as the administration of LA via an inferior alveolar nerve block, dentoalveolar surgery (tooth extractions, periodontal surgery, implant placement, biopsies) and subgingival scaling, as well as the prescribing of certain medications, may need modification. The discussion should include the patient's recent INR values, access to the patient's INR value on the day of surgery, consideration of optimizing blood pressure control to minimize intraoperative bleeding, and an assurance that the patient is not also receiving antiplatelet agents (such as aspirin and/or clopidogrel). Although it is not uncommon for the physician to concur with or support the guidelines that permit interruption of anticoagulation for a period of up to 1 week for surgical procedures that carry a risk of bleeding (e.g. those of the American Heart Association [AHA]), the dentist should alert the physician to more recent guidelines (such as those of the American Dental Association Council on Scientific Affairs [ADA/SCA]), as these recognize that, while the older guidelines may be relevant for patients undergoing major surgery, they are not applicable for patients having dentoalveolar surgery. The dentist can emphasize that the ADA/SCA, the British Dental Association, the National Patient Safety Agency and the Haemostasis and Thrombosis Task Force of the British Committee for Standards in Haematology, having reviewed the scientific literature, have concluded that warfarin therapy should *not* be discontinued for patients having routine dentoalveolar surgery if the INR is below 4. This is due to the difficulty in predicting the drop in the INR value in any given patient and because the risk of experiencing a thromboembolism (which may be fatal) outweighs the risk of excessive postoperative oral bleeding. These conclusions should be reassuring to the physician because this level of anticoagulation is far in excess of the 2.0–3.0 range (2.5 target) typically prescribed for patients with atrial fibrillation and thus provides an even greater margin of safety. The guidelines from the National Patient Safety Agency are available at <http://www.nrls.npsa.nhs.uk/resources/?entryid45=59814> (accessed 30 September 2013). Note, however, that there are no studies to date involving significant numbers of patients having more extensive surgeries, such as more than six extractions, removal of impacted teeth, alveolectomies and tori removal.

Previously published studies have identified certain procedures or precautions that may limit intraoperative and postoperative haemorrhage when performing oral surgery for these patients. The administration of LA agents containing vasoconstrictors assists in maintaining a dry surgical field, and intraligamentary and intrapapillary injections are preferred over regional blocks if the INR is above 4.0 because of an anecdotal risk of bleeding into the floor of mouth and fascial planes of the neck with consequent obstruction of the airway.

To minimize the risk and extent of postoperative bleeding, the number of teeth to be extracted at any one sitting should be limited and, when required, teeth should be sectioned so as to limit the need for bone removal. When needed, subperiosteal tension-free flaps should be raised and minimal bone removed so as to enhance clot stabilization. Resorbable gelatin or oxidized cellulose materials should be placed in the socket; the bony wound should be compressed; soft tissues should be closely apposed; and tight multiple interrupted sutures should be placed. The patient should be requested to bite on saline-soaked gauze compresses for 30 minutes and advised not to exercise or to rinse their mouth for 24 hours or to take anything other than a cold liquid diet for 48 hours. Some clinicians augment the above by also asking the patient to rinse their mouth with an antifibrinolytic, such as EACA (or tranexamic acid), four times per day for 2 minutes.

When more complex and invasive maxillofacial surgical procedures are planned, such as an extraoral open reduction of facial fractures, which is associated with extensive bleeding, for patients without a history of prior stroke, transient ischaemic attack, systemic embolisms or

Table 8.22 Warfarin therapy and surgery

	Prothrombin time(s)	Thrombotest	INR
Normal level	<1.3	>70%	1

Levels at which dentoalveolar surgery can be carried out ^a	<2.5	>15%	<4

^aUncomplicated forceps extraction of 1–3 teeth.

mechanical heart valve, the AHA's guidelines may be applicable. The warfarin therapy should be managed with the patient's physician and the INR must be evaluated on the day of surgery. Older individuals are slower to normalize an elevated INR and may experience warfarin-related bleeding events at lower INRs than do younger individuals. In some instances, the physician may prescribe 'bridging anticoagulation' of subcutaneous LMWH in order to shorten the time that the patient is unprotected from thromboembolism. Typically, the last preoperative dose of LMWH is administered 24 hours before surgery. The first postoperative dose is given no earlier than 24 hours after surgery, and commonly on the second postoperative day when haemostasis has been secured. Warfarin therapy may be reinstituted on the evening of surgery if haemostasis has been assured; if not, then it is started 24 hours postoperatively.

Most cases of postoperative bleeding are easily treated with local measures, such as packing with a haemostatic dressing, suturing and pressure.

For patients awaiting elective dental procedures who are taking warfarin for a limited period (e.g. 6 months for a DVT), the procedure should be postponed until the warfarin has been stopped.

UK Medicines Information (UKMI) summarizes these guidelines as follows:

- An INR should be measured within 24–72 hours of undertaking the procedure.
- The UKMI recommends that no individuals should have a dental procedure in primary care if they have an INR of more than 4.0; however, the British Committee for Standards in Haematology guidelines recommend that the INR should be no greater than 2 at the time of the procedure.
- The UKMI also recommends that warfarin patients with renal or hepatic disease or those on chemotherapy or cytotoxics should have dental procedures in hospital.

The management of patients on anticoagulants (Table 8.22) should consider: the type of procedure; the INR value, which can be tested approximately if necessary with a bedside machine (Fig. 8.14); the underlying condition for which anticoagulation is used; and other risk factors.

The INR should be checked on the day of operation or, if that is not possible, the day before. For patients with a constant INR level of up to 2.5 who need emergency surgery, an INR level determined within the week before surgery can be used. A bedside device, such as the CoaguChek (Roche Diagnostics), may be used. It appears that there may be statistically significant INR differences between CoaguChek and the international reference preparations, but these test strips achieve a clinically acceptable level of accuracy.

Medico-legal and other considerations suggest that one should err on the side of caution and fully inform and discuss treatment with the patient, take medical advice in any case of doubt, and arrange adjustment of warfarin for patients with INR greater than 4.0, or greater than 3.0 if the procedure is not minor.

Fig. 8.14 CoaguChek for measuring INR.

Table 8.23 Protocol for warfarinized patients having oral surgery

Preoperatively	Perioperatively	Postoperatively for 24 h
Check INR within 24 h of operation	Minimize trauma	Rest
If INR <3.5 (some suggest <3), and no liver disease, do not change warfarin	Use regional block LA only if essential	No mouth-rinsing
If INR <3.5, and liver disease, or if INR >4, consult physician about reducing warfarin	Local haemostatic measures ^a	No hot food or drink
No NSAIDs	No NSAIDs	No chewing

^aLocal haemostatic measures (see Table 8.14).

Always refer patients to hospital for care in the presence of any of the following conditions: INR of more than 4; the need for more than simple surgical procedures; the presence of additional bleeding risk factors or logistical difficulties; and drug interactions with warfarin.

If surgery is to be more than simple or minor, or the INR is over 4.0, or other risk factors are present, the patient should be treated in hospital and consideration given to whether the anticoagulation will need to be modified, possibly changing to heparin during the preoperative period (Table 8.23). If anticoagulants are to be continued after the operation, vitamin K should be avoided, as it makes subsequent anticoagulation difficult. Usually, it is simply best to discontinue the warfarin for 2 or 3 days preoperatively. A 2-day suspension appears to be a simple and safe policy for patients with prosthetic heart valves who are anticoagulated. If necessary, LMWHs can be used. To prevent postoperative bleeding, an antifibrinolytic agent (tranexamic acid; see later) can be used topically to control haemorrhage. Warfarin therapy should be restarted simultaneously with heparin unless a contraindication exists or the patient is suspected of having a hypercoagulable state. Heparin should be stopped once the INR reaches the required therapeutic level. Generally, heparin and warfarin overlap for approximately 4 days. Follow-up INR with the patient's physician should be arranged for 3 days after discharge.

Whenever possible, potentially problematic surgical procedures are best carried out in the morning, allowing more time for haemostasis before nightfall, and early in the week, to avoid problems at the week-end when staffing may be less intense. Unless the patient is also an active cocaine abuser, 2% lidocaine with 1:80 000 or 1:100 000 adrenaline (epinephrine) should be used. Adrenaline should then be avoided.

Bleeding should be assessed intraoperatively and, if there is concern, an absorbable haemostatic agent such as oxidized regenerated

cellulose, resorbable gelatin sponge or collagen (synthetic or microcrystalline or porcine) can be placed in the socket. Cyanoacrylate or fibrin glues provide rapid haemostasis, as well as tissue sealing and adhesion. Recombinant fibrin products are preferred.

Suturing is desirable to stabilize flaps and to prevent postoperative disturbance of wounds by eating. Resorbable sutures are preferred since they retain less plaque. Gauze pressure (a gauze soaked with tranexamic acid helps; see later), asking the patient to bite on the gauze for 10 minutes, helps haemostasis. If bleeding is controlled, the patient should be dismissed and given a 7-day follow-up appointment and the phone number of the surgery, with instructions to call if bleeding starts. Additional risk factors for bleeding should prompt the treating clinician to be more cautious (i.e. to place more sutures and to prescribe in advance an antifibrinolytic drug such as topical 4.8% tranexamic acid, for up to 7 days).

Postoperatively, the patency of the airway must be ensured. Care should be taken to watch for haematoma formation, often signified by swelling, dysphagia or hoarseness.

Many patients can be managed postoperatively with antifibrinolytic agents given topically as mouthwashes during the first 7–10 days. Systemic tranexamic acid does not result in therapeutic concentrations in saliva. Topical tranexamic acid is effective, even when anticoagulant therapy remains unchanged. Controlled studies have shown the efficacy and safety of tranexamic acid mouthwashes, and their lack of unwanted systemic effects. Overall, tranexamic acid reduces bleeding complications to 0–7% from 13–40% in controls. It is given topically as 10 mL of a 4.8–5% w/v solution, used as a mouthwash for 2 minutes, four times daily for 7 days.

Infection also appears to induce fibrinolysis and therefore antimicrobials, such as oral penicillin V 250–500 mg four times daily, or clindamycin, should be given postoperatively for a full course of 7 days if there is risk of secondary haemorrhage. Metronidazole is contraindicated, and amoxicillin and erythromycin are less appropriate because of possible drug interactions with warfarin, which may enhance bleeding.

For postoperative pain management, paracetamol is the analgesic and antipyretic of choice for *short-term use* in patients on oral anticoagulant therapy. It is preferred over NSAIDs since it does not affect platelets. Codeine is a suitable alternative analgesic. A diet of cool liquid and minced solids should be taken for several days.

Postoperative prolonged bleeding should be controlled by biting on a moist gauze, a gauze pad soaked in tranexamic acid, or a moist tea bag with firm pressure for 30 minutes. Faced with persistent bleeding, the dentist must establish whether the situation is urgent, when the patient will require admission for intravenous fluids or reversal of anticoagulation. This may be needed if the patient is losing large quantities of blood or is hypotensive (hypovolaemic).

To stop oral bleeding, an LA injection containing adrenaline (epinephrine) should be given and a sterile gauze pad soaked with tranexamic acid should be pressed over the extraction socket for 10–15 minutes. The socket edges should be approximated by squeezing with the fingers. The socket should then be sutured using black silk sutures to ensure tight closure. A resorbable haemostatic preparation may be placed in the socket before suturing. If the patient continues to bleed, consult the physician about possible use of vitamin K.

In people at high risk of bleeding or undergoing major surgery in which normal haemostasis is required, NOACs such as dabigatran etexilate should be stopped 2–5 days before surgery. If surgery is elective and the patient has normal renal function, two doses of the drug can be missed; if renal function is abnormal, the patient should miss three or four doses of dabigatran. Warfarin remains the treatment of choice for patients with a low creatinine clearance below 15 mL/min.

Heparins

Heparin acts by potentiating antithrombin III, which inhibits the activation of clotting factors II, IX, X and XI and prolongs the APTT. Use for more than 5 days can induce thrombocytopenia.

Unfractionated heparin (UFH) is given via intravenous infusion, with the dose titrated according to the APTT. The half-life of UFH is 1 hour, making it useful where rapid normalization of anticoagulation is required: for example, before surgery. If more rapid reversal of anticoagulation is needed, protamine can be used.

Low molecular weight heparins (LMWHs; ardeparin, dalteparin, danaparoid, enoxaparin, nadroparin, reviparin, tinzaparin) act more specifically on inhibition of factor X activation and the APTT is therefore normal. A factor Xa assay can be used to monitor the anticoagulant effect of LMWH but this is not routinely required. LMWH is at least as safe and effective as UFH in the treatment of uncomplicated DVT. Overlapping the initiation of warfarin permits long-term anticoagulation. Advantages include a decreased incidence of heparin-induced thrombocytopenia and fewer bleeding episodes.

General aspects

Heparin is a natural product, abundant in granules of the mast cells that line the vasculature, and is released in response to injury. It is also used as a parenteral anticoagulant given subcutaneously or intravenously, for acute thromboembolic episodes or for hospitalization protocols that include significant surgical procedures, to prevent DVT and pulmonary emboli. Heparin is a sulphated glycosaminoglycan and was originally obtained from liver (hence *heparin*). It acts immediately on blood coagulation to block the conversion of fibrinogen to fibrin, mainly by inhibiting the thrombin–fibrinogen reaction via its binding to and catalysing of antithrombin III, which then inhibits the serine proteases of the coagulation cascade to inactivate thrombin. Heparin also acts on activated factors IX–XII and increases platelet aggregation but inhibits thrombin-induced activation. The anticoagulant effect of standard or unfractionated heparin has an immediate action on blood clotting, which is usually lost within 6 hours of stopping it.

The PT, APTT and TT are prolonged. Most patients are monitored with the APTT and are maintained at 1.5–2.5 times the control value (the therapeutic range). Large doses of heparin can also prolong the INR. Platelet counts should also be monitored if heparin is used for more than 5 days, since it can cause thrombocytopenia. Autoimmune thrombocytopenia is possible within 3–15 days, or sooner if there has been previous heparin exposure.

Heparin is available as standard or unfractionated heparin or LMWHs. The latter, such as certoparin, interact with factor Xa but do not affect standard blood test results. Low-dose heparin therapy, such as Minihep, is used to reduce the risk of DVT. Some heparins are also being used for other effects, such as immunosuppression.

LMWHs have more predictable pharmacokinetic and pharmacodynamic properties than the largely replaced UFH. Antifactor Xa monitoring is superior to measurement of APPT, and is prudent in patients with severe obesity or renal insufficiency, and UFH infusion is preferable to LMWH injection in patients with renal failure. Protamine may help reverse bleeding related to LMWH. The synthetic pentasaccharide fondaparinux is a promising new antithrombotic agent. Exclusion criteria for outpatient therapy with LMWH are shown in [Box 8.6](#).

Dental aspects of heparin anticoagulation

For uncomplicated forceps extraction of 1–3 teeth, there is usually no need to interfere with heparin or LMWH anticoagulation.

Box 8.6 Exclusion criteria for outpatient therapy with low-molecular-weight heparins

- Clinical evidence of pulmonary embolism or suspected embolism
- Conditions that increase the risk of bleeding:
 - Recent surgery
 - Peptic ulcer disease
 - Malignant hypertension
 - Increased risk of falling
- High risk of recurrent thrombosis:
 - Extensive proximal deep venous thrombosis
 - Recurrent deep venous thrombosis
- Pregnancy
- Protein C or S deficiency
- Likelihood of non-compliance
- Unavailability for follow-up
- Inadequate home support system

Before more advanced surgery in a heparin-treated patient, medical advice should be sought. Heparin has an immediate effect on blood clotting but acts for only 4–6 hours and no specific treatment is therefore needed to reverse its effect. The effect of heparin is best assessed by the APTT. Withdrawal of heparin is adequate to reverse anticoagulation where this is necessary. In an emergency, anticoagulation can be reversed by intravenous protamine sulfate given in a dose of 1 mg per 100IU heparin, but a medical opinion should be sought first. Where heparin has been stopped, any surgery can safely be carried out after 6–8 hours. In renal dialysis patients, or those having cardiopulmonary bypass or other extracorporeal circulation with heparinization, surgery is best carried out on the day after dialysis. The effects of heparinization have then ceased and there is maximum benefit from dialysis.

LMWHs may have little effect on postoperative bleeding, despite their longer activity (up to 24 hours). However, the advice of the haematologist should be sought before surgery.

Aspirin and antiplatelet drugs

These include clopidogrel and glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide and tirofiban; [Table 8.24](#)). They can affect the APTT and postoperative bleeding.

Aspirin irreversibly impairs platelet aggregation and is used long-term in the prevention of cardiovascular events and stroke in patients at risk. In large doses, aspirin may also cause hypoprothrombinaemia. Even small doses prolong the bleeding time and impair platelet adhesiveness. Aspirin may worsen bleeding tendencies if there are other anticoagulation medications or other bleeding disorders, such as uraemia.

In patients with no other cause for a bleeding tendency who are receiving up to 100mg aspirin daily, in general, for uncomplicated forceps extraction of 1–3 teeth, there is no need to interfere with aspirin treatment. Suturing and packing the socket with resorbable gelatin sponge, oxidized cellulose or microfibrillar collagen can be carried out if necessary.

In patients with no other cause for a bleeding tendency who are receiving doses of aspirin higher than 100mg daily, if there is concern, the current value of the bleeding time should be established. If it is over 20 minutes, surgery should be postponed.

In practice, aspirin rarely interferes significantly with dental surgical procedures.

Table 8.24 Other parenteral anticoagulant agents

Antiplatelets	Heparinoids	Hirudins	Low-molecular-weight heparins	Prostacyclin
Abciximab	Danaparoid	Desirudin	Certoparin	Epoprostenol
Aspirin		Lepirudin	Dalteparin	
Clopidogrel			Enoxaparin	
Dipyridamole			Reviparin	
Eptifibatide			Tinzaparin	
Ticlopidine				
Tirofiban				

Other drugs affecting haemostasis

Other parenteral agents influencing haemostasis include *heparinoids*, such as danaparoid; and *hirudins*, such as lepirudin and desirudin (see [Table 8.24](#)). The physician should be consulted before any major surgical procedure but dentoalveolar surgery is usually uncomplicated.

VITAMIN K DEFICIENCY AND MALABSORPTION**General aspects**

Vitamin K is a fat-soluble vitamin present in the diet and also synthesized by the gut flora. It is absorbed in the small gut, in the presence of bile salts. After transport to the liver, vitamin K is used for the synthesis of factors II (prothrombin), VII, IX and X. Haemorrhagic disease may, therefore, result from interference with vitamin K use by:

- anticoagulants
- malabsorption
- obstructive jaundice
- severe liver disease.

General management

In liver disease, many haemostatic functions are severely impaired and vitamin K is of little or no value ([Box 8.7](#)).

Dental aspects

Dental management in vitamin K deficiency may be complicated by the clotting defect and the underlying disorder, particularly obstructive jaundice (Ch. 9). The latter may be caused by gallstones, viral hepatitis or carcinoma of the head of the pancreas.

The underlying disorder should preferably be corrected but vitamin K can be given if surgery is urgent. Phytomenadione (5–25mg) is the most potent and rapidly acting form and should preferably be given intravenously. The PT should be monitored after 48 hours; if the defect has not been corrected by then, this suggests parenchymal liver disease.

Liver disease is an important cause of bleeding disorders related to: impaired vitamin K metabolism; excessive fibrinolysis; failure of synthesis or overconsumption of normal clotting factors; synthesis of abnormal clotting factors; and thrombocytopenia.

Haemorrhage can be severe and difficult to manage because of the complexity of these defects.

Antifibrinolytic treatment and fresh-frozen plasma may sometimes be effective. If there is an obstructive element to the disease, vitamin K may be effective, but only if parenchymal disease is mild (Ch. 9).

Box 8.7 Causes of vitamin K deficiency^a

- Lack of vitamin K synthesis in the gut
- Broad-spectrum antibiotics used for prolonged periods
- Parenteral feeding in inpatients
- Poor absorption
- Malabsorption syndromes
- Blind loop syndrome
- Obstructive jaundice
- Failure of utilization
- Oral anticoagulant treatment
- Liver failure
- Viral hepatitis (has an obstructive component)

^aDeficiency responds to parenteral vitamin K.

FIBRINOLYTIC DRUGS

Fibrinolytic drugs, such as streptokinase, may cause abnormal bleeding and dental surgery should be deferred where possible.

ACQUIRED HAEMOPHILIA

Acquired haemophilia is a rare disorder caused by circulating antibodies to factor VIII; these typically are of unknown origin but may rarely form in autoimmune disorders such as rheumatoid arthritis, drug therapy (especially with penicillin), and pregnancy or the puerperium. In contrast to congenital haemophilia, females are affected just as frequently as males.

Specialist haematological attention is required before any operative treatment is considered.

OTHER DISORDERS ASSOCIATED WITH BLEEDING TENDENCIES

These may include:

- the period after massive transfusions
- antibodies to clotting factors
- chronic renal failure (Ch. 12)
- cyanotic congenital heart disease (Ch. 5)
- disseminated intravascular coagulopathy
- Gram-negative shock
- head injuries (Ch. 24)
- hypertension
- myelofibrosis, leukaemia or lymphoma (see later)
- polycythaemia vera (see later).

POSTOPERATIVE BLEEDING

Plasminogen and plasminogen activator are present in the oral environment, since plasminogen is secreted into the saliva and t-PA arises from oral epithelial cells and gingival crevicular fluid. Oral surgery induces changes of fibrinolysis; initially, the fibrinolytic activity of saliva is weakened, due to inhibitors of fibrinolysis originating from the blood and the wound exudates, but when the bleeding and exudation abate, the fibrinolytic activity of saliva increases. This may contribute to bleeding.

Prolonged bleeding after dental extraction is, however, one of the most common signs of haemorrhagic disease and may amount to a haemorrhagic emergency. It is sometimes how the bleeding tendency is first recognized.

Faced with a bleeding patient, the dentist must establish whether the situation is urgent; whether there could be a bleeding tendency; or if the patient is losing large quantities of blood, whether the patient is hypotensive (hypovolaemic) or bleeding internally.

MANAGEMENT OF POSTOPERATIVE BLEEDING

The precise site or origin of the bleeding must be discovered by cleaning out the mouth with swabs. Pressing firmly with a gauze pad over the socket for 10–15 minutes will usually stop the bleeding, even in some bleeding tendencies, but this is often only temporary. A quicker and more effective means is to suture the socket under LA. If the bleeding persists, consider a systemic cause such as ascertaining whether there are:

- acquired deficiencies of haemostasis, such as those caused by anticoagulants or thrombocytopenia
- hereditary deficiencies of clotting factors (e.g. vWD and haemophilia).

There could be a bleeding tendency if the bleeding is unexplained by the degree of trauma or there is a previous or family history of excessive bleeding, such as:

- a previous diagnosis of a bleeding tendency
- bleeding for more than 36 hours or restarting more than 36 hours after operation (however, this could indicate an infection)
- admission to hospital to arrest bleeding
- blood transfusion for bleeding
- spontaneous bleeding (e.g. haemarthrosis, deep bruising or menorrhagia from little obvious cause)
- a convincing family history of one of the above, combined with a degree of personal history
- treatment with significant drugs such as anticoagulants.

In emergencies, an intravenous line must be established and plasma expanders or blood given. Blood transfusions used to be refused by Jehovah's Witnesses, but their principles are being reconsidered and alternatives to allogeneic blood are becoming available. In this group, blood loss may be minimized by using aprotinin and tranexamic acid. Recombinant blood coagulation factors are acceptable to Jehovah's Witnesses (Ch. 30). Erythropoietin is acceptable, as often is intraoperative salvage of blood or acute normovolaemic haemodilution (ANH; the preoperative removal of blood and its replacement by crystalloid or colloid, followed by reuse of the patient's blood at operation). Some will accept the use of Hemopure, a polymerized bovine haemoglobin.

Transfusions carry the risk of blood-borne viral infections (Chs 9 and 21) and circulatory overload.

BLOOD TRANSFUSION

Blood can supply a range of products useful in a variety of situations (Fig. 8.15). Perioperative blood loss and anaemia is best dealt with by reducing the amount of blood lost at surgery through minimizing trauma, improving mechanical haemostasis, limiting phlebotomy to essential diagnostic tests, using microsample laboratory techniques; and giving antifibrinolytics, such as EACA or tranexamic acid (or, for high-risk procedures, aprotinin). Erythropoietin can also help where blood has been lost but the replacement of blood by transfusion can be essential after severe haemorrhage and in some other circumstances. Allogeneic blood transfusion (from a genetically similar but not identical donor) may carry hazards of:

- incompatibility
- fluid overload

Fig. 8.15 Blood products.

Box 8.8 Diseases known to be transmitted via allogeneic blood transfusion

- Bacterial infections (various)
- Chagas disease
- Cytomegalovirus infection
- Hepatitis A virus infections
- Hepatitis B virus infections
- Hepatitis C virus infections
- Human immunodeficiency virus (HIV-1 and HIV-2) infection
- Human T-lymphotropic viruses (HTLV-1 and HTLV-2) infection
- Malaria
- *Treponema pallidum* infection
- West Nile virus infection
- Variant Creutzfeldt–Jakob disease (prions)

- transmission of infections (Box 8.8)
- post-transfusion purpura
- transfusion-associated graft-versus-host disease
- transfusion-associated acute lung injury (TRALI).

In the UK, therefore, blood is now screened and leukodepletion also used, as this reduces the risk of infection and also of acute non-haemolytic transfusion reactions and transfusion-associated graft-versus-host disease.

Some medications may be transmitted, and this is especially a concern with pregnant women and prostatic medications such as dutasteride and finasteride (Ch. 25). Allogeneic transfusion may lead to an increased risk of postoperative bacterial infections and multiorgan failure.

Autologous transfusion (obtained from the same individual) reduces the need for allogeneic transfusion and is most widely used in elective surgery. The three main techniques are pre-deposit transfusion, intraoperative haemodilution, and intraoperative and postoperative salvage. Autologous transfusion is more cost-effective than allogeneic transfusion and clinical outcomes are improved.

If blood transfusion is needed:

- establish an intravenous line
- take blood for grouping and cross-matching
- seek a surgical opinion and begin a thorough secondary survey
- organize quarter- or half-hourly observations of pulse rate, blood pressure, respiratory rate, daily urine output and fluid balance (usually daily).

Fig. 8.16 Jehovah's Witness declaration.

Fig. 8.17 Transfusion-associated graft-versus-host disease warning card.

Blood transfusion is not needed to replace losses of less than 500 mL in an adult, unless there was pre-existing anaemia or deterioration of the general condition warrants transfusion. Blood should therefore never be given unless warranted. In people belonging to some faiths, such as Jehovah's Witnesses, transfusion is not permissible (Fig. 8.16 and Ch. 30), as discussed above.

Transfusion-associated graft-versus-host disease

Transfusion-associated graft-versus-host disease is a rare but serious complication of blood transfusion. People at risk include those who have:

- received blood transfusions from HLA-matched donors, including family members
- had a stem-cell transplant
- inherited immune defects
- acquired immune defects, such as Hodgkin disease
- been treated with purine analogues, such as fludarabine, cladribine or deoxycytosine.

Transfusion-associated graft-versus-host disease results from transfused leukocytes; gamma irradiation of the transfused blood will obviate the reaction.

Patients should be pre-warned and should carry a warning card themselves (Fig. 8.17).

THROMBOTIC DISORDERS

Superficial vein thrombosis may complicate intravenous injections, particularly of diazepam, but does not lead to pulmonary embolism. Treatment

Table 8.25 Disorders predisposing to thromboses

Factor involved	Genetic forms	Acquired forms	Management
Antithrombin deficiency	Autosomal dominant Affects ~1 per 2000 of population	Eclampsia, disseminated intravascular coagulation (DIC), nephrotic syndrome	Resistant to heparin anticoagulation – use oral anticoagulants or fresh-frozen plasma
Factor V Leiden	Autosomal dominant Affects ~5% of population	Liver transplantation	Warfarin
Platelets (thrombocytosis and thrombocythaemia)	–	Exercise, pregnancy, trauma, post-splenectomy, chronic inflammatory disease, malignancy	Treat underlying cause. Preoperative aspirin, dipyridamole or heparin
Protein C deficiency	Autosomal dominant	Warfarin, liver disease, vitamin K deficiency, sepsis, DIC, thrombosis, asparaginase (crisantaspase)	Protein C concentrate or anticoagulation
Protein S deficiency	Genetic	Liver disease, DIC	Management takes place in the event of acute venous thromboembolism or in patients with asymptomatic carrier states without a thrombotic event. Heparin therapy and then warfarin

of acute episodes of thrombosis is by subcutaneous injection or infusion of heparin (for 5–7 days), followed by oral anticoagulant therapy.

DEEP VEIN THROMBOSIS AND THROMBOEMBOLIC DISEASE

General aspects

Blood contains natural anticoagulants, mainly antithrombin, which inhibits several activated coagulation factors, including thrombin, factor IXa and factor Xa, by forming a stable complex with the various factors. Heparin and heparan sulphates increase the activity of antithrombin at least 1000 fold. Other natural anticoagulants include protein S and protein C, which inhibit activated factor V (Table 8.25).

Deep vein thrombosis (DVT) and subsequent pulmonary embolism (PE) are important sequelae and causes of death or significant morbidity, especially in older, bedridden and postoperative patients as a consequence of immobility and pressure on the calf from prolonged bed rest; there is also increased blood coagulability in pregnancy. They may also follow GA and surgery. Several other factors may contribute, including, sometimes, dehydration or oral contraceptives (Fig. 8.18).

About 30% of people who have had a DVT or PE are at risk for another episode. Factors that increase the risk of thrombosis include:

- injury to a vein:
 - ◆ fractures
 - ◆ muscle injury
 - ◆ major surgery (particularly involving the abdomen, pelvis, hip or legs)
- slowed blood flow:
 - ◆ confinement to bed or a chair
 - ◆ limited movement (e.g. after surgery or a plaster cast on a leg)
 - ◆ paralysis
- increased oestrogen:
 - ◆ hormonal contraceptives
 - ◆ hormone replacement therapy
 - ◆ pregnancy
- coagulation disorders:
 - ◆ factor V Leiden
 - ◆ prothrombin
 - ◆ antithrombin III deficiency
 - ◆ protein C deficiency
 - ◆ protein S deficiency
 - ◆ antiphospholipid syndrome
 - ◆ hyperhomocysteinaemia

**Fig. 8.18** Deep vein thrombosis causes.

- chronic medical disorders:
 - ◆ heart disease
 - ◆ lung disease
 - ◆ cancer
 - ◆ inflammatory bowel disease (Crohn disease or ulcerative colitis)
- other factors:
 - ◆ advancing age
 - ◆ central vein catheter
 - ◆ DVT or PE previously or positive family history
 - ◆ hypertension
 - ◆ obesity
 - ◆ smoking.

Hypercoagulability (thrombophilia) is when there is a risk of thrombosis under circumstances that would not cause thrombosis in a normal person and is common postoperatively, during long-haul air flights ('economy class syndrome') and in obesity. Oestrogen use, malignant and myeloproliferative disease, congestive cardiac failure, homocystinuria and systemic lupus erythematosus (anticardiolipin antibodies) also lead to a hypercoagulable state.

Activated protein C (APC) normally inactivates coagulation factor V, slowing down the clotting process and prevents clots from growing. Defects of protein C or other natural anticoagulants (antithrombin or protein S), as well as impaired fibrinolysis or Leiden factor (Table 8.26), can cause thrombosis.

Factor V Leiden thrombophilia is an inherited increased clotting tendency seen in about 5% of Europeans, who have an abnormal blood clotting factor V (termed factor V Leiden) that cannot be inhibited by protein C. These individuals are predisposed to blood clotting, with a

Table 8.26 Medications used as prophylaxis for thromboses

Antiplatelet agents	Heparins	Hirudins	Oral anticoagulants
Aspirin	Dalteparin	Lepirudin	Apixaban
Clopidogrel	Danaparoid		Dabigatran
Dipyridamole	Enoxaparin		Warfarin
Ticagrelor	Heparin sodium		
	Tinzaparin		

higher than average risk of DVT (most often in the legs but also the brain, eyes, liver and kidneys), pulmonary emboli and increased risk of pregnancy loss (miscarriage).

Clinical features of DVT

About half of people with DVT have no symptoms. Venous thrombosis usually affects the deep calf veins and there the most common symptoms include:

- pain, especially on flexing the ankle (Homan sign) – characteristic but its absence should certainly not be relied upon to exclude the diagnosis
- swelling
- tenderness
- redness.

About 30% of people who have a DVT develop complications (post-thrombotic syndrome [PTS]), caused by damage to the vein valves. PTS manifests with swelling, pain, discolouration, scaling or ulcers in the affected part. In some cases, PE may ensue and can be lethal.

General management of DVT

Prophylaxis against venous thromboembolism is important but not reliably effective. Consideration should be given to stopping the contraceptive pill preoperatively.

The calves must not rest on hard objects during surgery and stasis may be eliminated by calf contractions stimulated electrically, by use of compression hosiery or by pneumatic compression. Early mobilization and leg movements postoperatively must be encouraged. Heparin anticoagulation is the most effective method of preventing thromboembolism but must be balanced against the risks of haemorrhage. However, low-dose heparin, sufficient to provide an INR between 1.5 and 2, protects against DVT without inducing a significant risk of bleeding. Fondaparinux sodium (which blocks factor X) is an alternative.

DVT is often diagnosed clinically but confirmed using:

- duplex ultrasound to evaluate the vein blood flow
- venography
- blood D-dimer test – indicates abnormally high levels of fibrin degradation products, suggesting thrombosis. A negative D-dimer test virtually rules out DVT. D-dimers are breakdown products of a fibrin mesh stabilised by factor XIII.

Less frequently used tests include:

- MRI
- CT.

While DVT and PE are common clinically, they are rare in the absence of elevated blood D-dimer levels and certain specific risk factors. Imaging, particularly CT pulmonary angiography, is a rapid, accurate

and widely available test but has limited value in patients who are very unlikely, based on serum and clinical criteria, to have significant risk.

Treatment of DVT is by heparin, starting with at least 5000 units intravenously, then continuous infusion at 1000 units per hour or 15000 units subcutaneously every 24 hours, with APTT monitoring. Patients with acute DVT have traditionally been treated with UFH followed by oral anticoagulation. In severe cases, the clot might need surgical removal.

Compression stockings may help relieve pain and swelling. These might need to be worn for 2 years or more after having DVT.

Clinical features of PE

PE can occur without any symptoms of a DVT but features can include:

- dyspnoea
- arrhythmias
- chest pain, which worsens with a deep breath or coughing
- anxiety
- haemoptysis or pleurisy
- low blood pressure, light-headedness or fainting.

PE may gradually cause pulmonary hypertension and right-sided heart failure, or may be fatal as a result of sudden circulatory collapse.

General management of PE

Massive PE with collapse and cardiac arrest requires emergency care and early treatment with thrombolytics and anticoagulants:

- external cardiac massage, which may break up the embolus
- oxygen
- intravenous heparin
- a thrombolytic agent, such as streptokinase.

Minor PE usually resolves spontaneously but anticoagulants should be given. Tests to find the location of the embolus and the damage it has caused to the lungs include imaging with MRI or CT, angiography, or lung ventilation/perfusion scan (V/Q scan).

Dental aspects of thromboses

Venous thrombosis may affect the deep calf veins as a consequence of immobility, pressure on the calf and increased blood coagulability, which follows GA and surgery (see earlier).

Thrombophilia and hypofibrinolysis may possibly underlie so-called neuralgia-inducing cavitation osteonecrosis (NICO) or Ratner bone cavities, which may cause severe pain. NICO appears to be due to resistance to activated protein C or to low protein C levels, or low levels of stimulated t-PA. Bone sites most frequently involved, in decreasing order of prevalence, are mandibular molars, maxillary molars and maxillary canines/lateral incisors. Third molar sites account for 45% of all jawbone involvement. Unlike abscesses, cysts or periapical lesions, the cavities in NICO are often not apparent on radiographs, though thin-slice CT scanning may show the areas. They may be detectable by technetium-99 methylene diphosphonate radioisotope scanning or ultrasonography.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC; consumption coagulopathy or defibrination syndrome) is an uncommon, complex process with potentially fatal activation of the haemostasis-related

Fig. 8.19 Disseminated intravascular coagulopathy.

mechanisms within the circulation. Uncontrolled consumption of clotting factors and intravascular deposition of platelets may result in serious coagulopathy and thrombocytopenia.

DIC may be caused by many conditions, including sepsis, adenocarcinoma, acute myeloid leukaemia (M3 variant), obstetric complications such as amniotic fluid embolus, incompatible blood transfusions, burns, cancers or severe trauma. In one series of head injuries, a minor degree of DIC was found in 57%. Brain ischaemia by vascular occlusion may therefore complicate head injury, as a result of DIC.

DIC can lead to bleeding, thrombosis, haemolysis and shock (Fig. 8.19). Haemorrhagic tendencies result from the consumption of platelets and clotting factors internally and from activation of the fibrinolytic system. Purpura and bleeding from sites such as the gastrointestinal tract and gingivae can result. In the case of head injuries, DIC may lead to intracranial haemorrhage. Thrombotic phenomena include clotting in capillaries, which can damage any organ, but the kidneys, liver, adrenals and brain are particularly vulnerable. Red cells also become damaged as a result of the changes in the capillaries (microangiopathic haemolysis). Shock may be caused by adrenal damage or obstruction of the pulmonary circulation by fibrin deposition and other factors.

Symptoms suggestive of DIC include bleeding from the gingiva, nausea, vomiting, muscle and abdominal pain, seizures and oliguria. PT, APTT and FDPs and the D-dimer test are increased but, due to fibrin consumption, there are low levels of fibrinogen.

DIC is an acute emergency; the underlying cause and any hypoxia or acidosis should be corrected, and heparinization, replacement of clotting factors and platelets, or antifibrinolytic therapy given as appropriate. The management of DIC is controversial and must, in any case, depend on the cause and the pathological changes taking place. No single programme of treatment is effective for all cases.

Dental aspects

The main importance of DIC is in relation to head injuries, as discussed earlier. Gingival bleeding may be seen.

PLASMINOGEN DEFICIENCY (HYPOPLASMINOGENAEMIA)

In health, body fluid fibrinolytic activity clears fibrin deposits but does not cause systemic fibrinolysis.

Plasminogen can be activated by tissue plasminogen activator, kallikrein or drugs such as streptokinase. Tissue plasminogen activator is produced by damaged endothelial cells and activates plasminogen to plasmin when it is bound to fibrin. If plasminogen is deficient, this mechanism fails, leading to fibrin deposition.

Some patients develop gingival swelling, corneal involvement and blindness; others may also develop congenital occlusive hydrocephalus. Whether therapy with topical heparin or intravenous purified plasminogen concentrate will effectively control the lesions remains to be established.

Dental aspects

Plasminogen deficiency may rarely underlie ligneous conjunctivitis, an idiopathic form of chronic membranous conjunctivitis associated with fibrin deposits and often with lesions in the larynx, nose, cervix and gingivae.

ERYTHROCYTES (RED BLOOD CELLS)

Erythrocytes are responsible for oxygen (O_2) carriage from the lungs to the tissues. They are produced (*erythropoiesis*) in the bone marrow from nucleated stem cells (undifferentiated *pluripotent* stem cells), via immature intermediate cells (*reticulocytes*), which retain their organelles, have nuclear remnants and can still divide. Reticulocytes are prematurely released into the blood (reticulocytosis) when demand is high. Erythropoiesis is triggered by *erythropoietin* released from the kidney when low O_2 levels are detected, and this stimulates the pluripotent stem cells. Erythrocytes, when mature, contain only haemoglobin (Hb) – the molecule responsible for the transport of O_2 and carbon dioxide (CO_2). Hb production requires iron, protoporphyrin and globin chains. Hb is a heterogeneous group of proteins consisting of four globin chains and four haem groups. In adults, the normal haemoglobins are HbA, HbA₂ and HbF. Effete erythrocytes are broken down largely in the spleen, and Hb is degraded to haem and then bilirubin in the liver (Fig. 8.20).

ANAEMIA

General aspects

Anaemia is defined as an Hb level below the norm for the age, gender and ethnic background of the individual and may be due to insufficient red blood cell (RBC) numbers or Hb content. Up to puberty, an Hb level below 11.0 g/dL is the hallmark of anaemia; the corresponding figure in adult females is below 11.5 g/dL, and in adult males below 13.5 g/dL. The effect of anaemia is to lower the oxygen-carrying capacity of the blood. Its causes are outlined in Tables 8.27 and 8.28, and in Figure 8.21. Although common, anaemia is not a disease in itself but it may be a feature of many diseases (Fig. 8.22).

Fig. 8.20 Red-cell life history.

The most common cause of anaemia in developed countries is chronic blood loss and consequent iron deficiency, usually from heavy menstruation in women. Folate and vitamin B₁₂ (cobalamin) deficiencies are the next most common causes.

Anaemia is classified on the basis of red-cell size as microcytic (small), macrocytic (large) or normocytic (normal-size erythrocytes; Table 8.29).

Microcytic anaemia is the most common and is usually due to iron deficiency, or occasionally to thalassaemia or chronic diseases. The mean corpuscular (cell) volume (MCV) falls below 78 fl.

Table 8.27 Causes of anaemia	
Nature of anaemia	Cause
Increased red blood cell (RBC) loss	Menstrual blood loss
	Gastrointestinal blood loss
	Haemolysis
Reduced RBC production	Haematinic deficiency
	Bone marrow infiltration
	Puberty
Increased tissue requirements	Pregnancy
	Hypothyroidism

Table 8.28 Types of anaemia	
Cause	Examples
Poor intake of haematinics (uncommon)	Socioeconomic factors
	Dietary fads
	Dysphagia
Impaired absorption of haematinics	Diseases of small intestine in particular (e.g. coeliac disease)
Increased demands for haematinics	Pregnancy and haemolysis especially
Impaired erythropoiesis	Aplastic anaemia and leukaemia
	Drugs
	Chronic disease (e.g. rheumatoid arthritis)
	Viral infections
Haemolytic anaemias	Sickle cell and thalassaemia mainly
Blood loss (most common cause)	Menorrhagia
	Any gastrointestinal lesion (ulcers or carcinoma)
	Lesions of the urinary tract
	Trauma

Fig. 8.21 Main causes of anaemia.

Macrocytic anaemia (MCV more than 99 fl) is caused usually by vitamin B₁₂ or folate deficiency (not infrequently in alcoholics); sometimes by the consumption of folate and vitamin B₁₂ in chronic haemolysis, pregnancy or malignancy; and sometimes by drugs (methotrexate,

Fig. 8.22 Anaemia – features.

Table 8.29 Main types of anaemia

Type of anaemia	Examples	Comments
Microcytic hypochromic	Iron deficiency	Blood loss (e.g. from menstruation or occult – gastrointestinal or genitourinary – sources)
	Thalassaemia	Malabsorption (post-gastrectomy)
Macrocytic	Vitamin B ₁₂ deficiency	Malabsorption (post-gastrectomy)
	Folate deficiency	
	Haemolysis	
	Hypothyroidism

azathioprine, cytosine or hydroxycarbamide). Macrocytic anaemia may also be caused by liver disease, myxoedema or, sometimes, aplastic anaemia.

Normocytic anaemia (MCV between 79 and 98 fl) may result from chronic diseases such as leukaemia, chronic inflammatory disease, liver disorders, renal failure, infection, malignancy and sickle cell disease.

Box 8.9 Clinical features of anaemia

- Typically none in the early stages
- General lassitude
- Cardiorespiratory
 - Dyspnoea
 - Tachycardia
 - Congestive cardiac failure
 - Murmurs
 - Palpitations
 - Angina pectoris
- Cutaneous
 - Pallor
 - Brittle nails
 - Koilonychia (spoon-shaped nails – iron deficiency)
- Oral
 - Sore mouth
 - Ulceration
 - Angular stomatitis
 - Glossitis
 - Burning mouth symptoms

Clinical features

Patients with anaemia are commonly symptomless in the early stages or if the onset is slow. However, as the anaemia worsens and the oxygen-carrying capacity of the blood falls, cardiac symptoms and signs develop (tiredness, dyspnoea, palpitations, tachycardia, flow murmurs and eventual cardiac failure). Pallor of the oral mucosa, conjunctiva or palmar creases suggests severe anaemia but skin colour can be misleading. Anaemia may worsen the symptoms of pre-existing coronary, peripheral and cerebrovascular disease. The different types of anaemia have many clinical features in common (Box 8.9).

General management

Anaemia is diagnosed from the Hb level but the precise nature and underlying cause must be established. The key to management of anaemia is the establishment and treatment of the underlying cause. Depending on the clinical presentation, the following investigations may be indicated:

- Full blood count – to ascertain the Hb level and RBC indices; it is important to include a reticulocyte count
- Blood film – to demonstrate abnormal RBC forms (sickle cells in sickle cell disease and pencil cells in iron-deficiency anaemia; Figs 8.23 and 8.24)
- Erythrocyte sedimentation rate (ESR) or plasma viscosity (PV) – the latter is better, since it changes earlier in disease and is unaffected by drugs
- Hb electrophoresis – for haemoglobinopathy screening
- Haematinics – serum vitamin B₁₂, folate and ferritin levels; the ferritin is also an acute-phase reactant and can rise in inflammatory states
- Endoscopy – to identify sources of gastrointestinal blood loss
- Bone marrow biopsy – to exclude bone marrow infiltration and disease

Haematinic deficiency states must be corrected with iron, folic acid and/or vitamin B₁₂ supplements. If the onset of anaemia has been rapid, blood transfusion may be indicated so as to prevent worsening of

Fig. 8.23 Laboratory investigations for the cause of anaemia. HbF = fetal haemoglobin; MCV = mean cell volume; N = normal; PCV = packed cell volume; RBC = red blood cell; TIBC = total iron-binding capacity; *Fe = ferritin.

ischaemic symptoms. In end-stage renal failure, the hormone erythropoietin may be administered regularly to encourage haemopoiesis.

Automated examination of blood provides a quick and reliable Hb estimation and count of all the blood cells. It also shows important cytological features of red cells, such as red cell distribution width (RDW), MCV and Hb content. The laboratory investigation of the common anaemias is summarized in [Figure 8.23](#). A blood film may also be required, especially as a mixed macro- and microcytic picture may sometimes not be revealed by an automated counter (a mix of large and small cells may produce an average within the normal range) and other abnormalities may be seen. For this purpose, a sample of EDTA-anticoagulated blood should be sent, with as much clinical information as possible, to the haematologist. The terminology used to describe examination of a stained blood film is shown in [Figure 8.24](#).

Special investigations are discussed under the specific diseases.

Hb can be replaced by blood transfusions, haematinics or occasionally the hormone erythropoietin to encourage natural haemopoiesis. It is better to treat with haematinics such as iron or folic acid. Blood transfusions should be used only when absolutely necessary, if the Hb concentration has fallen below 7 g/dL, since they may carry the risk of infection, circulatory overload and allergic reactions. Erythropoietin is mainly used in the treatment of anaemia of chronic renal failure or cytotoxic therapy.

Dental aspects

LA is usually satisfactory for pain control. CS may be given only if there is supplemental oxygen. Deeper levels of sedation are more likely to lead to hypoxia. Nitrous oxide is theoretically contraindicated

in vitamin B₁₂ deficiency (see later). When GA is given, it is vital to ensure full oxygenation. Nevertheless, the myocardium may be unable to respond to the demands of anaesthesia. Whenever possible, therefore, the anaemia should be corrected preoperatively and the Hb level must be raised, if necessary by transfusion. Anaemia of sickle cell disease can make GA especially hazardous (see later). Elective operations under GA should not usually be carried out when the Hb is less than 10 g/dL (male). In an emergency, anaemia can be corrected by whole blood transfusion, but this should only be given to a young and otherwise fit patient. Packed red cells avoid the risk of fluid overload and can be given in an emergency to older patients or those with incipient congestive cardiac failure. A diuretic given at the same time further reduces the risk of congestive cardiac failure. The patient should be stabilized at least 24 hours preoperatively and it should be noted that Hb estimations are unreliable for 12 hours post-transfusion or after acute blood loss.

Some anaemias can also cause oral lesions, such as ulcers, glossitis or angular stomatitis ([Fig. 8.25](#)).

DEFICIENCY ANAEMIAS

Iron-deficiency anaemia

General aspects

Dietary iron is found mainly as iron salts, partly as haem from the myoglobin and Hb in meat. Dietary iron exists as haem iron only in animal tissues; in plant foods it is present as non-haem iron, which is less easily absorbed. In a mixed omnivorous diet, around 25% of dietary iron is non-haem iron. The amount of iron absorbed from

Red cell abnormalities	Causes	Red cell abnormalities	Causes
 Microcyte	Iron deficiency, haemoglobinopathy	 Spherocyte	Hereditary spherocytosis, autoimmune haemolytic anaemia, septicaemia
 Macrocyte	Liver disease, alcoholism, megaloblastic anaemia	 Fragments	DIC, microangiopathy, HUS, TTP, burns, prosthetic valves
 Target cell	Iron deficiency, liver disease, haemoglobinopathies, post-splenectomy	 Elliptocyte	Hereditary elliptocytosis
 Stomatocyte	Liver disease, alcoholism	 Tear drop poikilocyte	Myelofibrosis, extramedullary haemopoiesis
 Pencil cell	Iron deficiency	 Basket cell	Oxidant damage, e.g. G6PD deficiency, unstable haemoglobin
 Echinocyte	Liver disease, post-splenectomy	 Howell-Jolly body	Hyposplenism, post-splenectomy
 Acanthocyte	Liver disease, abetalipoproteinaemia, renal failure	 Basophilic stippling	Haemoglobinopathy, lead poisoning, myelodysplasia, haemolytic anaemia
 Sickle cell	Sickle cell anaemia	 Siderotic granules (Pappenheimer bodies)	Disordered iron metabolism, e.g. sideroblastic anaemia, post-splenectomy

Fig. 8.24 Red cell morphological changes. DIC = disseminated intravascular coagulation; G6PD = glucose-6-phosphate dehydrogenase; HUS = haemolytic–uraemic syndrome; TTP = thrombotic thrombocytopenic purpura.

Fig. 8.25 Glossitis in anaemia.

various foods ranges from around 1–10% from plant foods to 10–20% from animal foods. Fibre, phytates, oxalates and phosphates present in plant foods, and tannin in tea, can inhibit iron absorption. Foods rich in vitamin C, including citrus fruits, green peppers and fresh leafy green vegetables, promote absorption of non-haem iron. Citric acid, sugars, amino acids and alcohol, as well as meat, poultry, fish and orange juice, also promote intestinal absorption of iron. Good sources of iron for vegetarians include wholegrain cereals and flours, leafy green vegetables, pulses such as lentils and kidney beans, and some dried fruits. Gastric acid is needed for the adequate conversion of iron salts from ferric to ferrous forms for their absorption from the proximal small intestine. Iron is stored in the bone marrow as haemosiderin.

The remainder is stored in the liver and spleen, and a small amount is present as myoglobin, which acts as an oxygen store in muscle tissue. Iron is required for synthesis of haem, respiratory cytochromes and myeloperoxidase. It also plays a vital role in many metabolic reactions (Fig. 8.26).

The most common causes of anaemia in developed countries are iron deficiency as a result of nutritional deficiencies or chronic blood loss, while in developing countries, malaria and chronic blood loss (Fig. 8.27) are the most frequent.

Excessive chronic menstrual or gastrointestinal blood loss is the main cause – women of childbearing age and older are mainly affected. About 5% of American women may have mild iron-deficiency anaemia and up to 25% may have low iron levels without anaemia. Neonates maintained on a milk diet may become iron-deficient. Very many older children are mildly iron-deficient because of the high demands for growth, especially during adolescence. By contrast, iron deficiency in an adult male almost invariably indicates blood loss, usually from the gastrointestinal or genitourinary tract. The same holds true for postmenopausal women.

Clinical features

The important features of iron-deficiency anaemia are summarized in Box 8.10. Impaired exercise capacity, koilonychia (Fig. 8.28) and beeturia (urine appearing red after eating beetroot) may be seen. In childhood, iron deficiency may also predispose to developmental or behavioural disorders. However, symptoms ascribed to iron deficiency do not always respond to iron replacement.

Free erythrocyte porphyrins (FEP)	Raised	Normal	Raised
Serum iron	Low	Normal	Normal
Total iron-binding capacity (TIBC)	Raised	Normal	Normal
Ferritin	Low	Normal	Normal

^aMay be low if the blood lead concentration is in excess of 100 mg/dL.

General management

Iron deficiency is the main cause of a microcytic anaemia (see Table 8.29). In the early stages, stainable iron is lost from the bone marrow (Table 8.30); deficiency only appears after stores are depleted. Erythrocyte size changes show as an abnormal RDW on automated red cell sizing, before the transport iron, serum iron and ferritin levels fall.

Falling serum ferritin levels are one of the most sensitive indices of iron deficiency, but this test is not universally available and the level rises in inflammation, as ferritin is an acute-phase protein. The serum iron-binding capacity rises and transferrin saturation (total iron-binding capacity/serum iron) falls; a value of less than 16% indicates iron deficiency. Declining erythrocyte size (microcytosis and a low MCV) follows, with rising red cell protoporphyrin concentrations. Later there is a fall in Hb and a hypochromic microcytic anaemia. Hypochromic microcytic anaemia with normal marrow iron stores is

Fig. 8.29 Postcricoid carcinoma in patient with Paterson–Brown–Kelly. (Plummer–Vinson) syndrome.

not caused directly by iron deficiency but is a feature of thalassaemia and sideroblastic anaemia, as discussed later.

The cause of the iron deficiency must be sought and treated. The best treatment for iron deficiency is an iron salt such as ferrous sulfate 200mg three times daily orally, which is better absorbed than ferric salts. Ferrous gluconate 250mg/day can be given if ferrous sulfate is not tolerated. Nausea or constipation is fairly common. The stools are black whilst on oral iron therapy and this should not be mistaken for melaena. Oral iron may need to be given for 3 months or more after the Hb has reached normal levels, to replenish marrow iron stores. Parenteral iron does not raise the Hb level more rapidly than oral iron; it must be given intramuscularly and may cause reactions, including arrhythmias. Parenteral iron only has advantages when, for example, the patient cannot take iron by mouth or when inflammatory bowel disease is aggravated by oral iron.

Dental aspects

LA is satisfactory for pain control. CS can be given if full oxygenation is possible. For GA, see earlier.

A sore, physically normal tongue can develop before the Hb falls below the lower limit of normal. Atrophic glossitis – soreness of the tongue with depapillation or colour change – is the best-known effect of severe anaemia. It is seen much less frequently than in the past. The Paterson–Brown–Kelly (Plummer–Vinson) syndrome of glossitis and dysphagia with hypochromic (iron-deficiency) anaemia is uncommon. Women are mainly affected and the prevalence appears to be highest in northern Europe. There is a substantial risk of carcinoma in the postcricoid region or in the mouth (**Fig. 8.29**). Candidosis can be aggravated or precipitated by anaemia and may be the presenting feature. Angular stomatitis is a well-known sign of iron-deficiency anaemia but affects only a minority. Nowadays, it is more frequently caused by infection, mainly by *Candida albicans*, which may be promoted by the

Fig. 8.30 Vitamin B₁₂ sources and absorption.

anaemia itself. Occasionally, adequate treatment of anaemia alone, without antifungal treatment, relieves the infection. The majority of patients with chronic mucocutaneous candidosis, particularly the familial and diffuse types, are also iron-deficient and treatment with iron appears to improve the response to antifungal treatment.

Aphthous-like ulceration is sometimes associated with iron deficiency, which, if remedied, can sometimes bring about a cure. Deficiencies should be suspected, especially in patients of middle age or over who develop ulcers.

Staining of the teeth by iron can be prevented in children by using sodium iron edetate as the iron source, as it is also sugar-free and more palatable than ferrous sulfate. Some iron preparations can cause tooth erosion, as can chewable vitamin C.

Vitamin B₁₂ (cobalamin) deficiency

General aspects

Vitamin B₁₂ is needed by the body to synthesize and break down amino acids, and to synthesize deoxyribonucleic acid/ribonucleic acid (DNA/RNA). This is needed to build new cells, especially blood, skin and mucosal cells. Vitamin B₁₂ is found in the diet in meat, especially liver.

Vitamin B₁₂ is bound to gastric intrinsic factor secreted by parietal cells, and absorbed via the 'cubam receptor' in the terminal ileum. It is stored in the liver (**Fig. 8.30**). Vitamin B₁₂ is a cofactor for only two enzymes – methionine synthase and l-methylmalonyl-coenzyme A mutase – and is necessary for development and myelination of the central nervous system (CNS), as well as for the maintenance of its normal function.

Deficiency of vitamin B₁₂ is usually due to a defect in intrinsic factor (as a result of pernicious anaemia or gastrectomy), occasionally ileal disease or resection, or rarely a congenital ileal absorption defect, a

Box 8.11 Causes of vitamin B₁₂ deficiency

- Autoimmune (pernicious anaemia)
- Poor intake
 - Strict vegetarianism (diet of vegans and some Hindu Indians)
- Malabsorption
 - Defective intrinsic factor production
 - Congenital
 - Gastrectomy
 - Ileal disease
 - Coeliac disease
 - Tropical sprue
 - Crohn disease (more frequently folate deficiency)
 - Blind loop syndrome
 - Resections
 - Fish tapeworm (Finland, Asia)
 - Transcobalamin II deficiency
- Drugs (rarely)
 - Colchicine
 - Neomycin
 - Nitrous oxide
 - Omeprazole

Fig. 8.31 Vitamin B₁₂ deficiency. PA = pernicious anaemia.

vegan diet or drugs (Box 8.11 and Fig. 8.31). Nitrous oxide can also interfere with vitamin B₁₂ metabolism and with neurological function if administration continues for 12 hours or more, or if it is used as a drug of abuse.

Lack of vitamin B₁₂ leads to accumulation of homocysteine (with a possible risk of cardiovascular disease) and methylmalonic acid. Pernicious (Addisonian) anaemia, the most common type of macrocytic anaemia, is caused by a specific defect of absorption of vitamin B₁₂, and is due to autoantibodies against gastric parietal cells and/or the intrinsic factor directed against the gastric hydrogen/potassium-adenosine triphosphatase (H/K-ATPase), which accounts for an

associated achlorhydria. The underlying lesion is an atrophic gastritis causing failure of production of intrinsic factor by parietal cells and of gastric acid. There may be gastrointestinal symptoms and also a greater risk of stomach cancer. Ultimately, there is macrocytic (megaloblastic) anaemia with depressed production of all blood cells. Pernicious anaemia typically affects women in middle age or over, particularly those of northern European or African descent. It is sometimes seen with other autoimmune diseases, especially hypothyroidism, or less often as a feature of the autoimmune polyendocrinopathy syndrome (Ch. 6). Pernicious anaemia affects around 1 in 1000 of the northern European population and about 1% of females over age 70.

Clinical features

Deficiency of vitamin B₁₂ develops slowly since liver stores last up to 3 years. In addition to the usual signs and symptoms of anaemia, neurological symptoms – particularly paraesthesiae of the extremities – develop in about 10%. Early signs include loss of toe positional sense and diminished perception of the vibration of a tuning fork. These early neurological changes are reversible with treatment.

In the USA, 5% of persons over 50 appear to have low serum vitamin B₁₂ levels. Neurological damage can precede anaemia or even macrocytosis, and lead to subacute combined degeneration of the spinal cord and, ultimately, paraplegia. Absence of macrocytosis is occasionally due to concomitant iron deficiency, but in another study on 70 patients with very low (less than 100 ng/L) serum vitamin B₁₂ levels, anaemia was absent in 19% and macrocytosis was absent in 33%. In some of these cases, vitamin B₁₂ deficiency was manifested first as cerebral abnormalities and what has been termed ‘megaloblastic madness’.

Premature greying of the hair is another well-recognized feature. Less common conditions associated with vitamin B₁₂ deficiency include malabsorption, infertility and thromboses (attributed to the marked hyperhomocysteinemia seen in severe vitamin B₁₂ deficiency).

General management

The diagnosis of B₁₂ deficiency depends on the clinical findings and low serum B₁₂ levels, together with autoantibodies against gastric parietal cells and/or intrinsic factor. If the patient consumes adequate vitamin B₁₂ but has clinically confirmed B₁₂ deficiency, malabsorption must be present. The Schilling test for impaired vitamin B₁₂ absorption is obsolete. Measurement of the raised serum levels of methylmalonic acid and homocysteine seen in B₁₂ deficiency appears to be more sensitive and specific for deficiency than assay of serum vitamin B₁₂ itself, though renal and other disorders may confuse the interpretation.

Most patients with vitamin B₁₂ deficiency have malabsorption and will require parenteral or high-dose oral replacement. Pernicious anaemia is treated for life with intramuscular hydroxycobalamin 1 mg five times at 3-day intervals to replete liver stores, and then at about 3-monthly intervals.

Dental aspects

LA is satisfactory. CS can be given if the Hb level is only moderately depressed and supplemental oxygen can be given. Nitrous oxide is (theoretically) contraindicated. GA should be postponed until low Hb has been remedied.

A physically normal but sore or burning tongue can be caused by early vitamin B₁₂ deficiency, often with normal Hb levels. It is important for these patients to undergo haematological examination. As

Fig. 8.32 Folate source and absorption.

Fig. 8.33 Folate deficiency.

discussed earlier, anaemia or macrocytosis may be absent at this point. It can also, at this early stage, occasionally be associated with neurological disorders. In early B₁₂ deficiency, the tongue, rather than being sore, may show a pattern of red lines without depapillation; alternatively, red sore patches may form. These may come and go, and range from pinhead red spots to circular areas up to a centimetre across, which may resemble erythroplasia clinically; though they resolve with treatment of the anaemia, they may show dysplasia histologically.

Paterson–Brown–Kelly syndrome is rarely associated with a macrocytic anaemia.

Candidosis can be aggravated or precipitated by anaemia and may be the presenting feature. Angular stomatitis is uncommon. Aphthous stomatitis is occasionally the presenting feature and pernicious anaemia should be considered when ulceration starts in middle age or later.

Folate (folic acid) deficiency

General aspects

Folic acid is needed by the body to synthesize and break down amino acids, and to synthesize DNA/RNA, needed to build new cells, especially blood, skin and mucosal cells. Folic acid is found in fresh leafy and other vegetables, especially spinach, kale, Brussels sprouts and asparagus. Folic acid is absorbed from the proximal small intestine (Fig. 8.32). There are virtually no body stores of folic acid. Most folic acid deficiency is caused by dietary deficiency (Fig. 8.33). Some is caused by disease of the small intestine, such as coeliac disease, or drugs (Box 8.12), but occasionally no cause can be discovered.

Clinical features

The effects of folate deficiency are very similar to B₁₂ deficiency. Both cause megaloblastic changes in the marrow and macrocytic anaemia, defective DNA synthesis and impaired production of blood cells and, ultimately, of many other cells.

Box 8.12 Causes of folate deficiency

Poor intake

- Poverty
- Dietary ignorance
- Old age
- Alcoholism

Malabsorption

- Coeliac disease
- Crohn disease
- Other malabsorption states

Increased demands

- Infancy
- Pregnancy
- Chronic haemolysis (haemolytic anaemia)
- Malignant disease
- Exfoliative skin lesions
- Chronic dialysis

Drugs

- Alcohol
- Azathioprine
- Barbiturates
- Co-trimoxazole
- Methotrexate
- Oral contraceptives
- Pentamidine
- Phenytoin
- Primidone
- Pyrimethamine
- Sulfasalazine
- Triamterene
- Zidovudine

Folate deficiency in adults leads to anaemia. Folic acid deficiency in pregnancy appears to predispose to neural tube defects or cleft lip–palate in the fetus. Folic acid prophylaxis is thus recommended. Folate deficiency in adults does not lead to subacute combined degeneration of the cord, but does predispose to raised homocysteine levels and possibly ischaemic heart disease.

General management

The red-cell folate levels are low and serum B₁₂ normal. Red-cell folate levels, when low, are unequivocal evidence of folate deficiency but may remain normal for a time in a few folate-deficient patients until older erythrocytes are replaced. Serum folate assays are considerably less reliable. Once the cause has been found and rectified, treatment with folic acid (5mg daily by mouth) rapidly restores the normal blood picture. Treatment is usually given for at least 4 months.

Dental aspects

LA, CS and GA considerations apply as for pernicious anaemia, but there is no contraindication to nitrous oxide. Soreness of the tongue without depapillation or colour change can be caused by early deficiencies, often with normal Hb levels. Atrophic glossitis is the best-known effect of severe anaemia but is much less frequently seen than in the past. Angular stomatitis is also a well-known sign but affects only a minority. Aphthous stomatitis is sometimes associated and, if remedied, can sometimes bring about a cure.

HAEMOLYTIC ANAEMIAS

General aspects

Haemolytic anaemia may result from: inherited abnormalities of Hb formation (the haemoglobinopathies); inherited abnormalities of erythrocyte structure or function (spherocytosis; glucose-6-phosphate dehydrogenase [G6PD] deficiency); or from damage to erythrocytes (autoimmune, drug-induced or infective). Worldwide, malaria is the most common cause.

Clinical features

Accelerated erythrocyte destruction leads to bilirubin overproduction and sometimes jaundice. The spleen may enlarge and increased red cell turnover raises the reticulocyte count and plasma lactate dehydrogenase (LDH), bilirubin and uric acid levels. This raises the demand for folic acid and may in turn cause macrocytic changes.

General management

The cause should be treated if possible. Folic acid may be required and, in some instances, blood transfusion, but this carries the possibility of iron overload.

Dental aspects

LA is the safest method of pain control. CS may be given, with supplemental oxygen if necessary. Any of the haemolytic anaemias may be a contraindication to GA but, in practical terms, sickle cell disease is by far the most important cause of difficulties in dental management.

Haemoglobinopathies

The fetus is normally born with fetal haemoglobin (HbF) as the main haemoglobin and, in infancy, this is replaced with adult haemoglobin (HbA) and a small amount of HbA₂. These haemoglobins differ in their peptide chain composition (Table 8.31). Haemoglobinopathies are genetically determined disorders of Hb production. Each of the Hb peptide (globin) chains has a unique amino acid sequence, which can be altered as a result of DNA mutations. Qualitative defects in the production of Hb then lead to ‘variant haemoglobins’. Quantitative defects in the production of globins lead to the thalassaemias. Haemoglobinopathies are seen mostly in non-Caucasians. Sickling disorders are common in Afro-Caribbean, Mediterranean, Middle Eastern, Indian, Bangladeshi and Pakistani patients (Fig. 8.34). In the UK, about 1 in 10 Afro-Caribbeans and 1 in 100 Cypriots and Asians carry the sickle cell trait. Thalassaemias and G6PD deficiency are seen mainly in Mediterranean, Vietnamese, Cambodian, Laotian

Fig. 8.34 Distribution of sickling.

Table 8.31 Laboratory findings during development of iron-deficiency anaemia						
	Mean corpuscular (cell) volume (MCV)	Haemoglobin (Hb)	Mean corpuscular (cell) Hb concentration (MCHC)	Serum ferritin	Transferrin saturation ^a	Marrow iron stores
Normal	N	N	N	N	33%	N
Mild anaemia	↓	N or ↓	N	↓	<16%, <33%	↓
Moderate anaemia	↓	↓	↓	↓	<16%	↓
Severe anaemia	↓↓	↓↓	↓↓	↓↓	<16%	↓↓

N= normal.
^aIt is better to measure ferritin.

and Chinese peoples. In the UK, about 1 in 10 from the Indian sub-continent, about 1 in 30 Chinese and 1 in 50 Afro-Caribbeans have thalassaemia.

Haemoglobinopathies result in consequences ranging from significant morbidity and mortality in sickle cell disease, to no significant clinical effect as in haemoglobin E disease. Patients may have combinations of more than one haemoglobinopathy. Short stature, abnormal skeletal development and jaundice are often found, in addition to signs and symptoms of anaemia.

The diagnosis of haemoglobinopathy rests on the history, examination and laboratory investigations. A family history is especially important. A full blood picture and red cell indices should be obtained and blood should also be sent for electrophoresis (4mL of EDTA-anticoagulated blood) and for assay of variant haemoglobins. Special tests, such as the Sickledex, may also be useful (see later).

The sickling disorders

General aspects

Amino acid substitution in the Hb globin chain results in changes in haemoglobin (HbS), which assumes a propensity to polymerize or precipitate, causing gross distortions in the shape of erythrocytes, with impaired deformability and membrane damage. The erythrocytes cause vascular occlusions in the microcirculation. Integrins on the erythrocyte surface bind to vascular endothelial adhesion molecules, which are upregulated by tumour necrosis factor (TNF) and other pro-inflammatory cytokines; thus obstruction is more common during infections.

The sickling disorders include the sickle cell anaemia or disease, and sickle cell trait (Table 8.32 and 8.33). Inheritance in the sickling disorders is autosomal. Sickling disorders mainly affect people of African heritage. In West Africa about 2% of the population have sickle cell disease and up to 30% have the trait. Sickle cell trait is many times more common than sickle cell anaemia in Britain and affects some 10% of people of Afro-Caribbean descent, and 20% of African descent.

Sickle cell *anaemia or disease* (HbSS is present in erythrocytes) is homozygous and is usually a serious disease with widespread complications (Box 8.13; Fig. 8.35). It frequently becomes apparent in about the third month of life.

Sickle cell *trait* (HbSA is present) is heterozygous and at least ten times as common. Sickle cell trait is frequently asymptomatic, but

sickle cell crises can be caused by low O₂ tension (see later; GA, high altitudes or unpressurized aircraft). At times, such patients may have renal complications causing haematuria or splenic infarcts. Sickle cell trait may be associated with another haemoglobinopathy.

Clinical features

Sickle cell disease presents six main clinical problems, as listed below.

Painful crises, which are usually due to infarction as a result of sickling, are brought on by infection, dehydration, hypoxia, acidosis or cold, and cause severe pain and pyrexia. Infarcts form mainly in the spleen (with eventual autosplenectomy), bones and joints, brain, kidneys, lungs, retinae and skin. Bone infarcts can cause inflammation and pain, especially in the hands and feet. Pulmonary infarcts cause chest pain and eventually lead to pulmonary hypertension and right-sided cardiac failure. The kidneys may also be affected, causing haematuria and a nephrotic syndrome. Ocular defects or cerebrovascular

Box 8.13 Features of sickle cell anaemia

- Anaemia
- Crises
 - Painful crises
 - Aplastic crises
 - Dactylitis – painful osteitis in the hands (Fig. 8.35)
 - Infarcts of central nervous system, lungs, kidney, spleen, bone
 - Skin ulcers
- Haemolysis
 - Jaundice
 - Gallstones
 - Reticulocytosis
- Impaired growth
- Skeletal deformities
- Susceptibility to infections

Fig. 8.35 Dactylitis showing painful red swellings.

Haemoglobin	Alpha chain	Beta chain	Gamma chain	Delta chain
Fetal HbF	2		2	
Adult HbA	2	2		
HbA ₂	2			2

Table 8.33 The sickling disorders

Disorder	Hb type	Origins of predominant ethnic groups affected	Clinical features
Sickle cell anaemia	SS	Africa, West Indies, Mediterranean, India	Severe anaemia
Sickle cell trait	SA	Africa, West Indies, Mediterranean, India	Usually asymptomatic
Sickle cell – HbC disease	SC	West Africa, South-East Asia	Variable anaemia
Sickle cell – HbD disease	SD	Africa, India, Pakistan	Moderately severe anaemia
Sickle cell – HbE disease	SE	South-East Asia	Moderately severe anaemia
Sickle cell – thalassaemia	SAF	Mediterranean, Africa, West Indies	Moderately severe anaemia

accidents – often with hemiplegia – are possible. Priapism is a sustained painful erection due to infarction in the corpora cavernosa. Abdominal crises may mimic a surgical emergency.

Haematological crises are caused by parvovirus infection and can be haemolytic, aplastic or related to sequestration.

Chronic anaemia may feature an Hb level that is often as low as 5–9 g/dL.

Chronic hyperbilirubinaemia predisposes to bile pigment gallstones.

Infections, particularly by pneumococci, meningococci, *Haemophilus* and salmonellae, represent the main cause of death in sickle cell disease. An immune defect results from splenic infarction and dysfunction. Most patients are kept on prophylactic phenoxymethyl penicillin.

Sequestration syndromes include sequestration of sickle cells in:

- the lungs, impeding gas exchange (chest syndrome)
- the spleen (septicaemia may result)
- the liver ('girdle syndrome'; may be associated with bowel dilatation).

Morbidity and early mortality rates are high in sickle cell disease. Most patients eventually succumb to cardiac failure, renal failure, overwhelming infection or stroke.

General management

Sickling disorders should be suspected in those with a positive family history and in any patient of African, West Indian or (less frequently) Asian or Mediterranean descent. Many already carry warning cards (Fig. 8.36).

In sickle cell *disease*, the Hb level is typically below 9 g/dL. Target cells, reticulocytosis of 5–25%, and sometimes sickled erythrocytes may be seen in a stained blood film. Hb electrophoresis shows mainly HbS and up to 15% HbF, but no HbA.

In sickle cell *trait*, haematological findings are often normal. Electrophoresis shows 40% HbS and up to 60% HbA.

Sickling may be demonstrated both in sickle cell *disease* and in *trait*, by tests relying on the low solubility of HbS (Sickledex; Fig. 8.37) or by the addition of a reducing agent (such as 10% sodium metabisulfite or dithionite) to a blood sample.

Patients with sickle cell *disease* need regular blood pictures, a comprehensive care programme, regular folic acid, and sometimes blood transfusions for cerebrovascular symptoms in early childhood or recurrent pulmonary thromboses. However, many patients retain moderate degrees of anaemia for most of their lives. Transfusions can and should usually be minimized, especially because of the risk of hepatitis virus and HIV infection. A growing number of patients with sickle cell disease survive into late middle age. Infections and thromboses are the main causes of death.

The main principles in patients with sickle cell *disease* are to prevent trauma, infection, hypoxia, acidosis or dehydration, all of which can precipitate a crisis. Infections must be treated early. Painful crises should be treated promptly with analgesics, such as diamorphine or pethidine, and hydration. Patients with sickle cell anaemia are treated with hydroxycarbamide (hydroxyurea), which raises the levels of HbF and iron-chelating agents (desferrioxamine, deferasirox or deferiprone).

Patients with sickle cell *trait* are less liable to complications from trauma, infection, hypoxia, acidosis or dehydration, but if severe, these can precipitate a crisis.

Dental aspects

All those at risk from sickling disorders should be investigated if GA is to be given. Sickle cell anaemia is probable if the Hb is less than 11 g/dL, and presents a hazard for GA. If the sickle cell test is positive, Hb electrophoresis is required to confirm the diagnosis.

Fig. 8.36 Haemoglobinopathy card.

Fig. 8.37 Sickledex test.

Patients with sickle cell *trait* (HbSA) present few problems in management but, if GA is necessary, full oxygenation must be maintained.

For patients with sickle cell *disease* (HbSS), LA is the preferred mode of pain control. It may be preferable to avoid prilocaine, which may, in overdose, cause methaemoglobinaemia. Aspirin is best avoided as, in large doses, it may cause acidosis and precipitate a crisis; paracetamol (acetaminophen) and codeine are effective alternatives. CS with relative analgesia can be used safely. At least 30% O₂ is needed and, provided that there is no respiratory depression or obstruction, normal procedures can be used. Benzodiazepines are best avoided.

Elective surgery should be carried out in hospital and during a phase when haemolysis is minimal. Anaemia should be corrected before GA, and the Hb brought up to at least 10 g/dL. Exchange transfusion is occasionally required for major surgery but only in selected patients. It carries the risk of red cell alloimmunization in up to 20%. Blood should be available for transfusion. If a crisis develops, O₂ is given and bicarbonate infused. A packed red cell transfusion may be required if the Hb falls below 50%.

Prophylactic antimicrobials (penicillin V or clindamycin) should be given for surgical procedures and infections must be treated vigorously,

since the patient may be immunocompromised if the spleen is non-functional. As a consequence of multiple transfusions, some patients have become infected with blood-borne viruses. Drugs that can cause respiratory depression, including sedative agents, should not be given. Acidosis and hypotension must also be avoided.

Orofacial manifestations of sickle cell disease include painful infarcts in the jaws (which may be mistaken for toothache) or osteomyelitis. Pulpal symptoms are common in the absence of any obvious dental disease and pulpal necrosis has sometimes resulted. Lesions suggestive of bone infarction (dense radio-opacities) may be seen in the jaws and/or skull. Bone scans using technetium diphosphonate show stronger uptake in these areas. Radiographic findings include a 'stepladder' trabeculae pattern. Some patients have such severe pain during crises that they abuse analgesics and become addicts (Ch. 34). Hypercementosis may be seen. Bone marrow hyperplasia leads to an enlarged haemopoietic maxilla with excessive overjet, and overbite. Skeletal but not dental maturation is delayed. The skull is thickened but osteoporotic with a hair-on-end pattern to the trabeculae. The diploë are thickened, especially in the parietal regions, giving a tower skull appearance. Enamel hypomineralization and calcified pulp canals may be seen. The lamina dura is distinct and dense, and the permanent teeth may be hypomineralized, though neither caries nor periodontal disease is more severe.

The thalassaemias

Thalassaemias are autosomally dominant inherited disorders in which either alpha- or beta-globin chains are synthesized at a low rate, thereby lessening the production of HbA. The unaffected chains are produced in excess and precipitate within the erythrocytes to cause excessive erythrocyte fragility and haemolysis. Thalassaemias are characterized by a hypochromic microcytic anaemia, and are predominantly found in persons of Mediterranean, Middle Eastern or Asian descent. They may be severe (major; homozygous) or mild (minor; heterozygous), and may affect alpha-chain (alpha-thalassaemias) or beta-chain (beta-thalassaemias) production.

Alpha-thalassaemias

Alpha-thalassaemias result from deficient synthesis of alpha chains and are mainly found in Asians. There are four main subtypes, of varying degrees of severity. In alpha-thalassaemia major, there is no compensatory mechanism for the loss in alpha-chain production, so tetramers of the beta and gamma chains combine to form, respectively, HbH and Barts, both of which are ineffective O₂ carriers. Thus the condition is lethal *in utero* or infancy.

Beta-thalassaemias

General aspects Beta-thalassaemias (Mediterranean anaemia) result from the depressed production of beta chains. They mainly affect peoples from the Mediterranean littoral, Afro-Caribbeans, South-East Asians and Africans. In the homozygous form, they can be life-threatening. A relative increase in delta and gamma chains is associated with raised levels of HbA₂ and HbF. Homozygous beta-thalassaemia (Cooley anaemia; thalassaemia major) is characterized by failure to thrive, increasingly severe anaemia, hepatosplenomegaly and skeletal abnormalities. Heterozygotes for beta-thalassaemia may be asymptomatic.

Clinical features Homozygotes for thalassaemia suffer from chronic anaemia, marrow hyperplasia, skeletal deformities, splenomegaly, cirrhosis, gallstones and iron overload. There is no pubertal growth

spurt. Affected children are susceptible to folate deficiency (as in other chronic haemolytic states) and also to infection.

Patients with homozygous beta-thalassaemia become overloaded with iron (haemosiderosis) from high gut absorption and from repeated transfusions. The iron damages the heart (cardiac haemosiderosis), causing cardiomyopathy and arrhythmias, which often result in death in early adult life. Iron deposits lead to liver and pancreas dysfunction, and deposits in salivary glands can cause a sicca syndrome. Some patients survive, probably because they have a milder variant, such as beta-thalassaemia with high levels of HbF.

Heterozygous beta-thalassaemia (thalassaemia minor or thalassaemia trait) is common and usually asymptomatic, except for mild hypochromic anaemia. Anaemia may be aggravated by pregnancy or intercurrent illness.

General management Diagnosis of beta-thalassaemia is confirmed by finding severe microcytic hypochromic anaemia with gross aniso- and poikilocytosis, target cells and basophilic stippling of erythrocytes, normal or raised serum iron and ferritin, and normal TIBC. There is a great increase in HbF and some increase in HbA₂.

The main treatment measures in beta-thalassaemia are blood transfusions, folic acid supplements and iron-chelating agents (desferrioxamine, deferasirox or deferiprone) and ascorbic acid. Hydroxycarbamide is now used but the side-effects can be a significant disadvantage. Splenectomy may be required if there is hypersplenism causing greater blood destruction, which leads to accumulation of iron elsewhere and other complications.

Dental aspects of thalassaemia

Hepatitis B or C, or HIV carriage, may be a complication in repeatedly transfused patients. Since splenectomy results in an immune defect, it may be prudent to cover surgical procedures with prophylactic antimicrobials.

LA is safe. CS may be given with oxygen levels not less than 30%. GA induction may be complicated by enlargement of the maxilla, which may cause difficulties in intubation, but in any event, the chronic severe anaemia and often cardiomyopathy are contraindications.

Orofacial manifestations include expansion of the diploë of the skull, causing a hair-on-end appearance that is frequently conspicuous on lateral skull radiographs. Enlargement of the maxilla is caused by bone marrow expansion (chipmunk facies); there is often spacing of the teeth and forward drift of the maxillary incisors, so that orthodontic treatment may be indicated. Alveolar bone rarefaction produces a chicken-wire appearance on radiography. Pneumatization of the sinuses may be delayed. Less common oral complications include painful swelling of the parotids and hyposalivation caused by iron deposition, and a sore or burning tongue related to the folate deficiency.

Sickle cell trait with another haemoglobinopathy

Persons who have sickle cell trait with another haemoglobinopathy, such as thalassaemia, or both sickle cell haemoglobin S and C (SC disease) are usually not as ill as those with isolated sickle cell disease. However, they are at about the same level of risk from GA as are those with sickle cell disease. Patients with other combined defects should be managed in the same way as those with sickle trait alone.

Other haemoglobin variants

Other Hb variants that can lead to haemolytic anaemia, particularly when certain drugs are given, include Hb Zurich (which causes acute haemolytic reactions when sulphonamides are given) and HbH

(a relatively common variant in the Far East, in which oxidants cause acute haemolysis in homozygotes, similar to that in G6PD deficiency). Various drugs may worsen haemolysis and the physician must be consulted.

Erythrocyte membrane defects

General and clinical aspects

Hereditary spherocytosis (acholuric jaundice) is the main form of congenital haemolytic anaemia in Caucasians. It is an autosomal dominant trait characterized by haemolytic anaemia, jaundice, splenomegaly, gallstones, haemochromatosis and skin ulcers. Episodes of haemolysis may be precipitated by infections.

Hereditary elliptocytosis (ovalocytosis) and *hereditary stomatocytosis* are similar autosomal dominant disorders characterized by chronic haemolytic anaemia.

General management

Splenectomy and folic acid treatment are almost invariably required.

Dental aspects

LA is safe. CS or GA may be given if there is optimal oxygenation.

Erythrocyte metabolic defects

The most common disorder of this type is glucose-6-phosphate dehydrogenase deficiency; various drugs are contraindicated (Table 8.34).

Acquired haemolytic anaemias

Haemolysis can be caused by gross trauma, complement-mediated lysis, drugs, toxins, malaria and other factors. These may occasionally have dental relevance because of anaemia, corticosteroid treatment or haemorrhagic tendencies.

Microangiopathic haemolytic anaemia (MAHA) is caused by fibrin strands depositing in small vessels and damaging erythrocytes in: pre-eclampsia; DIC; malignant hypertension; TTP – usually caused by a defect in breakdown of vWF; and HUS, which is usually caused by *E. coli* O157 verotoxin (Ch. 21) or a defect in factor H – the complement regulatory protein.

OTHER ANAEMIAS

Aplastic anaemia

General aspects

Aplastic anaemia is pancytopenia with a non-functioning bone marrow. It is a rare disease causing leukopenia, thrombocytopenia and refractory anaemia.

Chemicals such as benzene, drugs, hepatitis viruses, irradiation and graft-versus-host disease (GVHD) are important causes (Box 8.14) but many cases are idiopathic, though probably immunologically mediated.

Clinical features

The clinical manifestations are those of anaemia (normochromic, normocytic or macrocytic), together with abnormal susceptibility to infection and bleeding. Purpura is often the first manifestation.

Table 8.34 Drugs in glucose-6-phosphate dehydrogenase (G6PD) deficiency

Contraindicated	Possible risk
Dapsone	Aspirin – although up to 1 g daily is usually harmless
Methylthioninium chloride (methylene blue)	Chloroquine, quinidine and quinine
Nitrofurantoin and quinolones, including ciprofloxacin, moxifloxacin, nalidixic acid, norfloxacin and ofloxacin	Vitamin K analogues (e.g. menadiol sodium phosphate)
Prilocaine	
Primaquine – although 30 mg weekly for 8 weeks has been found not to have harmful effects in African and Asian people	
Sulphonamides, including co-trimoxazole – although some sulphonamides like sulfadiazine are not haemolytic in many with G6PD deficiency	
Sulphonylureas	

Box 8.14 Causes of aplastic anaemia

- Genetic
 - Fanconi anaemia
 - Dyskeratosis congenita
- Immunological
 - Autoimmune
 - Graft-versus-host disease
- Drugs
 - Allopurinol
 - Anticonvulsants
 - Antithyroids
 - Chloramphenicol
 - Cytotoxic agents
 - Gold
 - Non-steroidal anti-inflammatory drugs (NSAIDs)
 - Penicillamine
 - Phenylbutazone
 - Sulphonamides
- Chemicals
 - Benzene
 - Glue-sniffing
 - Heavy metals
 - Toluene
- Viruses
 - Hepatitis
- Irradiation

General management

The principles of management include removal of the cause (even when this is discoverable, as in the case of drugs such as chloramphenicol, marrow damage may still be irreversible); isolation and antibiotics to control infection; bone marrow transplantation (BMT; haemopoietic stem cell transplantation, HSCT [Ch. 35]) after intense immunosuppression (this in turn may cause GVHD, which is often fatal [Ch. 35]); androgenic (anabolic) steroids, which may be of some value (corticosteroids are of questionable benefit); and blood transfusion – but this carries risks from iron overload or infection.

The prognosis is poor and 50% of patients die within 6 months, usually from haemorrhage or infection. Iron overload may result from repeated blood transfusions.

Dental aspects

Treatment modification needs to take into consideration:

- anaemia
- haemorrhagic tendencies
- susceptibility to infections
- effects of corticosteroid therapy (Ch. 6)
- hepatitis B and other viral infections (Ch. 9).

LA is satisfactory. CS and GA should be avoided because of the anaemia.

Oral manifestations of aplastic anaemia, and management, are somewhat similar to those of leukaemia, i.e. ulceration, haemorrhagic tendencies and susceptibility to infections. Oral lichenoid lesions, or a Sjögren-like syndrome, may develop if there is GVHD following marrow transplantation to relieve the anaemia (see later and Ch. 35). Gingival swelling may develop if ciclosporin is used.

Fanconi anaemia

Fanconi anaemia is a rare autosomal dominant disorder with bone marrow failure, absent radii and predisposition to malignant disease, including oral cancer. Birth defects occur in up to 75% of Fanconi anaemia patients, and complications include haemorrhages, infections, leukaemia, myelodysplastic syndrome, liver tumours and other cancers.

Pure red-cell aplasia

Pure red-cell aplasia is a rare disease that may be congenital or acquired. The latter is often associated with a thymoma and sometimes with chronic mucocutaneous candidosis. These patients need regular blood transfusions and are therefore at risk from hepatitis viruses and HIV infection.

Anaemia caused by bone marrow infiltration

Bone marrow infiltration by abnormal cells (metastases, leukaemias, myeloma or myelofibrosis) causes normocytic anaemia and often leukopenia or thrombocytopenia with a leukoerythroblastic peripheral blood picture. There may be extramedullary haemopoiesis in other organs. Dental care may be complicated by susceptibility to infections, haemorrhage (as in aplastic anaemia) or the underlying disease.

Anaemias associated with chronic systemic diseases

Anaemia of various types may be associated with chronic systemic disorders, which include chronic inflammation (infections, or connective tissue disease such as rheumatoid arthritis); neoplasms, particularly leukaemia; liver disease (Ch. 9); uraemia (Ch. 12); HIV infection (Ch. 20); or, rarely, endocrinopathies (hypothyroidism, hypopituitarism or hypoadrenocorticism (Ch. 6).

LEUKOCYTES (WHITE BLOOD CELLS)

Several types of leukocytes (white blood cells) exist, all derived from a multipotent bone marrow stem cell. Leukocytes are important defence cells found throughout the body and discussed in Chapter 20.

LEUKOPENIA

See Chapter 20.

MALIGNANT DISEASE OF LEUKOCYTES

Malignant diseases involving lymphoid cells (lymphoreticular malignancies – leukaemias and lymphomas) are potentially fatal. Lymphoid tissue is widely spread throughout the body, and thus lymphoreticular malignancies have wide effects.

In most forms of malignant disease, some form of staging is used to assist treatment planning and in making a possible prognosis. Staging aims to determine the spread of the malignant neoplasm from its original site. It is based on history, physical examination and investigations, such as blood tests, biopsies (e.g. of lesions, lymph nodes, bone marrow) and imaging – radiography, CT and MRI scans, or ultrasound.

Treatment of malignant disease can be with surgery, radiotherapy, cytotoxic drugs singly or in combination, stem cell transplantation, immunotherapy (monoclonal antibodies and, on the horizon, vaccines) and gene therapy.

Quality of life is as important as, or more important than, simply extension of survival.

LEUKAEMIAS

General aspects

Leukaemias are potentially fatal diseases in which there is neoplastic proliferation of bone marrow white blood stem cells associated with specific gene mutations, deletions or translocations. The aetiology is unknown in most cases but may include:

- a genetic predisposition (e.g. in Down syndrome)
- ionizing radiation
- chemicals (e.g. benzene or formaldehyde)
- chemotherapy (e.g. certain of the alkylating agents and topoisomerase inhibitors, used to treat cancers)
- viruses (e.g. human T-cell leukaemia virus 1 [HTLV-1] infection – linked to T-cell leukaemia)
- myelodysplastic syndromes (formerly called ‘pre-leukaemia’).

Leukaemias are classified by:

- cell of origin – lymphoblast or non-lymphoblast
- cell maturity – immature (acute) or mature (chronic).

This classification allows a patient’s prognosis to be assessed and has implications for treatment.

Acute leukaemias are characterized by primitive blast cells in the blood and bone marrow, account for nearly 50% of all malignant disease in children and are the most common cause of non-accidental death. A total of 85% of leukaemia in children is acute lymphoblastic leukaemia.

Chronic leukaemias are characterized by an excess of mature leukocytes in blood and bone marrow, are mainly diseases of adult life, and are chronic disorders but may progress to acute leukaemia.

Clinical features

Many of the manifestations of leukaemias arise from the crowding-out of normal blood cells from the marrow by the leukaemic cells, leading to:

- anaemia (fatigue, pallor, etc.)
- thrombocytopenia (purpura and a bleeding tendency)

Fig. 8.38 Herpes zoster (shingles) of the upper cervical nerves in a patient dying from leukaemia.

- liability to infections (Fig. 8.38)
- lymphadenopathy, especially in lymphatic leukaemias.

The clinical features of leukaemia are variable but broadly reflect the degree of tissue infiltration by the leukaemic cells and the extent of bone marrow failure (Table 8.35).

Symptoms usually develop fairly quickly in acute leukaemias but gradually in chronic leukaemias (about 20% of people with chronic leukaemia do not have symptoms at the time of diagnosis). However, as leukaemic cells grow and eventually outnumber normal cells, the following events may occur:

- Leukocytes falter in combating infections. The leukaemic cells may also collect in certain parts of the body, such as the testicles, brain, lymph nodes, liver, spleen, digestive tract, kidneys, lungs, eyes and skin – in effect, virtually every tissue site – causing pain, swelling and other problems
- Erythrocytes are crowded out, producing anaemia
- Platelets are crowded out, producing a bleeding tendency.

The following symptoms may arise, many of which are non-specific and common to all leukaemias:

- Unexplained fevers
- Frequent infections
- Night sweats
- Fatigue and malaise
- Weight loss
- Easy bleeding and/or bruising
- Headaches
- Confusion
- Balance problems
- Blurred vision
- Painful lymph node swellings in the neck, axillae or groin
- Shortness of breath
- Nausea or vomiting
- Abdominal discomfort and/or swelling
- Testicular discomfort and/or swelling
- Pain in the bones or joints
- Weakness or loss of muscle control
- Seizures.

General management

The following investigations should be carried out:

- Blood tests: the leukocyte count is very high (although it is not uncommon for this to be normal in childhood acute lymphocytic leukaemia), whereas the platelet and erythrocyte counts are low

Table 8.35 Clinical features of leukaemia

Site of disease	Clinical manifestation
<i>Bone marrow failure</i>	
Anaemia	Pallor, lethargy, dyspnoea
Neutropenia	Recurrent infection
Thrombocytopenia	Mucosal bleeding and bruising
<i>Tissue infiltration</i>	
Lymphatics	Lymphadenopathy
Liver and spleen	Hepatosplenomegaly
Mediastinum	Hilar lymphadenopathy
Gingiva and skin	Gingival and skin deposits
Meninges and brain	Meningitis-like syndrome
Bone	Bone pain and pathological fractures

- Liver and kidney function tests
- Bone marrow biopsy: via an aspirate
- Lymph node excision
- Chest X-ray
- Genetic studies: help in classifying the various leukaemia types
- Lumbar puncture or spinal tap for the possible presence of leukaemic cells.

Staging

In general, in order to determine the most appropriate therapy, leukaemias are classified according to their genotypes rather than staged. Chronic myelocytic leukaemia is also classified by phase – chronic, accelerated and blast (or ‘blast crisis’) phases defined by the number of blasts (immature leukaemia cells) in the blood and bone marrow.

Treatment

Leukaemia treatment depends almost exclusively on the type. Modifying factors may be age, overall health, and prior therapy. General factors affecting outcomes include:

- age
- percentages of leukaemia cells in blood and bone marrow
- degree to which specific systems of the body are affected by leukaemia
- chromosome abnormalities in leukaemia cells.

Specific factors are associated with outcomes in each leukaemia type, and outlook is measured in terms of survival rates. The number of people who are still alive 5 years after treatment varies by type of leukaemia. After 5 years, more than 80% of patients without detectable disease are likely to maintain a lifelong remission. Patients in remission for longer than 15 years are considered unequivocal cures.

Leukaemia therapy includes measures to fight the cancer and treatments to relieve both the symptoms and the adverse effects of the treatment (supportive care).

Leukaemias vary in their response to treatment. In general:

- acute leukaemias respond well to treatment and can be cured. Others do not have such a positive outlook
- chronic leukaemias usually cannot be cured, but they can be controlled for long periods.

Chemotherapy

The most widely used antileukaemic treatment is chemotherapy; the goal is to cure the patient, meaning that blood tests and bone marrow

biopsy show no evidence of leukaemia (i.e. a remission – no evidence of disease) and the leukaemia does not come back (relapse) over time. Only time can determine whether there will be disease-free survival (cure). Remission may be short-lived, thereby requiring administration of new, previously unseen therapy (second-line therapy).

Haematologists and oncologists often refer to phases of chemotherapy as:

- *induction*. The purpose of this first phase is to kill as many leukaemia cells as possible and bring about a remission
- *consolidation*. In this phase, the goal is to seek out and kill the residual leukaemia cells not destroyed by induction. Often, these cells are not detectable but they are assumed still to be present
- *maintenance*. The third phase is used to keep numbers of leukaemia cells low, i.e. to keep the disease in remission. The doses of chemotherapy are not as high as in the first two phases. This phase can last as long as 2 years.

However, only in certain leukaemia types are all three phases used.

Chemotherapy usually involves different combinations of drugs, and may be administered via a vein or by mouth. Many patients have a semi-permanent intravenous central line inserted. People who have leukaemia in their cerebrospinal fluid receive chemotherapy directly into the cerebrospinal canal (intrathecal chemotherapy); sometimes the therapy is inserted into a sac (Ommaya reservoir) placed in one of the brain ventricles.

Chemotherapy kills malignant cells or stops them from reproducing. Unfortunately, it also destroys rapidly growing healthy cells – leading to many of the adverse effects of treatment. These may include:

- common side-effects, such as nausea and vomiting, diarrhoea, hair loss and oesophagitis
- some effects similar to those of leukaemia itself: infections, anaemia and bleeding problems
- severe effects on the bone marrow, hair follicles and digestive system (from mouth to anus); occasionally, the nails may splinter, crack, develop ridges or cease growing
- effects on fertility
- an increase in the risk of developing cancer.

Chemotherapy is usually given in cycles, each cycle consisting of intensive treatment over several days, followed by a few weeks without treatment for rest and recovery from adverse effects caused by the therapy. The sequence is then repeated. Regimens may be administered for 2–6 cycles, depending on the leukaemia type. Blood and bone marrow examinations may be carried out prior to each cycle of chemotherapy and after completion of treatment.

Biological drug therapy

Biological drugs act in a similar way to the body's natural immune system; they include monoclonal antibodies, interferon or interleukins (see below).

Radiation therapy

Radiation is another treatment occasionally used in some types of leukaemia:

- A high-energy radiation beam is targeted at an organ, such as the brain, bones or spleen, where large numbers of leukaemia cells have collected.
- Radiation to the brain can have negative cerebral long-term effects, especially in children.

Table 8.36 Examples of chemotherapy regimes for lymphoproliferative disorders

Disease	Specific type	Agents
Acute leukaemias	Acute lymphoblastic leukaemia	Vincristine, prednisolone (prednisone), asparaginase (crisantaspase), daunorubicin
	Acute myeloblastic leukaemia	Daunorubicin and cytosine arabinoside
Chronic leukaemias	Chronic lymphoblastic leukaemia	Sometimes chlorambucil
	Chronic myeloblastic leukaemia	Hydroxycarbamide
Lymphomas	Hodgkin disease	ABVD or MOPP (see Table 8.45)
	Non-Hodgkin lymphomas	CHOP (see Table 8.45)

Stem cell transplantation

Haemopoietic stem cell transplantation (HSCT) uses high doses of chemotherapy along with total body irradiation in order to kill the leukaemic cells. After this, the immune system is essentially depleted, patients becoming at high risk of developing serious life-threatening infections; they are thus treated in specially designed, sterile, air-filtered marrow transplant rooms. Stem cells from a healthy, complete blood cell-matched donor (usually a sibling or, less commonly, a parent) are then transplanted allogeneically into a vein, whereupon they migrate to the marrow and grow and multiply before entering the circulation. This whole process may take 2–3 weeks to be completed. Marrow or stem cells from an identical twin are referred to as syngeneic. If an allogeneic donor is not available, the patient's own marrow cells, usually pretreated in order to remove residual, but otherwise unseen, leukaemic cells, are infused. This autologous approach is far less successful than the use of matched donor cells.

Prognosis and adverse effects of treatment

Diagnosis and prognosis of leukaemias are established by haematological examination (especially white cell count and blood film examination). This is supplemented by bone marrow biopsy, chest radiography, CT and MRI scans, and lumbar puncture. There is an excess of circulating white blood cells but there may be phases when few are released from the bone marrow (aleukaemic leukaemia). Cytochemistry, analysis of membrane markers and immunophenotyping are required for categorization of the cell type. Detection of chromosomal abnormalities may guide treatment and prognosis.

The treatment of leukaemia is dependent upon accurate diagnosis and generally involves combination chemotherapy with a variety of cytotoxic agents (Table 8.36). Induction of remission with cytotoxic drugs, singly or in combination, is increasingly followed by bone marrow transplantation (haemopoietic stem cell transplantation; Ch. 35). Post-remission treatment (consolidation) and, in some instances, maintenance therapy are indicated.

Newer treatments include retinoids, monoclonal antibodies, T-cell infusions, peptide vaccines and cytokines (such as granulocyte colony-stimulating factor [G-CSF]). Minimal residual disease (MRD) may remain and this guides further care. Prognosis of most leukaemias in the absence of treatment is very poor; few patients survive more than a year after diagnosis.

Cytotoxic chemotherapeutic drugs, given by intravenous, oral, intramuscular or intrathecal routes, damage all proliferating cells, including epithelium, bone marrow and reproductive tissues. Their toxic nature causes nausea and vomiting, impaired immunity, alopecia and mucositis. They are also teratogenic.

Table 8.37 Synopsis of principles of oral health care in leukaemia

Pre-chemotherapy	During induction chemotherapy	During remission	Long-term
Assessment	Continuation of preventive oral health care	Continuation of preventive oral health care	Continuation of preventive oral health care
Treatment planning			
Removal of unsalvageable teeth	Antifungal prophylaxis (e.g. nystatin)		Monitoring of craniofacial and dental development
Treatment of caries	Antiviral prophylaxis (e.g. aciclovir)		
Dietary advice			
Initiation of fluoride prophylaxis			
Oral hygiene advice			
Initiation of chlorhexidine prophylaxis			

Patients are highly susceptible to infection during the induction of remission and may need to be isolated. Supportive care includes control of nausea, infections, haemorrhagic tendencies, anaemia, hyperuricaemia (gout) and renal malfunction. Nausea may be controllable with phenothiazines (prochlorperazine) or domperidone; if it is severe, 5-hydroxytryptamine (5HT) antagonists, such as granisetron, may be needed.

Dental aspects of leukaemias

Orofacial manifestations include mucositis, ulcers or gingival swelling and bleeding. Oral health care principles are summarized in Table 8.37.

Dental management can often be complicated by bleeding tendencies and susceptibility to infection. Septicaemias may spread from oral infections in these patients, as in other immunocompromised persons (Ch. 20).

Cytotoxic drugs are potentially hazardous to staff, who should only handle them wearing medical gloves and protective eyewear, should dispose of waste and sharps carefully, and should not handle them at all while pregnant.

The main types of leukaemia are:

- acute lymphocytic leukaemia (ALL) – accounts for 65% of childhood acute leukaemias but affects both children and adults
- chronic lymphocytic leukaemia (CLL) – almost twice as common as chronic myelocytic leukaemia and is essentially an adult disorder affecting older people
- acute myelocytic leukaemia (AML) – the most common acute leukaemia in adults
- chronic myelocytic leukaemia (CML) – most common in adults.

Less common types include hairy cell and human T-cell leukaemias.

Acute lymphocytic leukaemia (ALL)

General aspects

ALL is the most common childhood leukaemia; it has a peak incidence at 2–4 years but can affect any age group. Aetiological factors may include exposure to ionizing radiation or benzene. Electromagnetic radiation from power lines has little observable effect.

ALL presumably arises from malignant transformation of B- or T-cell progenitor cells and is characterized by the accumulation of malignant lymphoblasts, which proliferate and infiltrate the bone marrow (causing granulocytopenia, anaemia and thrombocytopenia), viscera, skin and nervous system. B- and T-cell lymphoblastic leukaemia cells express surface antigens that parallel their respective lineage developments. Precursor B-cell ALL cells typically express

Table 8.38 Acute leukaemia: typical features

General features	Features due to leukaemic infiltration of bone marrow	Features due to leukaemic infiltration of lymphoreticular system
Weight loss	Anaemia (pallor)	Lymphadenopathy
Weakness	Bone pain	Splenomegaly
Anorexia	Ineffective leukocytes (infections)	Thrombocytopenia (purpura and bleeding from mucous membranes)

B-cell surface markers CD10, CD19 and CD34, along with nuclear terminal deoxynucleotide transferase (TdT), while precursor T-cell ALL cells commonly express CD2, CD3, CD7, CD34 and TdT. ALL is associated with translocations that involve movement of the *c-myc* proto-oncogene to the immunoglobulin gene loci t(2;8), t(8;12) and t(8;22). Some patients with acute leukaemia may have a cytogenetic abnormality that is indistinguishable from the Philadelphia chromosome (Ph1). This occurs in 1–2% of patients with AML, but in about 20% of adults and a small percentage of children with ALL. In most children and more than one-half of adults with Ph1-positive ALL, the molecular abnormality is different from that in Ph1-positive CML. Ph1 is characterized by a *BCR-ABL* fusion gene.

Clinical features

Anaemia, lymphadenopathy, splenomegaly, infections, fever, bruising and bleeding tendencies are the main features. CNS involvement is not uncommon. ALL is clinically indistinguishable from non-lymphoblastic (myeloblastic) leukaemia (Table 8.38).

General management

Remission induction therapy over the first 3–4 weeks after diagnosis is designed to destroy most leukaemia cells, reduce symptoms and return blood counts to normal. During induction of remission, the child may need to be kept in isolation, such as in a laminar flow room, because of the high susceptibility to infection. Strict asepsis is indicated, live vaccines must not be given and infected persons should be kept away.

Specific treatments used may include:

- doxorubicin, cyclophosphamide or vincristine, by intravenous injection
- asparaginase (crisantaspase), given by injection
- dexamethasone or prednisolone (prednisone) orally
- methotrexate or cytarabine (Ara-C) by injection into the spinal fluid.

Chemotherapy for ALL in the *induction phase*, which normally lasts 3–8 weeks, may include:

- daunorubicin
- doxorubicin
- idarubicin
- mitoxantrone
- methotrexate
- asparaginase (crisantaspase)
- mercaptopurine
- cyclophosphamide
- vincristine.

Corticosteroids are often given as part of chemotherapy. Allopurinol or rasburicase helps to protect against uric acid-induced renal damage. Apart from the common chemotherapy adverse effects, some of the above drugs may affect heart muscle.

Intensification (*consolidation*) treatment usually lasts several months, involving the same drugs as used in induction, plus some of:

- cytarabine (Ara-C)
- etoposide
- tioguanine.

Remission *maintenance* or continuation therapy is a less intensive chemotherapy course using mercaptopurine, methotrexate and vincristine. Steroids are usually continued in short courses. Some patients are given high-dose treatment with a stem cell transplant, with high doses of a chemotherapy drug such as etoposide or busulfan, and total body irradiation (TBI). Treatment is given both orally and intravenously over a 2–3-year period to keep the ALL from returning.

CNS prophylaxis, given directly into the spinal fluid by lumbar puncture and/or by vein, helps prevent the leukaemia spreading to the brain or spinal cord, and is often given in combination with radiation therapy to the head. Craniospinal irradiation is no longer routine in low-risk ALL patients but intrathecal methotrexate may be given.

Targeted therapy for ALL is recommended in addition to standard chemotherapy for patients with Philadelphia chromosome-positive ALL (Ph+ ALL). Such drugs include imatinib, dasatinib and nilotinib. Nelarabine targets T-cell ALL. Monoclonal antibodies such as rituximab target B-cell ALL.

The goal is a complete remission, which is achieved in about 95% of children and 75% of adults. The risk of relapse is greatest in the first 18 months and maintenance therapy is usually continued for 2–3 years. Relapse is higher in males, partly because of occult testicular or CNS disease. Bone marrow transplantation (haemopoietic stem cell transplantation; Ch. 35) may give better control if chemotherapy fails to prevent relapse.

Dental aspects

Dental treatment should only be carried out after consultation with the physician, as it may be affected by various aspects of management and the probable life expectancy.

Preventive oral health care is essential and, where indicated, conservative dental treatment may be possible. Surgery should be deferred (except for emergencies such as fractures, haemorrhage, potential airways obstruction or dangerous sepsis) until a remission phase.

The main dental management problems to consider in ALL are listed in Box 8.15.

Regional LA injections may be contraindicated if there is a severe haemorrhagic tendency. CS is usually possible. Anaemia may be a

Box 8.15 Considerations in the care of acute lymphoblastic leukaemia

- Abnormal susceptibility to infection – patient may be kept in isolation, such as in a laminar flow room, where strict asepsis is indicated. Antimicrobial cover is needed for surgery, particularly for those with indwelling atrial catheters
- Anaemia
- Bleeding tendencies
- Complications of bone marrow transplantation (haemopoietic stem cell transplantation; Ch. 35)
- Corticosteroid treatment (Ch. 6)
- Disseminated intravascular coagulopathy
- Hepatitis B or C (Ch. 9) and HIV infection (Chs 20 and 21; preoperative precautions include screening for hepatitis B and HIV in blood transfusions)
- Interaction between methotrexate and nitrous oxide (largely theoretical)

contra-indication to GA – intravenous sedation or relative analgesia may be used as alternatives. However, nitrous oxide, which interferes with vitamin B₁₂ and hence folate metabolism, is possibly contraindicated if the patient is being treated with methotrexate. The toxic effects of the latter may be exacerbated.

Due to the dangers of haemorrhage and infections such as osteomyelitis or septicaemia, desmopressin (DDAVP) or platelet infusions or blood may be needed preoperatively, and antibiotics may be given until the wound has healed. Penicillin is the antibiotic of choice; intramuscular injections should be avoided because a haematoma may result. Sockets should not be packed, as this appears to predispose to infection. Operative procedures must be performed with strict asepsis and with the least trauma. Absorbable polyglycolic acid sutures are preferred.

Aspirin and other NSAIDs should not be given, since they can aggravate bleeding.

Oropharyngeal lesions can be the presenting complaint in over 10% of cases of acute leukaemia. Oral bleeding and petechiae are typical manifestations, together with mucosal pallor and sometimes gingival swelling (localized or generalized), mucosal or gingival ulceration, pericoronitis and cervical lymphadenopathy. Severe bleeding from the mouth, particularly from the gingival margins, may result from the thrombocytopenia. It needs treatment with desmopressin or even platelet transfusion. Gentle oral hygiene measures should control gingivitis, which otherwise aggravates the bleeding.

Herpetic oral and perioral infection is common and troublesome, as are varicella-zoster infections. They should be treated vigorously, usually with aciclovir. Varicella-zoster (VZV) and measles viruses can also cause encephalitis or pneumonia. Prophylactic aciclovir has greatly reduced the incidence, morbidity and mortality from VZV infections, including those secondary to bone marrow transplants.

Candidosis is particularly common in the oral cavity and the paranasal sinuses, and is usually caused by *Candida albicans*. Prophylactic antifungal therapy, such as nystatin mouthwashes or pastilles, or amphotericin lozenges, is therefore indicated. Fluconazole-resistant candidal species and a rising number of cases of infection with *Candida krusei* are seen.

Aspergillosis or mucormycosis can involve the maxillary antrum and be invasive.

Bacterial infections with Gram-negative species occasionally cause oral lesions, which can be a major source of septicaemia or metastatic infections in leukaemic patients. Lesions tend to become infected

with bacteria such as *Pseudomonas* or *Escherichia*, or with *Candida* or *Aspergillus*. In severely immunosuppressed patients, over 50% of systemic infections result from oropharyngeal microorganisms. Microbiological investigations with care to obtain specimens for anaerobic culture are essential to enable appropriate antimicrobial therapy to be given. Meticulous oral hygiene should be carefully maintained, with regular frequent warm 0.2% aqueous chlorhexidine mouth rinses and the use of a soft nylon toothbrush.

Gram-negative bacteria can sometimes form a white adherent plaque on the tongue.

Other oral findings include tonsillar swelling, paraesthesiae (particularly of the lower lip), extrusion of teeth, and painful swellings over the mandible and of the parotid (Mikulicz syndrome).

Bone changes seen on radiography may include destruction of the crypts of developing teeth, thinning or disappearance of the lamina dura, especially in the premolar and molar regions, and loss of the alveolar crestal bone. Bone destruction near the apices of mandibular posterior teeth may also be seen. These bone changes may be reversible with chemotherapy.

Many of the cytotoxic drugs can precipitate mucositis with oral ulceration.

Adult acute lymphocytic leukaemia

Adult acute lymphoblastic leukaemia has a worse prognosis than childhood ALL but treatment schedules are similar.

Acute non-lymphocytic (myeloblastic) leukaemia (ANLL)

General aspects

ANLL is less common than ALL in children. Acute myeloblastic leukaemia (AML) is the most common of the seven subtypes described, and is the most common acute leukaemia of adults. The classification of AML has been revised by a group of pathologists and clinicians under the auspices of the World Health Organization (WHO). While elements of the French–American–British classification have been retained (i.e. morphology, immunophenotype, cytogenetics and clinical features), the WHO classification incorporates recent discoveries regarding genetics and clinical features of AML. Increased morbidity and mortality during induction appear to be directly related to age, CNS involvement, systemic infection, treatment-induced AML, and history of myelodysplastic syndromes or another antecedent haematological disorder. Patients with leukaemias that express the progenitor cell antigen CD34 and/or the P-glycoprotein (*MDR1* gene product) have a worse outcome. Deletions of the long arms or monosomies of chromosomes 5 or 7; translocations or inversions of chromosome 3, t(6; 9), t(9; 22); or abnormalities of chromosome 11q23 have particularly poor prognoses with chemotherapy. Cytogenetic abnormalities that indicate a good prognosis include t(8; 21), inv(16) or t(16;16), and t(15;17).

Although each criterion has prognostic and treatment implications, for practical purposes, current antileukaemic therapy is similar for all subtypes.

Clinical features

Anaemia, lymphadenopathy, splenomegaly, infections, fever, bruising and bleeding tendencies are the main features. CNS involvement is rare, though the disease occasionally causes cranial nerve palsies.

General management

AML (ANLL) treatment endeavours to achieve complete remission, since partial remission offers little survival benefit. Up to 70% of adults with AML can nowadays be expected to attain complete remission and about 45% of those can survive 3 or more years.

Chemotherapy drugs are usually given in combination. In some situations, high-dose chemotherapy plus stem cell or bone marrow transplant are used.

People who have acute promyelocytic leukaemia (APL) are treated with tretinoin (all trans-retinoic acid; ATRA) for up to 3 months alongside chemotherapy. ATRA has adverse effects, which can include:

- headaches
- nausea
- dry skin
- dry mouth
- dry eyes
- bone pain.

Induction chemotherapy is two cycles of one or more of:

- cytarabine (Ara-C)
- daunorubicin
- etoposide
- fludarabine
- idarubicin
- mitoxantrone.

Other agents used include clofarabine, everolimus, gemtuzumab, arsenic trioxide (for APL), midostaurin, lenalidomide, sorafenib, calicheamicin and tipifarnib. Consolidation chemotherapy usually involves cytarabine (Ara-C), etoposide, amsacrine and mitoxantrone.

Combination chemotherapy has greatly improved the prognosis in AML but is less successful than in childhood ALL. Remission can be obtained in up to 85% of patients but is rarely maintained. Whenever possible, bone marrow transplantation (haemopoietic stem cell transplantation; Ch. 35) is employed and 5-year survival rates of up to 60% are then reported.

Dental aspects of acute leukaemias

Treatment modifications are as provided earlier for ALL. Orofacial manifestations develop in 65–90% of cases (Box 8.16).

Box 8.16 Oral and perioral manifestations of leukaemia

- Lymph node enlargement
- Pallor
- Purpura, bleeding from gingivae
- Infections
 - Candidosis and other fungal infections
 - Herpesvirus infections
- Oral ulceration
 - Caused by herpesviruses, drugs and other factors
- Gingival swelling
 - Caused by leukaemic infiltrate
- Drug side-effects
 - Mucositis and ulceration (many of the cytotoxics)
 - Dry mouth (doxorubicin [Adriamycin])
 - Pigmentation (busulfan)
 - Candidosis (antimicrobials)

Oral bleeding and petechiae are typical manifestations, together with mucosal pallor and sometimes gingival swelling (localized or generalized), mucosal or gingival ulceration, pericoronitis and cervical lymphadenopathy. AML in particular may cause gingival swelling in 20–30% of patients. Gingival swelling results from an abnormal response to dental plaque, causing the tissues to be distended by dysfunctional white cells. Improvement in oral hygiene, aided by chlorhexidine, for example, can greatly ameliorate or abolish the swelling. ATRA, used in the treatment of APL, may also cause gingival swelling.

Chronic lymphocytic leukaemia (CLL)

General aspects

CLL is the most common type of leukaemia. In 10% there is a positive family history of the disease. Men are particularly affected but CLL is rare in Asians. CLL is almost invariably a B-cell neoplasm but there are several variants (Table 8.39).

Clinical features

Many patients with CLL are asymptomatic; some 60% of cases are detected coincidentally during a blood screen for an unrelated reason, and life expectancy may not be affected.

In others, CLL is insidiously progressive, with fatigue, fever, weight loss, anorexia, lymphadenopathy, haemorrhage and infections. Lymph nodes enlarge early, whereas the liver and spleen enlarge later. Other effects are anaemia and thrombocytopenia. Leukaemic infiltration of the skin is more common than in CML and may be a major manifestation. In some, autoimmune disorders – such as haemolytic anaemia or thrombocytopenia, or both (Evan syndrome) – may develop.

About 15% of patients with CLL undergo transformation to a more rapidly progressive form of leukaemia, or lymphoma (Richter syndrome).

General management

Asymptomatic patients may not need treatment. CLL patients may choose a watchful waiting approach but may need to start treatment, e.g. with biological drugs, when:

- the number of CLL cells spikes to much higher levels
- the number of non-cancerous cells drops precipitously
- lymph nodes become swollen
- the spleen becomes swollen.

Fludarabine is standard chemotherapy for CLL but pentostatin (2-deoxycoformycin) and cladribine are also used. Currently, the following combinations involve fludarabine often with:

- rituximab (FR)
- cyclophosphamide (FC)
- cyclophosphamide and rituximab (FCR).

Alternatives are rituximab with:

- pentostatin (2-deoxycoformycin) and cyclophosphamide (PCR)
- bendamustine (BR).

Chlorambucil and cyclophosphamide can be given orally, while cyclophosphamide can also be given intravenously, alone or with prednisolone (prednisone). Other monoclonal antibodies approved for CLL treatment include alemtuzumab and ofatumumab. Interferon, pentostatin (2-deoxycoformycin) and cladribine are used for hairy cell leukaemia.

Splenectomy may be needed. The 5-year survival of CLL is over 50%.

Chronic myeloid leukaemia (CML)

General aspects

CML is characterized by proliferation of myeloid cells in the bone marrow, peripheral blood and other tissues. A total of 90% of patients with CML have the Philadelphia chromosome and the *BCR-ABL* gene, which can aid diagnosis and treatment monitoring. Most patients with CML suffer from chronic granulocytic leukaemia (CGL) and are over 40 years of age, but there are several rare subgroups (Table 8.40).

Clinical features

Anaemia, weight loss, joint pains, splenomegaly and hepatomegaly are common but lymphadenopathy is rare.

After about a 4–5-year phase, CML transforms to an acute phase similar to AML (blast crisis). Fever, haemorrhage or bone pain is then common.

Table 8.39 Chronic lymphoid leukaemias^a

Disorder	Particular features
Chronic lymphocytic leukaemia	Splenomegaly, skin lesions Prolonged survival possible
Sézary syndrome	Generalized lymph node enlargement; pruritus; exfoliating erythroderma, sometimes oral deposits
Hairy cell leukaemia	Chemotherapy relatively ineffective Splenomegaly; may be associated with HTLV-1 infection; predisposes to mycobacterial infection Relatively long survival Responds to interferon-alpha
Prolymphocytic leukaemia	Splenomegaly; resistant to chemotherapy and radiotherapy
Adult T-cell leukaemia–lymphoma	Resembles lymphocytic leukaemia Poor prognosis

HTLV = human T-cell lymphotropic virus.

^aMost involve B cells, except for T-cell leukaemia and Sézary syndrome, which involve T cells.

Table 8.40 Chronic myeloid leukaemia

Disorder	Particular features
Chronic granulocytic leukaemia	Splenomegaly Positive for Philadelphia chromosome Fairly responsive to chemotherapy
Atypical chronic granulocytic leukaemia	Negative for Philadelphia chromosome Less responsive to chemotherapy
Juvenile leukaemia	Mainly young children Lymphadenopathy Poor response to chemotherapy
Chronic myelomonocytic leukaemia	Little response to chemotherapy
Chronic neutrophilic leukaemia	Difficult to differentiate from a benign leukocytosis
Eosinophilic leukaemia	Eventual cardiac damage

General management

Cytoreductive chemotherapy agents, such as busulfan and hydroxyurea, have been the mainstay, but the discovery of the Philadelphia chromosome and the identification of *BCR-ABL* have revolutionized treatment. Newer agents, such as imatinib mesylate, dasatinib, nilotinib and bosutinib, target leukaemia cells and inhibit the *BCR-ABL* enzyme, causing CML cells to die but only minimally affecting healthy cells. Radiotherapy may be useful later.

The prognosis of CML is variable, but sooner or later there is transformation to a blast crisis. In blast transformation, the same treatment is given as for AML, but the acute phase is usually refractory and the patient may die within a few months.

Dental aspects of chronic lymphocytic and myeloid leukaemia

The prognosis of chronic leukaemia is better than that for acute leukaemia and routine dental treatment is more likely to be required. Close cooperation with the haematologist is needed since there may be:

- bleeding tendencies
- liability to infection
- anaemia
- susceptibility to hepatitis B, C and HIV infection.

Side-effects of treatment include pulmonary fibrosis as a result of busulfan. In addition, ampicillin and amoxicillin may cause irritating rashes similar to those seen in infectious mononucleosis and unrelated to penicillin allergy. Gingival bleeding, oral petechiae or oral ulceration may also be features. Ulceration may be aggravated by cytotoxic therapy. Interferon-alpha can disturb taste and cause dry mouth. Herpes simplex or zoster, and candidosis, are common. Gingival swelling is less frequent than in the acute leukaemias. Palatal swelling (submucosal leukaemic nodules) may develop.

LA is satisfactory. CS can be given if required. GA must be carried out in hospital.

In CML, oral haemorrhage may result from platelet deficiency. Leukaemic infiltration can cause swelling of lacrimal and salivary glands (Mikulicz syndrome). Granulocytic sarcoma is a rare tumour-like proliferation of leukaemic cells, which can affect the jaws or soft tissues, and may rarely precede other manifestations or herald a blast crisis.

MYELODYSPLASTIC (PRE-LEUKAEMIC) SYNDROMES

General aspects

The myelodysplastic syndromes (MDSs; [Box 8.17](#)) are a group of diseases, found especially in the elderly, which originate in a bone marrow stem cell. Though the bone marrow is initially active, erythrodyspoiesis and dysplastic changes develop later.

There is a tendency to transform to AML. The poor quality of the blood cells means that a significant number of them are destroyed, leading to pancytopenia.

Clinical features

MDSs mainly affect males over the age of 60 who have neutropenia, macrocytic anaemia and/or thrombocytopenia.

The usual signs and symptoms are therefore excessive tiredness on exertion, breathlessness, bleeding, easy bruising, infection and enlargement of spleen or liver. Some patients succumb to marrow failure.

Box 8.17 The myelodysplastic syndromes

- Refractory anaemia alone (RA)
- Refractory anaemia with ring sideroblasts (RAS)
- Refractory anaemia with excess blasts (RAEB)
- Refractory anaemia with blasts in transformation (RABT)
- Chronic myelomonocytic leukaemia (CML)

General management

Diagnosis is from examination of blood and bone marrow. There is usually a monocytosis.

Treatment of MDSs is mainly supportive, since the majority of patients with these syndromes are too old to be eligible for a bone marrow transplant. This treatment includes erythrocyte and platelet transfusions, erythropoietin, G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF), antibiotics, folic acid and vitamin B₆, and systemic corticosteroids.

Dental aspects

Dental management may be complicated by:

- bleeding tendencies due to thrombocytopenia
- anaemia
- neutropenia and a liability to infection, including hepatitis B and HIV (Ch. 20)
- corticosteroids (Ch. 6)
- gingival infiltration and oral ulceration; these may develop in CML but not in the other MDSs.

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome (HES) is an uncommon disorder in which there is hypereosinophilia in the absence of allergic disease. T-cell proliferation or parasitic infestation, together with disease of various organs, especially cardiomyopathy, and various rashes, are typical. Mucosal erosions and ulcers may be an early feature. HES is sometimes pre-lymphomatous.

Management is with systemic corticosteroids and usually hydroxycarbamide, or interferon.

MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders, characterized by proliferation of bone marrow cells other than leukocyte stem cells, are regarded as separate entities from leukaemias but may progress to acute leukaemia. They have several common features and transition between them is common ([Table 8.41](#)). All are rare. Chronic granulocytic leukaemia is sometimes also included in this group.

Polycythaemia rubra vera

General aspects

Polycythaemia is an expansion mainly in the red cell population. It may be primary and idiopathic, and associated with normal erythropoietin levels. Polycythaemia rubra vera (PRV; [Fig. 8.39](#)) is mainly a disease of the elderly and of smokers; it has a slight male predominance and also causes proliferation of other blood cells.

Table 8.41 Important laboratory findings in myeloproliferative diseases

	Red blood cell count	White blood cell count	Platelet count	Alkaline phosphatase	Marrow fibrosis	Splenomegaly
Polycythaemia rubra vera	↑	↑	↑	↑	–	+
Agnogenic myeloid metaplasia	↓	↑	N or ↑	↑	+	++
Essential thrombocythaemia	N	N	↑↑↑	N	–	+

N = normal.

**Fig. 8.39** Polycythaemia.**Clinical features**

Red cell overproduction leads to hyperviscosity syndrome (see later) and the risk of thromboses because of changes in platelets and clotting mechanisms. Stroke, myocardial infarction or less serious consequences can follow.

Granulocyte overproduction and excessive cell turnover may lead to hyperuricaemia, gout and renal damage. Platelet overproduction with platelet dysfunction leads to haemostatic defects, bruising or bleeding. Bone marrow replacement by erythropoietic tissue causes bone pain and there may eventually be myelofibrosis, and myeloid metaplasia in the liver and spleen.

General management

In the absence of treatment, few patients with PRV survive more than 2 years.

Repeated venesection shrinks the red cell mass and extends survival to more than 10 years. Phosphorus-32 is also a simple and effective method of depressing erythropoiesis but may increase the risk of

leukaemia. Cytotoxic agents (busulfan, chlorambucil or melphalan) may be given to suppress marrow activity, especially if there is thrombocytosis, but they also raise the risk of neoplasia. Cyproheptadine to control pruritus and allopurinol for gout may also be needed.

Dental aspects

The main dental management problems are susceptibility to thrombosis and haemorrhage. Venesection is especially important, if surgery is indicated, since postoperative morbidity and mortality are greatly increased by thrombotic complications.

LA regional blocks should be avoided. CS can be given. GA is a matter for expert attention in hospital.

There may be oral complications from cytotoxic chemotherapy.

Agnogenic myeloid metaplasia and myelofibrosis**General aspects**

Myelofibrosis may be primary (agnogenic myeloid metaplasia) or it may be secondary to PRV, carcinomatosis or tuberculosis. Most patients are elderly.

Clinical features

Fibrosis of the bone marrow gradually depresses cell proliferation and extends throughout the reticuloendothelial system. There may be loss of weight, anaemia, thrombocytopenia purpura and bleeding tendencies, weakness, bone pain, splenomegaly, hepatomegaly and gout.

General management

Most patients require correction of anaemia and thrombocytopenia by transfusion. Bone pains and hyperuricaemia also need to be controlled. Corticosteroids are used occasionally. The median survival time is about 5 years, but less in myelofibrosis secondary to carcinomatosis or polycythaemia.

Dental aspects

Management problems may result from:

- anaemia
- haemorrhage
- possible hepatitis B and C or HIV carriage
- corticosteroid treatment.

Essential thrombocythaemia**General aspects**

Thrombocythaemia (increased platelets) may be an isolated abnormality or associated with other myeloproliferative disorders.

Table 8.42 *Lymphomas*

	Hodgkin lymphoma	Non-Hodgkin lymphoma
Sites mainly affected	Lymphatic tissues	Lymphatic tissues
Clinical features	Swellings, fevers, chills, weight loss, night sweats, lack of energy, itching	Swellings, fevers, chills, weight loss, night sweats, lack of energy, itching
Prevalence	More common, especially in young adults 16–34 years of age and in older people ≥ 55 years	Less common; seen mainly in older people
Lymphocyte of origin	B	B or T
Subtypes	5 are microscopically distinct; typing is based on microscopic differences, as well as extent of disease	30 look similar but are functionally quite different and respond to different therapies
Main treatments	Early stage usually treated with chemotherapy before radiotherapy; chemotherapy is nearly always the main treatment when disease is more widespread	Chemotherapy
Staging	I–IV plus A or B	I–IV plus A or B
Survival	Greater	Lesser

Clinical features

The common effects are thromboses or haemorrhages. There is usually gross thrombocytosis with functionally defective, giant platelets.

General management

Radioactive phosphorus is the treatment of choice. If this fails, cytotoxic drugs are used. Aspirin and dipyridamole are useful for preventing thrombosis but heparin may be required.

Dental aspects

Surgery must be avoided until the disease is controlled, particularly because of the haemorrhagic tendencies.

LYMPHOMAS

General aspects

Lymphoma is a malignant transformation of either B or T lymphocytes or one of about 35 subtypes. The malignant lymphocytes multiply and may aggregate in, and enlarge, organs such as lymph nodes or other lymph tissues such as the spleen. Lymphomas fall into one of two major categories (Table 8.42):

- Hodgkin lymphoma (HL; previously termed Hodgkin disease)
- non-Hodgkin lymphomas (NHLs; all other lymphomas).

Most lymphomas (90%) are NHLs. About 10% of all lymphomas are Hodgkin disease, which can affect any age group but particularly males in their thirties. They are not reliably distinguishable clinically.

Lymphoma risk factors include:

- advancing age
- infections
 - ◆ HIV
 - ◆ HTLV-1
 - ◆ Epstein–Barr virus (EBV)
 - ◆ hepatitis B virus
 - ◆ hepatitis C virus
 - ◆ *Helicobacter pylori*
- immune disorders
 - ◆ autoimmune disease
 - ◆ immune suppressive therapy
 - ◆ immune defects such as HIV/AIDS
 - ◆ inherited immunodeficiency diseases (e.g. severe combined immunodeficiency, ataxia telangiectasia)

Table 8.43 *Revised European–American Lymphoma (REAL)/World Health Organization (WHO) classification of lymphomas*

Classical Hodgkin disease

Lymphocyte-rich
Nodular sclerosing
Mixed cellularity
Lymphocyte-depleted
Nodular lymphocyte predominant (some suggest this is NHL)

Non-Hodgkin lymphoma (NHL)

Nodular	Indolent course usually
Poorly differentiated lymphocytic	Most frequent; disseminated
Mixed cellular (lymphocytic and histiocytic)	Good response to chemotherapy
Histiocytic	Aggressive; behaves like diffuse
Diffuse	Aggressive course usually
Lymphocytic	Chronic if well differentiated
	Others disseminated
Mixed cellular	Disseminated
Histiocytic	Formerly called reticulum cell sarcoma
Lymphoblastic	50% develop acute lymphoblastic leukaemia
Burkitt lymphoma	Good response to chemotherapy

- chemicals
 - ◆ farm work or exposure to toxic chemicals such as pesticides, herbicides, or benzene and/or other solvents
 - ◆ hair dye
- genetics
 - ◆ family history of lymphoma.

Classification of lymphomas has been confusing; the European Organization for Research and Treatment of Cancer (EORTC) classification (1997) and the World Health Organization (WHO) classification of haematological malignancies (2000) – the Revised European–American Lymphoma (REAL) modification – are usually used (Table 8.43).

Clinical features

Lymphomas are mainly focused in lymphatic tissue but can spread to other tissues; lymphoma outside of lymphatic tissue is called extranodal disease.

Table 8.44 Staging and treatment of lymphomas

Stage ^a	Spread	Definition	Treatment
I	Early disease	Lymphoma located in a single lymph node region or in one area or organ outside the lymph node	Radiotherapy
II	Locally advanced disease	Lymphoma located in two or more lymph node regions, all located on the same side of the diaphragm, or in one lymph node region and a nearby tissue or organ	Radiotherapy
III	Advanced disease	Lymphoma affects two or more lymph node regions, or one lymph node region and one organ, on opposite sides of the diaphragm	Radiotherapy (IIIA) or quadruple therapy (IIIB) ^b
IV	Widespread or disseminated disease	Lymphoma is outside the lymph nodes and spleen, and has spread to another area or organ, such as the bone marrow, bone or CNS	Quadruple therapy ^b

^aBoth HL and NHL are further classified with the following letters:

- 'B' indicates that the person with lymphoma had symptoms such as fevers and/or weight loss at the time of diagnosis.
- 'A' indicates the absence of such symptoms.
- 'E' indicates that the tumour spread directly from a lymph node into an organ or that a single organ outside the lymphatic system is affected with no apparent lymphatic involvement.
- 'S' indicates that the spleen is involved.

^bQuadruple therapy is combined chemotherapy, either MOPP or ABVD (see Table 8.45).

Often, the first sign of lymphoma is a painless lymph node enlargement – in the neck, under an arm or in the groin. Lymph nodes or lymphatic tissues elsewhere may also swell; the spleen, for example, often enlarges.

An enlarged lymph node sometimes causes pressure effects against a vein or lymphatic (swelling of an arm or leg), or a nerve (pain, numbness or tingling). Splenic enlargement may cause abdominal pain or discomfort. Many people have no other symptoms.

Non-specific symptoms of lymphoma may include:

- fevers
- chills
- weight loss
- night sweats
- lack of energy
- pruritus (most common in the lower extremity but can occur anywhere).

General management

Microscopic appearance, immunological characterization of the cell lineage and the clinical extent of the disease (staging) determine the treatment and prognosis (Tables 8.44–8.46): the higher the stage, the worse the prognosis.

Diagnosis depends on:

- blood tests
- liver and kidney function tests: high levels of LDH in NHL may indicate a more aggressive form of lymphoma
- biopsy
- imaging: a simple X-ray can sometimes detect lymphoma. CT may detect enlarged lymph nodes and other masses anywhere in the body. MRI gives three-dimensional images with excellent detail and provides better definition than CT in brain and spinal cord. The positron-emission tomographic (PET) scan is a newer alternative to the lymphangiogram and gallium scan
- bone marrow examination

Other tests include lumbar puncture and spinal tap.

Staging

Lymphoma staging is classification by size and spread; it is based on the results of imaging and related studies, and helps indicate appropriate treatment and prognosis.

Table 8.45 Chemotherapeutic regimens

Acronym	Regimen
ABVD	Doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine
BEACOPP	Bleomycin, etoposide, doxorubicin (Adriamycin), plus COPP
ChIVPP	Chlorambucil, vinblastine, procarbazine and prednisolone (prednisone)
CHOP	Cyclophosphamide, doxorubicin (Adriamycin), vincristine (Oncovin), prednisolone (prednisone)
COPP	Cyclophosphamide, vincristine (Oncovin), procarbazine, prednisolone (prednisone),
CVP	Cyclophosphamide and vincristine (Oncovin) intravenously, and prednisolone (prednisone)
M-BACOD	Methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), dexamethasone (Decadron)
MOPP	Mechlorethamine, vincristine (Oncovin), procarbazine, prednisolone (prednisone)
Pro-MACE-MOPP	Prednisolone (prednisone), methotrexate, doxorubicin (Adriamycin), cyclophosphamide, etoposide followed by MOPP
Pro-MACE-CytaBOM	Prednisolone (prednisone), methotrexate, doxorubicin (Adriamycin), cyclophosphamide, etoposide, cytarabine (Ara-C), bleomycin, vincristine (Oncovin), methotrexate
MACOP-B	Methotrexate, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisolone (prednisone), bleomycin
PACEBOM	Prednisolone (prednisone), doxorubicin (Adriamycin), cyclophosphamide, etoposide, bleomycin, vincristine (Oncovin), methotrexate
Stanford V	Mustine, vinblastine, vincristine (Oncovin), bleomycin, doxorubicin (Adriamycin), etoposide and steroids

The newest classification system takes into account not only the microscopic appearance of the lymphoma but also its location in the body and genetic and molecular features. The staging, or evaluation of extent of disease, is similar for both HL and NHL (see Table 8.44).

Grade is also an important component of the NHL classification:

- Low-grade lymphomas: often called 'indolent' because they grow slowly. They are often widespread when discovered but usually do not require immediate treatment unless organ function is compromised. They are rarely cured but can transform over time to a combination of indolent and aggressive types.

Table 8.46 Factors predicting a poor outcome for lymphomas

Hodgkin lymphoma	Non-Hodgkin lymphoma
Male sex	Age >60 years
Age ≥45 years	Stage III or IV disease
Stage IV disease	High lactate dehydrogenase
Albumin (blood test) <4.0 g/dL	More than one extranodal site
Hb <10.5 g/dL	Poor performance status (as a measure of general health)
Elevated white blood cell count (WBC) of 15 000/mL	
Low lymphocyte count <600/mL or less than 8% of total WBC	

- Intermediate-grade lymphomas: rapidly growing (aggressive) lymphomas that usually require immediate treatment but are often curable.
- High-grade lymphomas: rapidly growing aggressive lymphomas that require immediate, intensive treatment and are less often curable.

Several risk factors have been extensively evaluated and shown to play a role in treatment outcome (see Table 8.46). From these factors, the following risk groups have been identified:

- Low risk: one risk factor, 5-year lymphoma-free survival (LFS) of 70%
- Intermediate risk: 2–3 risk factors, 5-year LFS of 49–50%
- Poor risk: 4–5 risk factors, 5-year LFS of 26%.

Treatment

Treatment for lymphomas depends mainly on type and stage. Standard first-line therapy (primary therapy) for lymphoma includes radiation therapy for most early-stage lymphomas, or a combination of chemotherapy and radiation. For later-stage lymphomas, chemotherapy is primarily used, with radiation therapy added for control of bulky disease.

Dental aspects of lymphomas

Lymphomas often involve cervical lymph nodes and occasionally are seen in the mouth. Dental management may be complicated by corticosteroid or cytotoxic therapy, liability to infection, radiation or anaemia.

Hodgkin disease (lymphoma)

General aspects

Hodgkin lymphoma (HL) appears to originate in a cell of the monocyte–histiocyte series, and is defined by the presence of the Reed–Sternberg cell. It is usually classified using the REAL/WHO classification (see Table 8.43).

HL may be related to Epstein–Barr virus (EBV) infection, and the prevalence is greater in persons who are immunocompromised. Hodgkin disease pursues a more aggressive course in HIV/AIDS.

Clinical features

There is progressive involvement of lymphoid tissue, often beginning in the neck (Fig. 8.40). The lymph nodes become enlarged, discrete and rubbery, and can cause symptoms by pressure on other organs or ducts. Alcoholic drinks may cause pain in affected lymph nodes in nodular sclerosing Hodgkin disease.

Fig. 8.40 Lymphoma.

Systemic symptoms, which indicate a poor prognosis, include pain, remittent fever, night sweats, weight loss, malaise, bone pain and pruritus. Anaemia is common late in the disease.

Cellular immunity is impaired so that fungal and viral infections are common and may disseminate.

General management

Treatment of HL includes chemotherapy and radiotherapy, depending on the staging. People with early-stage HL are usually given chemotherapy before radiotherapy (see Table 8.45), and when the disease is widespread, chemotherapy is nearly always the main treatment. If HL fails to respond well to standard chemotherapy, or recurs, high-dose chemotherapy with stem cell support may be used. The drug combinations most commonly used include:

- ABVD – doxorubicin (Adriamycin), bleomycin, vinblastine and dacarbazine (DTIC)
- ChlVPP – chlorambucil, vinblastine, procarbazine and prednisolone (prednisone)
- BEACOPP – bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine (Oncovin), procarbazine and prednisolone (prednisone)
- Stanford V – mustine, vinblastine, vincristine, bleomycin, doxorubicin, etoposide and steroids
- OEPA, COPP and COPDAC – the following drugs in varying combinations: vincristine, procarbazine, doxorubicin, etoposide, dacarbazine, cyclophosphamide and prednisolone (prednisone).

Radiotherapy, especially mantle radiotherapy, may be required but can lead to radiation damage to lungs (pneumonitis), heart (pericarditis) and thyroid (hypothyroidism), and predisposes to acute leukaemia.

The 5-year survival in HL in the earlier stages approaches 100%, and is over 60% even in more advanced Hodgkin disease. Those who relapse usually do so within the first 2 years.

Dental aspects

Hodgkin disease very rarely affects the mouth. When it does, it is not clinically distinguishable from NHL. Orofacial manifestations are as follows:

- Painless enlarged cervical lymph nodes – the initial complaint in 50%
- Oral infections – especially with viruses and fungi
- Mucositis and oral ulceration – caused by cytotoxic drugs

- Hyposalivation – from salivary gland irradiation damage
- Herpes zoster, herpetic stomatitis and oral candidosis – especially in those on cytotoxic or radiation therapy; zoster, secondary to immunodeficiency, may be the first sign of the disease.

Hodgkin disease of salivary glands is exceptionally rare and usually involves juxtaglandular lymphoid tissue.

The main problems from lymphomas that may influence oral health care are:

- anaemia
- corticosteroid therapy
- bleeding tendencies
- impaired respiratory function – pulmonary fibrosis due to irradiation
- mediastinal irradiation – may impair lung function or cause cardiac disease
- acute leukaemia – 7% of treated patients.

LA regional blocks should be avoided if there is any haemorrhagic tendency. CS may be given if required. GA is a matter for expert attention in hospital.

Non-Hodgkin lymphomas

General aspects

NHLs are more common than HL and have a variable but generally poor prognosis. European types of NHL (seen in Europe, the USA and Australia) are seen mainly in older persons, differ in age profile from NHL in other areas, and are growing in frequency.

Most NHLs are of B-cell origin. Most are Diffuse Large B Cell Lymphomas (DLBCL). They are found more commonly in association with immune defects such as HIV infection, in which NHL may be EBV-related and is second only to Kaposi sarcoma in frequency. Chronic immunosuppression or cytotoxic chemotherapy also predisposes to the condition. Post-transplantation lymphoproliferative disease is often NHL (Ch. 35).

NHLs are also more frequent in association with connective tissue diseases and may sometimes have a recognized microbial aetiology, such as EBV, hepatitis C virus, HTLV-1 or *Helicobacter pylori*.

A further strong risk factor is a family history of NHL, which entails a 3–4-fold greater risk to relatives. Weaker factors are occupational exposure, especially to pesticides and herbicides, and a slight, inconsistent association with hair dye use.

Clinical features

NHLs have a predilection for sites such as the gastrointestinal tract and CNS. They frequently involve the mesenteric lymph nodes and bone marrow, but often enlargement of cervical lymph nodes is the first sign. About one half NHL are extra-nodal and most of these affect the head and neck region.

General management

NHLs are broadly classified as either indolent (usually follicular types) or aggressive (usually diffuse). NHL is staged along the same lines as Hodgkin disease. In general, NHL is treated by multiple chemotherapy, since early dissemination is common. The most commonly used treatments include:

- CVP – cyclophosphamide and vincristine intravenously, and prednisolone (prednisone)

- CHOP – cyclophosphamide, doxorubicin (Adriamycin) and vincristine intravenously, and prednisolone (prednisone)
- chlorambucil – orally
- fludarabine – intravenously or as tablets, often given in combination with another chemotherapy drug
- bendamustine – intravenously.

In addition to chemotherapy, many indolent lymphomas are treated with the monoclonal rituximab; if chemotherapy and rituximab are given together, 'R' is added to the treatment name – for example, R-CVP or R-CHOP.

Dental aspects

The main problems from lymphomas that may influence oral health care are:

- oral infections, especially with viruses and fungi
- mucositis or oral ulceration caused by cytotoxic drugs
- anaemia
- corticosteroid therapy
- bleeding tendencies
- impaired respiratory function – pulmonary fibrosis due to irradiation
- acute leukaemia – 7% of treated patients
- painless enlarged cervical lymph nodes – the initial complaint in 50% of cases.

LA regional blocks should be avoided if there is any bleeding tendency. CS can be given if required. GA should be given in hospital.

Lymphomas rarely form in the oral cavity or oropharynx, but do so more frequently in HIV infection. Involvement of Waldeyer's ring is more common in NHL than in Hodgkin disease. Lesions appear as erythematous swellings, often with surface ulceration as a result of trauma. The jaws are rarely involved.

Herpes zoster, herpetic stomatitis and oral candidosis may be seen, especially in those receiving cytotoxic or radiation therapy.

NHL is one of the most common types of non-epithelial tumour of salivary glands in adults, but accounts for only about 5% of salivary gland tumours. Its diagnosis causes difficulties in this site because of possible confusion with benign lymphoepithelial lesion and Sjögren syndrome, and the fact that these may progress to lymphoma in about 20% of cases.

Other lymphomas

African Burkitt lymphoma is often EBV-related and is seen particularly in children, presenting mainly with jaw swellings but also frequently involving abdominal viscera (Fig. 8.41). It responds well to chemotherapy.

T-cell lymphomas are rare but are the cause of midline granuloma syndrome. The mouth may be involved by spread from the nasal cavity. Mycosis fungoides is the most common form of cutaneous T-cell lymphoma. Sézary's syndrome is a variant, in which the patient has more than 1000 per mm³ atypical T lymphocytes in the blood – Sézary cells – CD4+ T lymphocytes with a convoluted and bizarre appearance. It is characterised by erythroderma, leukaemia, generalised lymphadenopathy and hepatosplenomegaly.

Nasopharyngeal (peripheral) T-cell lymphomas

Nasopharyngeal (peripheral) T-cell lymphomas can be clinically indistinguishable from Wegener granulomatosis in their early stages. If allowed to progress, they can cause mid-facial destruction; when

Fig. 8.41 Burkitt lymphoma.

this is neglected, it can be so severe as to open the cranial cavity to the exterior. In such cases, death from intercurrent infection was common.

Downward spread of the disease from the nasal cavity can lead to palatal necrosis and ulceration. In such cases, superimposed infection from the oral cavity can seriously confuse the microscopic picture and make diagnosis even more difficult. In uncomplicated cases, the microscopic picture is highly pleomorphic but typically characterized by angiocentric and angiodestructive changes, which mimic vasculitis.

T-cell lymphomas can have a highly variable course, sometimes with prolonged survival or even apparently spontaneous remissions. Wide dissemination follows sooner or later.

The optimal form of treatment is therefore uncertain, but radiotherapy and cytotoxic chemotherapy may be effective if the disease is not too far advanced.

Midline granuloma syndromes (fatal midline granuloma)

These ‘idiopathic’ diseases mainly affect adults between 40 and 50 years of age, males more than females, and are usually nasopharyngeal T-cell lymphomas (the so-called Stewart-type granuloma) or Wegener granulomatosis diseases, which are not reliably distinguishable clinically (Box 8.18). The diseases start in the nasal or paranasal tissues and can cause mid-facial destruction, sometimes of hideously disfiguring degree and often with a fatal systemic involvement (Table 8.47).

The most common upper respiratory tract symptoms are nasal stuffiness and crusting, and often discharge, which can be bloody.

PLASMA CELL DISEASES

Plasma cells derive from B lymphocytes. Plasma cell diseases are uncommon disorders, sometimes termed paraproteinaemias or monoclonal gammopathies, and are characterized by overproduction of a specific immunoglobulin detectable on electrophoresis, and often dominating other proteins (Box 8.19).

These homogeneous immunoglobulins (monoclonal immunoglobulins) are defective, leading to immunodeficiency; the rates of production of immunoglobulin light or heavy chains may be unbalanced, leading to overproduction of light chains appearing in the urine (Bence Jones protein) or heavy chains detectable in the serum and urine (Table 8.48).

Multiple myeloma (myelomatosis: Kahler disease)

General aspects

Multiple myeloma is a disseminated plasma cell neoplasm, predominantly causing bone lesions. The malignant plasma cells produce

Box 8.18 Important causes of midline granuloma syndromes

- Idiopathic
- Wegener granulomatosis
- Peripheral T-cell lymphomas^a
- B-cell lymphomas (rarely)
- Infections
- Tuberculosis^b
- Syphilis^b
- Deep mycoses

^aPreviously called lymphomatoid granulomatosis, polymorphic reticulosis, midline malignant reticulosis, Stewart-type granuloma, etc.

^bUnlikely to be seen as a cause of this syndrome now.

Table 8.47 Features of the main types of idiopathic midline granuloma syndrome

	Wegener granulomatosis	Peripheral T-cell lymphomas
Destruction of facial skeleton and soft tissues	±	+++
Systemic involvement	Pulmonary cavitation Glomerulonephritis	Predominantly lymphatic spread. Liver, kidneys or other viscera may become involved
Biopsy findings	Necrotizing vasculitis, fibrinoid necrosis, multiple giant cells, ill-formed granulomas	Highly pleomorphic cellular picture, T cells recognizable by immunocytochemistry. Angiocentric and angiodestructive changes
Suggested treatment	Cyclophosphamide or azathioprine + prednisolone (prednisone) ^a	Radiotherapy + cytotoxic chemotherapy

^aOr co-trimoxazole.

Box 8.19 Plasma cell diseases (dyscrasias)

- Multiple myeloma
- Solitary myeloma
- Waldenström macroglobulinaemia
- Heavy-chain disease
- Idiopathic monoclonal gammopathy

defective immunoglobulins and release osteoclast-activating factors, which cause bone resorption and pain.

Multiple myeloma is a disease mainly of the middle-aged and elderly. It has a slight predilection for males and is occasionally related to exposure to ionizing radiation or petroleum products.

Clinical features

Abnormal serum immunoglobulins form early and are occasionally detectable by chance during routine haematological examination, by a raised ESR, rouleaux formation or high plasma viscosity, or during serum protein investigations. Many years may elapse before symptoms appear.

Neoplastic proliferation of plasma cells in the bone marrow and their release of cytokines, such as IL-1, ultimately cause pain,

Table 8.48 Paraproteins found in the serum and urine in plasma cell diseases

	Serum	Bence Jones proteinuria
Heavy-chain disease	Alpha chain (or gamma or mu)	–
Idiopathic monoclonal gammopathy	IgG (or IgA or IgM)	–
Multiple myeloma	IgG (50%) IgA (25%) IgD or IgE rarely	+
Waldenström macroglobulinaemia	IgM	Rarely

**Fig. 8.42** Multiple myeloma in mandible, presenting with pathological jaw fracture.

osteolysis and bone destruction, hypercalcaemia, suppression of haemopoiesis, and other secondary effects. Circumscribed areas of bone destruction are seen (Fig. 8.42), typically in the vault of the skull. The defective immunoglobulins may lead to plasma hyperviscosity with a clotting or bleeding tendency, renal failure, liability to infections and neurological sequelae (Box 8.20).

General management

Diagnostic findings include those listed in Box 8.21.

Symptomatic patients, or those with progressive bone lesions or worsening paraproteinaemia, are treated by chemotherapy with melphalan, cyclophosphamide or chlorambucil plus corticosteroids. More complicated chemotherapeutic regimens have not been shown to be consistently superior, though relapses are probably best treated with vincristine, doxorubicin (Adriamycin) and dexamethasone (VAD). New treatments include interferon, thalidomide, lenalidomide (Revlimid), bortezomib, bone marrow transplantation (haemopoietic stem cell transplantation; Ch. 35) and haemopoietic growth factors. Bisphosphonates, such as pamidronate, help prevent pathological fractures.

The prognosis is variable but the survival of treated symptomatic patients averages 3 years. Anaemia, chronic renal failure, low serum albumin and high levels of serum beta₂-microglobulin in the absence of renal disease indicate a poor prognosis. A few patients treated with cytotoxic chemotherapy develop acute myelomonocytic leukaemia.

Box 8.20 Multiple myeloma: clinical findings

- Bone infiltration and destruction
- Bone pain (especially spinal)
- Pathological fractures
- Hyperviscosity syndrome
- Weakness
- Visual disturbances
- Bleeding tendencies
- Renal failure
- Anaemia
- Susceptibility to infections
- Neurological lesions
- Paraesthesiae
- Weakness

Box 8.21 Multiple myeloma: investigational findings

Biochemical

- Hypergammaglobulinaemia
- Bence Jones proteinuria
- Monoclonal immunoglobulin (Ig) G (less often IgA, rarely IgD or IgE) on electrophoresis of serum or urine (IgG in 55%, IgA in 25% and only light chains in 20%)
- Plasma cell proliferation on marrow biopsy
- Uraemia (in renal disease)
- Hypercalcaemia
- Hyperuricaemia (after treatment)

Haematological

- Normochromic anaemia
- Leukopenia
- Thrombocytopenia
- Erythrocyte sedimentation rate (ESR) very high

Skeletal radiographs or bone scanning

- Osteolytic lesions

A growing number of asymptomatic patients are found to have myelomatosis by electrophoretic evidence of hypergammaglobulinaemia. Such patients must be followed and treatment started when appropriate.

Dental aspects

Dental treatment may be complicated by anaemia, infections, haemorrhagic tendencies, renal failure or corticosteroid therapy.

The skull, especially the calvarium, is ultimately affected, with rounded, discrete (punched-out) osteolytic lesions in about 70%. Jaw lesions are seen less frequently but can be the first sign; small, punched-out, osteolytic lesions involving the posterior mandible are typical. Root resorption, loosening of teeth, mental anaesthesia and, rarely, pathological fractures are other possible effects. Rare complications are gingival bleeding, oral petechiae, cranial nerve palsies and herpes simplex or zoster infections. Amyloid may be deposited in the oral soft tissues, causing local or more widespread swellings, such as macroglossia, the nature of which can be confirmed by biopsy.

Melphalan can cause severe mucositis. Bisphosphonates may cause osteonecrosis (Chapter 16).

Solitary plasmacytoma

Solitary plasmacytomas (localized myeloma) occasionally form in the jaws or soft tissues nearby, and are more likely than bone lesions to remain localized for a time. There is usually no abnormal immunoglobulin production but, even when present, levels are low.

Local radiotherapy may be useful, but cytotoxic chemotherapy is contraindicated. Patients should be kept under observation, as multiple myeloma develops in many, even after 20 years.

Waldenström macroglobulinaemia (primary macroglobulinaemia)

General aspects

Macroglobulinaemia is a rare disease in which B lymphocytes produce excessive amounts of monoclonal IgM.

Clinical features

The large monoclonal IgM molecules increase blood viscosity and cause hyperviscosity syndrome (see later).

There is usually also anaemia, recurrent infections, haemorrhagic tendencies and a wide variety of other possible manifestations, particularly lymphadenopathy and splenomegaly. In contrast to myeloma, foci of bone destruction and hypercalcaemia are not features, and renal involvement is uncommon.

The prognosis of macroglobulinaemia is slightly better than that of myeloma, but it may progress to lymphoma and a more rapid termination.

General management

The clinical course is very variable; nearly 25% of patients need no treatment for long periods and there is a median survival of over 3 years.

Dental aspects

The major problems of dental treatment are bleeding tendencies, corticosteroid therapy (Ch. 6) or anaemia. LA regional blocks should be avoided if there is a bleeding tendency. CS can be given if required. GA must be given in hospital.

Haemorrhagic tendencies may cause spontaneous gingival bleeding or post-extraction haemorrhage. Deep punched-out ulcers of the tongue, buccal mucosa or palate may form, but are rare.

Heavy-chain diseases

Heavy-chain diseases are rare disorders in which gamma, alpha or mu immunoglobulin heavy chains appear in serum and urine. Gamma-chain disease (Franklin disease) may cause palatal swelling due to lymphoid proliferation in Waldeyer's ring.

Benign monoclonal gammopathy

Benign monoclonal gammopathy or monoclonal gammopathy of undetermined significance (MGUS) occurs when excessive amounts of monoclonal immunoglobulins are found in the serum of older patients, who appear otherwise healthy. MGUS occurs when particular plasma cells produce abnormally large amounts of a single type of antibody/immunoglobulin called a paraprotein (or M-protein). Clinical features may be absent (MGUS is usually found by chance), though occasionally people with MGUS have hypoaesthesia, paraesthesia or ataxia.

Table 8.49 Differentiation of myeloma from monoclonal gammopathy

	Myeloma	Benign monoclonal gammopathy
Plasma paraprotein level at presentation	High	Low
Plasma paraprotein levels observed over months and years	Rising	Stable
Other plasma immunoglobulin levels	Depressed	Normal
Imaging	Bone lesions	No evidence of lesions

'Benign' is only a relative term, since 20% ultimately develop myeloma and some others die from amyloid renal disease. Investigations such as urinalysis, serum protein electrophoresis, blood calcium, radiographs and marrow biopsy are needed to rule out myeloma (Table 8.49) but it is essential not to interpret monoclonal gammopathy as necessarily predicting myeloma. Amyloid deposition in the tongue may cause macroglossia. Further information on MGUS can be found at <http://www.macmillan.org.uk/Cancerinformation/Causesriskfactors/Pre-cancerous/MGUS.aspx> (accessed 30 September 2013).

Secondary macroglobulinaemia

Large amounts of serum IgM, which is often polyclonal and not a precursor to myeloma or macroglobulinaemia, can be an incidental finding on blood examination. It can be secondary to chronic disorders, such as connective tissue diseases, liver disease or lymphocytic leukaemia.

Hyperviscosity syndrome

General aspects

Hyperviscosity syndrome is caused by excessive amounts of high-molecular-weight plasma proteins, which adsorb to platelets and erythrocytes and cause excessive platelet adhesiveness and erythrocyte rouleaux formation.

Polycythaemia, Waldenström macroglobulinaemia and myeloma account for most cases.

Clinical features

Hyperviscosity syndrome is characterized by slowing of the peripheral circulation. The large protein molecules also activate clotting factors and complement, causing local thrombosis and inflammation.

General management

Venesection may be tried. Plasmapheresis reduces the viscosity but treatment should be aimed at the primary condition. Penicillamine is useful for a short period only, since the side-effects can be severe.

Dental aspects

Gingival or post-extraction haemorrhage, or taste loss and oral ulceration due to penicillamine, may be features.

CRYOGLOBULINAEMIA

Cryoglobulinaemia is a condition where cryoglobulins – immunoglobulins that precipitate when cooled below the normal body temperature – are formed.

Cryoglobulins are of three main types:

- Type I is monoclonal, and is a typical feature of lymphoproliferative and related diseases.

Table 8.50 *Langerhans cell histiocytoses*

	Age of onset	Bone lesions	Skin or mucosal lesions	Visceral lesions	Pituitary lesions	Treatment	Prognosis
Solitary eosinophilic granuloma	>10 y	+	+/-	–	–	Surgery Local radiotherapy	Good
Multifocal eosinophilic granuloma (Hand–Schuller–Christian disease)	<5 y	+	+	±	+	Chemotherapy	Variable
Letterer–Sive disease	Infancy	+	+	+	+	Chemotherapy Steroids	Often fatal

- Types II and III are typically associated with connective tissue diseases and infections, where the effects may result from immune complex formation.

Cryoglobulins can occasionally cause effects as a result of their physical properties, particularly Raynaud phenomenon. Occasionally, they cause peripheral thromboses and obstruction of small vessels. Purpura or bleeding tendencies may also result. Plasmapheresis may be beneficial.

LANGERHANS CELL HISTIOCYTOSIS (SOLITARY AND MULTIFOCAL EOSINOPHILIC GRANULOMA)

Langerhans cell histiocytosis is a group of tumours or tumour-like lesions of Langerhans cells, antigen-presenting counterparts of macrophages. This cell is recognizable on electron microscopy by the presence of rod-shaped Birbeck granules and by immunohistochemistry. The three main types of Langerhans cell histiocytosis are shown in Table 8.50.

Solitary eosinophilic granuloma

General aspects

Eosinophilic granuloma is an osteolytic lesion of bone with a predilection for the mandible.

Clinical features

Adults mainly are affected. Typical symptoms are pain, tenderness, swelling or bone destruction.

General management

Radiographs show a tumour-like area of rarefaction. A bone scan should be carried out to ensure that the disease is not multifocal. Diagnosis is confirmed by biopsy, which typically shows foamy histiocytes and eosinophils with an ill-defined, somewhat fibrillar background and areas of necrosis.

Eosinophilic granuloma is relatively benign and sometimes resolves spontaneously. Otherwise, it responds to curettage or, if recurrent, to modest doses of irradiation or to chemotherapy.

Dental aspects

Eosinophilic granuloma is an osteolytic lesion of bone with a predilection for the mandible. It can produce a characteristic form of periodontal destruction with gross gingival recession and alveolar bone loss, typically involving a small group of teeth and often exposing the roots of the teeth, with a ‘teeth floating in air’ appearance on radiography.

Eosinophilic granuloma can also affect the oral soft tissues, but less frequently than the mandible. However, a lesion that is histologically somewhat similar (eosinophilic granuloma or ulcer) can be traumatic in origin or reactionary without any history of trauma, and there is some doubt about the nature of eosinophilic granulomas of soft tissues reported in the past. ‘Traumatic’ eosinophilic granuloma eventually resolves spontaneously, though it may need to be excised for cosmetic reasons. Alternatively, the lesion may be excised because of its clinical resemblance to a tumour.

Multifocal eosinophilic granuloma and Hand–Schuller–Christian disease

General aspects

These lesions are the same histologically as the solitary eosinophilic granuloma and are sometimes referred to indifferently as Hand–Schuller–Christian disease.

Clinical features

Multifocal eosinophilic granuloma most frequently develops before the age of 5 years.

Hand–Schuller–Christian disease, strictly speaking, comprises osteolytic lesions of the skull, exophthalmos and diabetes insipidus; it is a variant of multifocal eosinophilic granuloma but develops in only 25%.

Flat bones, including the mandible, are the main sites. Soft tissues also become involved. Lymphadenopathy and hepatosplenomegaly may develop in up to 50%. Malaise, fever and infections of the ear, mastoid and respiratory tract are common.

General management

Diagnosis is by biopsy (which shows essentially the same features as solitary eosinophilic granuloma) and skeletal radiography or bone scans (show the disease extent).

In approximately 50%, the lesions gradually resolve spontaneously over the course of years but can leave residual disabilities as a result of limb lesions or diabetes insipidus. To reduce such complications, or in refractory cases, chemotherapy in relatively modest doses may be given as for solitary lesions. The mortality may be 25–30%; the younger the patient and the more widespread the disease, the worse the prognosis.

Dental aspects

Complications can arise from radiotherapy to the oral or para-oral regions, or chemotherapy with corticosteroids or cytotoxic agents.

Multifocal eosinophilic granuloma of childhood or Hand–Schüller–Christian disease rarely has initial manifestations in the jaws. However, it can produce a characteristic form of periodontal destruction like that seen in solitary eosinophilic granuloma.

Letterer–Siwe disease

General aspects

Letterer–Siwe disease typically affects children between the ages of 2 and 3 years.

Clinical features

The main features of Letterer–Siwe disease are lymphadenopathy, hepatosplenomegaly and bone and skin lesions. Fever, infections and bleeding tendencies are secondary to pancytopenia, which results from marrow displacement by the histiocyte-like cells.

It sometimes follows a rapidly fatal course. Rarely, death follows within a week of diagnosis.

General management

Diagnosis is by biopsy, showing infiltration of the tissues by proliferating histiocyte-like cells. Treatment is with radiotherapy, corticosteroids and cytotoxic drugs, and may be successful. Occasionally, the course of the disease is less acute and recoveries are possible.

Dental aspects

In view of the age group mainly affected and the rapidity of the course, patients are unlikely to be seen by dentists. In the few older patients with a more chronic form of the disease, the features relevant to dentistry are essentially those of severe types of multifocal eosinophilic granuloma. Corticosteroid or cytotoxic treatment may complicate dental management.

MASTOCYTOSIS

Proliferation of mast cells with release of their mediators may result in urticaria pigmentosa, pruritus, flushing, diarrhoea, bone pain and neuropsychiatric problems. The condition is treated with steroids and antihistamines. Trauma, stress, extremes of temperature and various drugs (NSAIDs, codeine, opiates, radiographic media and some GA agents) may precipitate exacerbations.

APPENDIX 8.1 EXAMPLES OF HAEMOSTASIS DEFECTS

Vascular phase of haemostasis		Platelet phase of haemostasis		Coagulation phase of haemostasis	
Congenital	Acquired	Congenital	Acquired	Congenital	Acquired
Hereditary haemorrhagic telangiectasia	Senile purpura	Bernard-Soulier syndrome	Bone marrow diseases	Haemophilias	Warfarin
Ehlers-Danlos syndrome	Steroid purpura		Chronic kidney disease	Von Willebrand disease	Heparins
			Aspirin		Liver disease
			Antiplatelet agents		

APPENDIX 8.2 RARE GENETIC COAGULATION-RELATED FACTOR DEFECTS

Coagulation factor defect	Bleeding tendency	APTT	PT	Basic defect
V	+	—	—	AR, streptomycin, liver disease, others
VII	+	—	—	AR, liver disease, anticoagulants, many others
X Stuart-Prower factor	+ usually	—	—	AR, primary amyloid, others
XI Plasma thromboplastin antecedent	+	—	—	High frequency in Ashkenazi Jews
XII Hageman factor	—	—	—	AR, liver disease
XIII Fibrin-stabilizing factor	+	— ^a	— ^a	AR
α-Antiplasmin (Miyasato disease)	+	—	—	AR, many others
Fibrinogen	+	—	—	AR
Prekallikrein (Fletcher factor)	—	—	—	AR, nephritic syndrome, liver disease

AR = autosomal recessive.

^aAssay by clot solubility.

KEY POINTS

- Alcoholic liver disease is increasing, as are deaths from liver disease
- Viral hepatitis is common, increasing and transmissible in health-care facilities
- Health-care professionals must be immunized against hepatitis B virus
- Liver disease can lead to bleeding and drug intolerance

Life is impossible without the liver. The liver (*hepar*) consists of hepatocytes, organized for optimal contact with sinusoids (blood vessels) and bile ducts. It makes and breaks down sugar, proteins and fats; stores nutrients; produces bile; and removes metabolic products and other toxins from the blood. Bile drains to the gallbladder and, via the bile duct, to the small intestine, at which point it is intimately associated with the head of the pancreas, swelling of which may cause biliary obstruction and jaundice (Fig. 9.1).

The liver, through the function of the Kupffer cells (mononuclear phagocytes) that line the sinusoids forms part of the lymphoreticular system (along with macrophages in the lymphoid tissue and spleen) and plays an important role by capturing and digesting bacteria, fungi, parasites, effete blood cells, and cellular debris. The liver turns glucose into glycogen (stored in the liver). This is converted back into glucose when required, maintaining stable blood glucose levels. Excess carbohydrates and protein are converted to fat. The liver also makes proteins – blood proteins (e.g. most blood-clotting factors using vitamin K metabolites), and albumin, hormones, transporter proteins and complement. The liver underlies normal haemostasis, since it produces blood clotting factors I, II, VII, IX, X and XI; bile salts which aid vitamin K absorption (needed for clotting factors); and the hormone thrombopoietin which stimulates the bone marrow megakaryocyte production of platelets. The liver also forms bile essential for fat digestion and absorption of fat-soluble vitamins (A, D, E and K), and produces or stores these vitamins and vitamin B₁₂; it also stores minerals (e.g. copper and iron). Bile (gall) is made up of water, cholesterol, phospholipids, bicarbonate, bile pigments and bile salts; it is a bitter yellow or green fluid secreted by hepatocytes, stored in the gallbladder between meals, and discharged into the duodenum upon eating, being required for fat and fat-soluble vitamin absorption. The bile salts sodium glycocholate and sodium taurocholate are produced by the liver from cholesterol; they help emulsify fats for their absorption and facilitate the activity of pancreatic lipase.

The breakdown of haemoglobin, cholesterol, proteins, sex steroids and many drugs occurs, at least partly, in the liver. The enzyme haem oxygenase acts on haem to form biliverdin, which in turn is converted into bilirubin. Biliverdin and bilirubin are termed bile pigments. Bilirubin is not water-soluble (unconjugated bilirubin) and needs a carrier (albumin) to be transported. In the liver, bilirubin is conjugated by combining with glucuronic acid and becomes water-soluble *conjugated* bilirubin. This then enters the bile, and flows into the bile duct and finally the intestine, where it can be excreted in, and colours, the stool after being changed into urobilinoids. Alternatively, the process of conjugation can be reversed by beta-glucuronidase, which converts the conjugated bilirubin back into unconjugated bilirubin. Unlike conjugated bilirubin, unconjugated bilirubin can be reabsorbed from the

Fig. 9.1 Liver anatomy.

Table 9.1 Some drugs metabolized by the liver

Local anaesthetics	Bupivacaine, lidocaine, mepivacaine, prilocaine, articaine
Analgesics	Paracetamol (acetaminophen), aspirin, codeine, ibuprofen, meperidine
Antimicrobials	Ampicillin, azole antifungals, clindamycin, metronidazole, tetracyclines, vancomycin
Sedatives	Diazepam

intestine back into the blood (enterohepatic recirculation). Conjugated bilirubin can also be excreted in the urine, which it darkens. Increased levels of bilirubin in the blood can cause the body, especially the sclerae of the eyes, to appear yellow (jaundice).

Water-soluble toxins and waste products can be eliminated via the kidneys in the urine, but non-water-soluble toxins need to be chemically modified by the liver to allow this process to occur. Digested proteins in the form of amino acids are broken down further in the liver, a process known as deamination. Nitrogenous products such as ornithine and arginine are converted to urea, which is excreted into the urine by the kidneys. Sex steroids, such as the masculinizing hormone testosterone and the feminizing hormone oestrogen, are inactivated in the liver.

Most drugs, including alcohol, are metabolized/excreted via the liver (Table 9.1). In particular, oral drugs are absorbed by the gut and transported via the portal circulation to the liver. In the liver, these drugs may undergo first-pass metabolism, in which they are modified, activated or inactivated before they enter the systemic circulation.

The diagnosis of liver disease depends on the history, physical examination and evaluation of liver function tests (Table 9.2). Apart from bilirubin, liver enzyme levels may also be increased in the blood in various disorders. Aminotransferase levels are sensitive indicators of liver-cell injury (Table 9.3).

Alkaline phosphatase levels may be raised if there is biliary obstruction, but also vary with age. Rapidly growing adolescents can have serum alkaline phosphatase levels that are twice those of healthy adults as a result of the leakage of bone alkaline phosphatase into blood. Also, serum alkaline phosphatase levels normally increase gradually between the ages of 40 and 65 years, particularly in women.

Table 9.2 *Liver function tests^a*

Serum test	Comments
Bilirubin	Positive in urine in most patients with jaundice, except unconjugated hyperbilirubinaemia. Bilirubin rises in serum because of overproduction or obstruction. In liver disease, the total serum bilirubin may rise (hyperbilirubinaemia). The total bilirubin includes that which has undergone conjugation (the direct or conjugated bilirubin) plus the portion of bilirubin that has not been metabolized (unconjugated bilirubin). When the direct bilirubin fraction is elevated, the cause is typically gallstones. If the direct bilirubin is low while the total bilirubin is high, this reflects liver cell damage or bile duct damage within the liver itself
Hyaluronic acid (HA)	Raised serum levels in liver fibrosis; marker of pre-cirrhosis
Alanine aminotransferase (ALT)	Leaks from damaged liver. Most sensitive marker of any form of hepatocyte damage. Also known as serum glutamic-pyruvic transaminase (SGPT)
Aspartate aminotransferase (AST)	Leaks from damaged liver, heart or muscle. Rises in liver, heart or muscle damage. Also known as serum glutamic-oxaloacetic transaminase (SGOT)
5'-Nucleotidase	Found in liver, thyroid and bone. Rises in biliary obstruction
Gamma-glutamyl transferase (GGT or GGTP)	Found in liver, kidneys, pancreas, prostate. Rises in obesity, alcoholism, most liver diseases, pancreatitis, diabetes, myocardial infarct and with some drugs. Medications commonly cause GGT to be elevated but alcohol is the main drug cause of an increase in the GGT
Alkaline phosphatase	Found in biliary canaliculi, osteoblasts, intestinal mucosa and placenta. Rises in pregnancy, liver disease, gallstones and bone disease Renal or intestinal damage can also cause the alkaline phosphatase to rise. One way to assess the aetiology of a raised level is to examine isoenzymes
Albumin	Low albumin (hypoalbuminaemia) may indicate that the synthetic function of the liver has been markedly diminished, such as in cirrhosis. Falls in malnutrition, nephrotic syndrome and gastrointestinal disease
Prothrombin time (and international normalized ratio [INR])	Prolonged in liver disease, malnutrition (decreased vitamin K ingestion)

^aStatins and other drugs can disturb liver function tests.

Raised levels of gamma-glutamyl transferase (GGT) have been reported in a wide variety of clinical conditions, including pancreatic disease, myocardial infarction, renal failure, chronic obstructive pulmonary disease, diabetes and alcoholism. High serum GGT levels are also found in patients who are taking medications such as phenytoin and barbiturates.

CONGENITAL LIVER DISEASE

General and clinical aspects

Transient neonatal jaundice is common, usually due to the normal breakdown of haemoglobin around birth, and is of little consequence. Severe neonatal jaundice can be caused by prematurity, or haemolysis such as in rhesus incompatibility, biliary atresia or hepatic disease; it can lead to kernicterus (damage to the brain basal ganglia), which can be fatal, or cause epilepsy or choreoathetosis (with or without learning impairment) and deafness. Rare familial liver enzyme disorders that can cause jaundice are shown in Appendix 9.1.

Table 9.3 *Causes of raised aminotransferase levels*

Causes	Examples
Hepatic	Alcohol abuse Alpha-antitrypsin deficiency Autoimmune hepatitis Chronic hepatitis B Chronic hepatitis C Drugs Haemochromatosis Steatosis and non-alcoholic steatohepatitis Wilson disease
Non-hepatic	Acquired muscle diseases Coeliac sprue Inherited disorders of muscle metabolism Strenuous exercise Drugs Antibiotics Synthetic penicillins Ciprofloxacin Nitrofurantoin Ketoconazole and fluconazole Isoniazid Antiepileptic drugs Phenytoin Carbamazepine Inhibitors of hydroxymethylglutaryl-coenzyme A reductase Simvastatin Pravastatin Lovastatin Atorvastatin Non-steroidal anti-inflammatory drugs (NSAIDs) Sulphonylureas for hyperglycemia Glipizide Herbs and homeopathic treatments Alchemilla (lady's mantle) Chaparral Chinese herbs Ephedra (ma huang) Gentian Germander Jin bu huan Scutellaria (skullcap) Senna Shark cartilage Drugs and substances of abuse Anabolic steroids Chloroform Cocaine Ecstasy Phencyclidine Glues and solvents Glues containing toluene Trichloroethylene

Dental aspects

Disorders associated with an early rise in serum levels of conjugated bilirubin (mainly biliary atresia and haemolysis, such as in rhesus disease) can cause a greenish discolouration of the teeth and dental hypoplasia.

ACQUIRED LIVER DISEASE

Liver disease is increasing, due especially to alcohol use, obesity and infections; in the decade to 2009 in the UK, liver-associated deaths increased by one-fifth. A bleeding tendency, dangers from certain drugs, liability to infections and sometimes infectious hazards are factors to consider in the dental patient with liver disease.

HEPATITIS

The liver has some powers of regeneration but this capacity can be exceeded by repeated or extensive damage by infective agents, alcohol, drugs or poisons. The word ‘hepatitis’ means inflammation of the liver and also often refers to a group of viral infections that affect the liver, but hepatitis can also be caused by drugs or autoimmune disorders. The most common types of viral infection are hepatitis A, hepatitis B and hepatitis C. Alcohol abuse is the major drug causing acute hepatitis.

Chronic hepatitis is the term for hepatitis that persists longer than 6 months; it may follow acute hepatitis (or appear without warning) and may progress to cirrhosis. The most important causes of chronic hepatitis are hepatitis C virus, alcohol, drugs and autoimmune hepatitis (Table 9.4). Chronic liver disease includes chronic hepatitis, and cirrhosis.

Excessive alcohol intake, viral hepatitis and drugs also account for the majority of cases of cirrhosis (Box 9.1). Liver diseases can have many effects, according to the degree of liver damage – including jaundice, a bleeding tendency, and impaired drug and metabolite degradative and excretory activities (Table 9.5). Many patients with liver disease are asymptomatic and the problem frequently remains subclinical for years or decades. Malaise, anorexia and fatigue are common, sometimes with low-grade fever and upper abdominal discomfort.

Bilirubin ester is normally excreted in bile and is one of the factors that colour the faeces. If bilirubin is not conjugated (enzyme defect or parenchymal liver disease) or excreted (biliary obstruction), it accumulates in the body and colours the skin and mucous membranes (jaundice) and the whites of the eyes (icterus); it is detectable clinically at levels greater than 40 micromol/L, and the urine darkens.

Jaundice is often caused by liver disease but may also result from haemolysis, abuse of alcohol or other drugs, or infection (Table 9.6).

Pale, fatty faeces and malabsorption result from failure of bile salts to reach the intestine (obstructive diseases), causing malabsorption of fats, and of the fat-soluble vitamins (e.g. vitamin K) needed for clotting-factor synthesis. Bile salts accumulating in the blood may cause itching, nausea, anorexia and vomiting.

A bleeding tendency results from depressed synthesis of blood-clotting factors and excess fibrinolysins. Prothrombin time (PT), the international normalized ratio (INR) and activated partial

Table 9.4 Causes of chronic hepatitis

Hepatitis	Drugs	Autoimmune	Inflammatory bowel disease	Metabolic
Hepatitis B or C virus	Alcohol			Alpha ₁ -antitrypsin deficiency
	Aspirin			
	Cytotoxics			Wilson disease
	Halothane			
	Isoniazid			
	Methyldopa			
	Nitrofurantoin			
	Paracetamol (acetaminophen)			

Box 9.1 Causes of chronic liver disease

- Alcoholic and drug-induced liver disease
- Autoimmune hepatitis
- Gaucher disease
- Haemochromatosis
- Portal hypertension
- Primary biliary cirrhosis
- Primary sclerosing cholangitis
- Sarcoidosis
- Viral hepatitis
- Wilson disease
- Zellweger syndrome (cerebrohepatorenal syndrome; a rare congenital leukodystrophy)

Table 9.5 Manifestations of liver diseases

Impaired	Main causes	Consequences	Clinical features
Bilirubin metabolism	Congenital hyperbilirubinaemia	Hyperbilirubinaemia	Jaundice
Bilirubin excretion	Hepatocellular disease	Hyperbilirubinaemia	Jaundice
	Extrahepatic obstruction	Bilirubinuria	Dark urine
Excretion of bile salts	Extrahepatic obstruction		Pale stools
	Hepatocellular disease	Rise in serum alkaline phosphatase and 5'-nucleotidase	Pruritus
		Malabsorption of fats and fat-soluble vitamins (especially vitamin K), causing prolonged prothrombin time	Fatty stools
Liver cell function	Hepatocellular disease	Impaired clotting factor synthesis and prolonged prothrombin time	Bleeding tendencies
		Impaired albumin synthesis	Bleeding tendencies
		Impaired drug metabolism	Oedema
		Rise in serum transaminases	Coma or neurological disorders
		Portal venous hypertension	Bleeding from oesophageal varices
		Disorganized liver structure	
		Cirrhosis	

Table 9.6 Causes of jaundice

Congenital	Acquired		
	Hepatocellular disease (parenchymal liver disease)	Extrahepatic biliary obstruction	Haemolysis
Haemolysis, such as in rhesus incompatibility	Viral hepatitis	Gallstones	Malaria
Prematurity	Drug-induced hepatitis	Carcinoma of pancreas	Yellow fever
Gilbert syndrome (Appendix 9.1)	Cirrhosis (often alcoholic)	Biliary atresia	Sickle cell diseases
Various rare syndromes (Appendix 9.1)	Primary biliary cirrhosis	Others	Incompatible transfusion
Others	Chronic hepatitis		
	Others		

thromboplastin time (APTT) are all increased. Chronic bleeding may cause anaemia.

Drugs (e.g. alcohol and barbiturates) that can induce the hepatic cytochrome P450 system can lead to diminished effects of other drugs, such as the contraceptive pill, phenytoin or warfarin. By contrast, some drugs (e.g. cimetidine, omeprazole, sulphonamides and valproate) impair P450 activity, causing enhanced activity of drugs such as carbamazepine, ciclosporin, phenytoin or warfarin (Table 9.7).

Cirrhosis chiefly affects the middle-aged or elderly, and is frequently asymptomatic in its earlier stages. Anorexia, malaise and weight loss are common, and effects can be widespread (Box 9.2; Fig. 9.2).

VIRAL HEPATITIS

Many viruses cause hepatitis (Table 9.8). The term 'viral hepatitis' used in health care usually refers to infection by hepatitis B, D or C viruses (HBV, HDV, HCV), which are transmitted parenterally (Table 9.9). Jaundice during childhood is often caused by hepatitis A virus (HAV) and typically is of little consequence; hepatitis B and C are the most relevant to health care, since the delivery of health care has the potential to transmit viral hepatitis to both health-care professionals (HCPs) and patients. Outbreaks have occurred in outpatient settings, haemodialysis units, long-term care facilities, and hospitals, primarily as a result of unsafe injection practices; reuse of needles, fingerstick devices and syringes; and other lapses in infection control.

Jaundice in the teenager or young adult may be due to viral hepatitis A, B, C, D or E. Several of these viruses, particularly HAV and hepatitis E virus (HEV), are transmitted faeco-orally. Some, especially HAV and HBV, and probably HCV, can be spread sexually. Hepatitis A and E are more of a problem in resource-poor areas and are transmitted faeco-orally; hepatitis E is more severe among pregnant women, especially in the third trimester.

Hepatitis B has long been of greatest importance but, in the absence of a vaccine, hepatitis C has become a more serious problem. Standard (universal) precautions against transmission of infection must always be employed, since these viruses, particularly HBV, HCV and HDV can be transmitted in blood and blood products and in other body fluids; they may be passed on by practices in which infection control is lacking, particularly in intravenous drug use where there is needle- or syringe-sharing. Any practice in which there is a skin breach, such as body-piercing or tattooing (Fig. 9.3), can also constitute a risk. Co-infection with other blood-borne agents, such as the human immunodeficiency virus (HIV), is common, particularly in intravenous drug users.

All hepatitis viruses can cause acute, or short-term, illness, and jaundice is common (Fig. 9.4). Some hepatitis viruses, particularly HCV and HBV, also have a small acute mortality. HBV, HCV and HDV

can also cause chronic hepatitis, in which the infection is prolonged – sometimes lifelong – and may be associated with virus carriage, chronic liver disease and liver cancer (hepatoma; hepatocellular cancer); they can also be responsible for aplastic anaemia and other extrahepatic manifestations. The clinical and laboratory features of viral hepatitis are summarized in Table 9.10.

Hepatitis A ('infectious hepatitis')

General aspects

Hepatitis A is caused by HAV and is rarely serious. Hepatitis A is endemic throughout the world, seen particularly where socioeconomic and living conditions are poor and, in those areas, infection (and consequent immunity) is common in childhood (Fig. 9.5). In the developed world, many people reach adulthood without infection and have no immunity, and therefore are at risk from infection if they travel to endemic areas.

Spread of hepatitis A is largely faeco-oral, by consumption of contaminated water or food, particularly raw shellfish. For example, nearly 300 000 persons were infected in one outbreak in Shanghai, originating from contaminated clams. Hepatitis A can also be transmitted sexually and by close person-to-person contact, and in body fluids including saliva. Persons in the armed forces, food handlers, HCPs, sewage workers, travellers to areas of high endemicity, children and employees at day-care centres, promiscuous individuals who do not practise safe sex, and injecting drug users are at greatest risk.

Clinical features

The incubation period is 2–6 weeks. The disease is frequently subclinical or anicteric, but clinical features are similar to those of other forms of viral hepatitis (though muscle pains, rashes and arthralgia are rare); they include fatigue, nausea and vomiting, abdominal pain or discomfort, loss of appetite, low-grade fever, jaundice and itching. Recovery is usually uneventful. Blood and faeces become non-infective during or shortly after the acute illness. There is no evidence of either a carrier state or progression to chronic liver disease. About 15% have relapses over a 6–9-month period but the mortality is less than 0.1%. Hepatitis A can be lethal, however, if the patient is also infected with HBV/HCV. Hepatitis A gives long-lasting immunity.

General management

The diagnosis of hepatitis A can be confirmed if necessary by demonstrating serum antibodies to the virus (HAAb). No specific treatment

Table 9.7 Drugs contraindicated and alternatives in liver disease

Type of drug	Drugs contraindicated	Alternatives to use
Analgesics	Aspirin	Oxycodone
	Codeine	Paracetamol (acetaminophen) ^a

	Pilocarpine	
	Sumatriptan	

^aOr given in lower doses than normal. In a variety of liver diseases there is no evidence of increased risk of hepatotoxicity at currently recommended doses. Therefore, paracetamol/acetaminophen can be used safely in patients with liver disease and is a preferred analgesic/antipyretic because of the absence of the platelet impairment, gastrointestinal toxicity, and nephrotoxicity associated with nonsteroidal antiinflammatory drugs.

is usually needed; normal human immunoglobulin may prevent or attenuate the clinical illness and is used mainly in sporadic outbreaks.

HAV vaccine is available, especially for prophylaxis in travellers to high-risk endemic areas such as Asia, South America and Africa. A combined vaccine against HAV and HBV may also be used.

Dental aspects

Patients are unlikely to seek dental treatment during the acute phase. There appears to be no risk of transmission of hepatitis A during dentistry that is conducted properly.

Hepatitis B

General aspects

Hepatitis B (serum hepatitis; homologous serum jaundice) is caused by HBV and is a serious disease. Genotype A is most common in the UK. HBV can cause lifelong infection, cirrhosis (scarring) or cancer of the liver, liver failure and occasionally fulminant hepatitis and death. Hepatitis B affects one-third of the world population, and one-quarter of those infected at birth die from liver disease.

Hepatitis B infection is endemic throughout the world, especially in institutions (such as those for custodial care), in cities and in poor socioeconomic conditions. It is especially common in the developing world; sub-Saharan Africa, the Pacific Basin, South-East Asia, Central Asia, parts of the Middle East, South America's Amazon Basin and some Eastern European countries are the areas of highest endemicity. Over 75% of some populations such as Australian aboriginals (hence the older term 'Australia antigen') are carriers. In parts of sub-Saharan Africa, Asia and the Pacific, nearly all children are infected. The prevalence is low (under 2%) in north-western Europe, North America and the Antipodes. Intermediate levels (2–8%) are found in Mediterranean countries, the Middle East, the Indian subcontinent and Japan.

Spread of HBV is mainly parenteral (via unscreened blood or blood products, particularly by intravenous drug abuse and by tattooing/body-piercing), sexual (especially among promiscuous individuals who do not practise safe sex) and perinatal. HBV is a robust virus, surviving for a week or more in dried blood on surfaces, and has been

transmitted to patients and staff in health-care facilities and between patients in a dental setting. HCPs in the past were not infrequently infected, but adherence to standard infection control procedures, and immunization, have resulted in a decline in infections. Nevertheless, in the USA, 91 HCPs were known to have transmitted HBV to patients in the health-care setting over the decade to 2006. Apart from HCPs, those in the armed forces, missionaries, aid workers, and persons travelling to the developing world are at risk (Box 9.3).

Clinical features

The incubation period for HBV is 2–6 months and the acute mortality rate is less than 2%. About 30% have no signs or symptoms, and most patients with clinical hepatitis recover completely with no untoward effect, apart perhaps from some persistent malaise. The effects of HBV infection, therefore, range from subclinical infections without jaundice (anicteric hepatitis) to fulminating hepatitis, acute hepatic failure and death.

Fig. 9.4 Outcomes of infection with blood-borne viruses such as hepatitis B, C or D.

The prodromal period of 1–2 weeks is characterized by anorexia, malaise and nausea. Hepatitis B viraemia usually precedes the clinical illness by weeks or months and lasts for some weeks before clearing completely.

As jaundice becomes clinically evident, the stools become pale and the urine dark due to bilirubinuria. The liver is enlarged and tender, and pruritus may be troublesome (see Table 9.10). Muscle pains, arthralgia and rashes are more common in hepatitis B than hepatitis A, and there is often fever.

Complications of hepatitis B include a carrier state, chronic infection, cirrhosis, liver cancer, polyarteritis nodosa or death. A carrier state, in which HBV persists within the body for more than 6 months, develops in 5–10% of people with chronic HBV infection and has the following phases:

- immune tolerance
- immune clearance
- low replication
- reactivation.

A carrier state is more frequent in anicteric infections or those contracted early in life. Although 5–10% of carriers lose the hepatitis antigen each year, carriage may persist for up to 20 years and may be asymptomatic. Some patients, especially those who have received blood products, those infected with HDV and those who have immune defects, are ‘high-risk’ and predisposed to the carrier state. Most carriers are healthy but others, especially those with persistently abnormal liver function tests, develop chronic liver disease (see later) and 15–25% of these patients die from it.

Infection with HBV confers immunity. Active immunity can therefore be acquired naturally. In the past, a high proportion of health-care staff working in developing countries or in institutions were not immunized and developed antibody to hepatitis B, despite a low incidence of overt hepatitis. However, rarely, where there has been co-infection with HDV, the death rate from HBV has been as high as 30%.

Fig. 9.5 Hepatitis A is seen worldwide.

Box 9.3 Viral hepatitis – high-risk groups for hepatitis B

- Patients (e.g. haemophiliacs, thalassaemics) who have received unscreened blood products or multiple plasma or blood transfusions, especially in the Far East or Africa
- Patients receiving haemodialysis for end-stage renal disease
- Immunosuppressed or immunodeficient patients (e.g. those who are HIV-infected, have received a transplant or have malignant disease)
- Residents and staff of long-stay institutions, particularly prisons
- Persons in occupations that involve exposure to human blood – health-care and laboratory personnel (especially surgeons)
- Intravenous drug abusers
- Sexually active individuals, especially promiscuous individuals who do not practise safe sex
- Patients from the developing world, especially Africa and Asia
- Tattooing and acupuncture, especially in the Far East
- Individuals travelling to regions with high infection rates of hepatitis B virus (HBV), such as sub-Saharan Africa, South-East Asia, the Amazon Basin, the Pacific Islands and the Middle East
- People with certain other disorders (e.g. Down syndrome, polyarteritis nodosa)
- Partners of patients with hepatitis or any of the above groups
- Patients with some chronic liver diseases
- Household contacts of someone who has a chronic HBV infection
- Newborns whose mothers are infected with HBV – at high risk, as are infants and children whose parents were born in areas where HBV infection is widespread

General management

Electron microscopy of serum from HBV-infected patients shows three types of particle:

- The Dane particle, which probably represents intact HBV, and consists of an inner core containing DNA and core antigens (HBcAg), and an outer envelope of surface antigen (HBsAg)
- Smaller spherical forms and the tubular forms, which represent excess HBsAg.

Initial tests for HBV infection include serological tests for HBV surface antigen, surface antibody and core antibody. A positive test for surface antibody and core antibody indicates the presence of immunity to HBV. A positive test for surface antigen and core antibody indicates the presence of infection. Tests to determine whether there is viral replication, including serological tests for HBV e antigen, HBV e antibody and HBV DNA, should be undertaken. In patients with positive tests for HBV DNA and e antigen, liver biopsy and treatment should be considered. Serum enzyme estimations are useful; aspartate transaminase (AST) and alanine transaminase (ALT) are raised in proportion to the severity of acute hepatitis. Alkaline phosphatase, alpha-fetoprotein and serum bilirubin levels are also raised.

Diagnosis and prognosis depend, however, on serological markers. HBsAg (Australia antigen, hepatitis-associated antigen, hepatitis B antigen) is a non-infectious protein found transiently in those with acute hepatitis B, and persists in the serum in carriers and in some who are non-infectious. In a typical case, HBsAg develops 20–100 days after exposure, is detectable in the serum for 1–120 days and then disappears. The serum becomes negative for HBsAg about 6 weeks after the onset of clinical jaundice. Persistence of HBsAg beyond 13 weeks of the clinical illness often implies that a carrier state is developing. Hepatitis B surface *antibody* (anti-HBs) develops after infection or vaccination and, in the absence of HBsAg, implies immunity.

HBcAg is found in liver biopsies in acute hepatitis B. Hepatitis B core *antibody* is a sensitive marker of viral replication, indicating either current or recent infection. Anti-HBc associated with anti-HBs appears to indicate recovery and immunity to hepatitis. However, if anti-HBs is absent, anti-HBc suggests the carrier state or chronic hepatitis.

Hepatitis B e antigen (HBeAg) and its antibody, anti-HBe, are useful markers to determine the likelihood of spread of HBV (transmissibility) by persons affected with chronic hepatitis B viral infection; the presence of HBeAg means ongoing viral activity and the ability to infect others, whereas the presence of anti-HBe signifies a more inactive state of the virus and less risk of transmission. HBeAg indicates high infectivity and is found only in serum that is also HBsAg-positive, but in only about 25% of those who are HBsAg-positive. If HBeAg persists beyond

Table 9.11 Hepatitis B serum markers in relation to disease progress

Marker	HBsAg	Anti-HBs	Anti-HBc (total)	Anti-HBc IgM	HBeAg	Anti-HBe	HBV DNA

Chronic infection in the inactive phase	+	–	+	–	–	+	–
Recovery, false positive or chronic infection	–	–	+	–	–	+ or –	–

Anti-HBc = hepatitis B core antibody; anti-HBs = hepatitis B surface antibody; anti-HBe = hepatitis B e antibody; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M.

about 4 weeks after the onset of symptoms, the patient will probably remain infectious and develop chronic liver disease. Absence of HBeAg has usually indicated low infectivity. However, in some individuals infected with HBV, the genetic material for the virus has undergone a particular structural change, called a pre-core mutation, which results in an inability of the HBV to produce HBeAg, even though it is actively reproducing. This means that, even though no HBeAg is detected in the blood, HBV is still active in these persons and they can infect others.

Anti-HBe usually indicates complete recovery and loss of infectivity, provided HBeAg is lost. Asymptomatic HBsAg carriers often possess anti-HBe, and are usually at lower infective risk than those with HBeAg and DNA polymerase (supercarriers). The most specific marker of HBV reproduction is the measurement of HBV DNA in the blood; the polymerase chain reaction (PCR) is the most sensitive assay (Table 9.11).

Acute hepatitis B will resolve on its own in most symptomatic individuals and so management usually includes a high-carbohydrate diet and avoidance of hepatotoxins (e.g. alcohol). Antiviral therapy is not warranted.

HBV viral load increases in cirrhosis or hepatocellular carcinoma, and chronic HBV infection can be effectively treated with pegylated interferon-alpha 2b (PEG-IFN). Adefovir, entecavir, lamivudine, telbivudine, tenofovir and dipivoxil are also available. PEG-IFN is given for 4–6 months but can have several adverse reactions. Lamivudine is used for those who fail to respond to interferon and is usually better tolerated, but treatment for 1–3 years is usually needed and a variant mutant virus strain –YMDD – eventually emerges in 50% of treated patients.

Health clearance for HCPs is defined in the UK as *standard* or *additional*. Standard health clearance applies to all staff; additional health clearance is needed for anyone who undertakes exposure-prone procedures (EPPs). EPPs are defined as:

those invasive procedures where there is a risk that injury to the worker may result in the exposure of the patient's open tissues to the blood of the worker. These include procedures where the worker's gloved hands may be in contact with sharp instruments, needle tips or sharp tissues (e.g. spicules of bone or teeth) inside a patient's open body cavity, wound or confined anatomical space where the hands may not be completely visible at all times.

Additional health clearance also means being hepatitis B surface antigen-negative or, if positive, being e antigen-negative with a viral

load of 103 genome equivalents/mL or less; and hepatitis C antibody-negative or, if positive, being negative for HCV RNA. There is also guidance for tuberculosis.

Prevention is best achieved by HBV vaccination and by avoiding contact with the virus (Box 9.4). Vaccination is recommended for all clinical students and staff, and is essential for anyone (trainee or qualified) who undertakes EPP – which includes most of dentistry – and for people working with high-risk groups, and those travelling to high-prevalence areas. Infection of infants born to HBV-infected mothers from contact with HBV can also be minimized by giving hepatitis B immunoglobulin (HBIG) and vaccine within 12 hours of birth.

The HBV vaccine is a recombinant vaccine of HBsAg. After vaccination, anti-HBs develops and confers 90% protection for many years and possibly for life, but may not protect against pre-core variants. HBV vaccination also protects indirectly against hepatitis D. Hepatitis B vaccine rarely causes any significant adverse effects.

After routine vaccination of most infants, children, adolescents or adults, post-vaccination testing for adequate antibody response is not necessary. For HCPs with normal immune status who have demonstrated an anti-HBs response following vaccination, booster doses of vaccine are not recommended; neither is periodic anti-HBs testing. Post-vaccination testing is recommended for persons who:

- are immunocompromised (e.g. haemodialysis patients)
- received the vaccine in the buttock
- are infants born to HBsAg-positive mothers
- are HCPs who have contact with blood
- are sex partners of persons with chronic HBV infection.

Post-vaccination testing in these groups should be completed 1–2 months after the third vaccine dose for results to be meaningful. A protective antibody response is 10 mIU/mL or more.

Combined hepatitis A and hepatitis B vaccine is available for some travellers, injecting drug users, promiscuous individuals who do not practise safe sex, and persons with clotting factor disorders who receive therapeutic blood products. It is indicated for vaccination of persons aged over 18 years in these groups. Hepatitis B vaccine is recommended for travellers to areas of high or intermediate hepatitis B endemicity, who plan to stay for more than 6 months and have frequent close contact with the local population.

Dental aspects

All dental professionals should be immunized against HBV. Drugs should be used with caution (see Tables 9.1 and 9.7). There may be

Box 9.4 Prevention of viral hepatitis

- Always follow routine barrier precautions and handle needles and other sharps safely
- Never share needles, syringes, or water for injection if a drug addict
- Do not share personal care items that might have blood on them (razors, toothbrushes)
- Avoid having a tattoo or body-piercing, unless the piercer follows strict health practices
- Use condoms: hepatitis B virus (HBV) can be spread by sex, as can hepatitis C virus (HCV)
- Do not donate blood, organs, or tissue if HBV- or HCV-positive
- Do not inhale cocaine through contaminated straws!

a bleeding tendency if the platelet count is low (Ch. 8), or if the prothrombin time (and INR) is prolonged. Patients with normal platelet counts and normal prothrombin times (INR) can undergo dental intervention safely.

Although pure parotid saliva does not contain HBsAg, saliva collected from the oral cavity may contain HBV (presumably derived from serum via gingival exudate) and may be a source for non-parenteral transmission. However, the risk of transmission by this route appears to be low except where there is very close contact, as in families, children's nurseries or sexual contact. HBV can also be transmitted by human bites. Blood, plasma or serum can be infectious. As little as 0.0000001 mL of HBsAg-positive serum can transmit hepatitis B.

The main danger is from needlestick injuries; some 25% may transmit HBV infection. There is a higher risk for oral surgeons and periodontologists, and for those working with high-risk patients, probably because of needlestick injuries. However, if adequate precautions are taken, the dental surgery is no longer a significant source of transmission. In the past, HBsAg carriage was found in about 1% of dental practitioners and up to 20% of oral surgeons, who occasionally transmitted the infection to their patients. Now the risk appears to be low, since standard infection control precautions are taken and dental professionals have been immunized against HBV. Practitioners who are ill with hepatitis should stop dental practice until fully recovered. Testing for HBeAg may indicate those individuals likely to spread hepatitis B. HBeAg-positive dental surgeons and those who are HBeAg-negative but have more than 1000 HBV viral particles per millilitre of blood should discontinue practice involving exposure-prone procedures.

Needlestick injuries involving HBV can transmit the virus; post-exposure prophylaxis (PEP) with HBIG and/or hepatitis B vaccine series should be considered for occupational exposures after evaluation of the HBsAg status of the source and the vaccination and vaccine-response status of the exposed person within 24 hours of contact (Ch. 31).

Hepatitis C

General aspects

HCV infection was identified from what was formerly known as post-transfusion non-A non-B hepatitis (NANBH). HCV now ranks second only to alcoholism as a cause of liver disease in the developed world and is responsible for much sporadic viral hepatitis, particularly in intravenous drug abusers, among whom its prevalence is rising. Hepatitis C is increasing in the UK and many intravenous drug abusers are infected here too, most asymptotically.

By contrast, transfusion-associated hepatitis C has declined, as blood is now routinely tested for HCV. The virus can also be transmitted between HCPs and patients. Persons at special risk for hepatitis C

include those who: have received blood from a donor who later tested positive for hepatitis C; have ever injected illegal drugs; have received a blood transfusion or solid organ transplant before about 1992; have received a blood product for clotting disorders produced before about 1987; have ever been on long-term renal dialysis; or have evidence of liver disease (e.g. persistently abnormal ALT levels).

Six major HCV genotypes (different genetic variations or strains) are recognized; genotype 1 accounts for most cases. HCV genotypes and subtypes are distributed differently across the world:

- Genotypes 1, 2 and 3 are found worldwide:
 - ◆ Subtype 1a is prevalent in North and South America, Europe and Australia.
 - ◆ Subtype 1b is common in North America and Europe, and is also found in parts of Asia.
- Genotype 4 is prevalent in the Middle East and Africa.
- Genotype 5 is prevalent in South Africa.
- Genotype 6 is prevalent in South-East Asia.

Some studies suggest that different types of HCV may be associated with different transmission routes. Subtype 3a appears to be prevalent among injection drug users and it is believed to have been introduced into North America and the UK with the widespread use of heroin in the 1960s. It has been suggested that genotype 1b is associated with a more severe disease progression than genotype 1a or 2. People with HCV genotype 3 are more likely to develop steatosis; it is believed that this genotype is an independent risk factor and may actually play a direct role in the development of steatosis.

Clinical features

Hepatitis C has a similar incubation period to hepatitis B (usually less than 60 but up to 150 days) but most HCV-infected persons develop no signs or symptoms. Clinical hepatitis C is also usually a less severe and shorter illness than hepatitis B (see Table 9.9), but a greater proportion (25–80%) of patients have persisting abnormal liver function tests, many develop chronic liver disease (up to 85%), and some develop liver cancer, or die (<3%). There are associations of HCV in some populations with sicca syndrome, lichen planus, lymphoma, cryoglobulinaemia and other extrahepatic manifestations.

About 15% of patients infected with HCV are co-infected with hepatitis G virus (HGV). Co-infection with HBV and SEN (see below) is also common.

General management

The initial test for HCV infection is serological testing for the hepatitis C antibody. Diagnosis is usually confirmed by measurement of serum levels of HCV RNA with use of the reverse-transcriptase PCR.

Acute HCV infection resolves spontaneously in 50% of patients; both interferon-alpha and PEG-IFN, with or without ribavirin, have been used with some success but can have significant adverse effects. A protease inhibitor (e.g. boceprevir or telaprevir) may also be given.

Genotype-1 patients require the longest treatment duration and have the lowest response rates. Treatment is with PEG-IFN plus ribavirin (PR) for 6–12 months. Testing for interleukin (IL)-28 polymorphisms could be used for the purposes of counselling patients, since a patient with the IL-28 CC genotype may require only 28 weeks of PR therapy instead of 48 weeks. Side-effects may include influenza-like symptoms, fatigue and bone marrow suppression. Boceprevir or telaprevir may be added to PR. Ribavirin causes anaemia as its main side-effect. Telaprevir is associated with a rash. Boceprevir may cause dysgeusia,

neutropenia and anaemia; it is a reversible inhibitor of cytochrome P450 3A4, so all who receive boceprevir therapy require an assessment of drug–drug interactions.

There is as yet no vaccine against HCV. Hepatitis C prevention is shown in [Box 9.4](#).

Dental aspects

HCV has been transmitted to patients and staff in health-care facilities. There has been a raised prevalence of HCV infection in some dental populations studied, and the virus has been found in saliva and infection has followed a human bite. HCV is transmitted in about 10% of needlestick injuries.

For HCV PEP, the HCV status of the source and of the exposed person should be determined; for health-care personnel exposed to an HCV-positive source, follow-up HCV testing should be performed to determine whether infection has developed. Immune globulin and antiviral agents (e.g. interferon with or without ribavirin) are not recommended for PEP of hepatitis C. However, early treatment of acute hepatitis C infection may prevent chronic hepatitis C infection (Ch. 31).

Staff infected with HCV should not perform exposure-prone procedures (see above, Ch. 31 and Appendix 9.2).

HCV may be associated with oral features – sicca syndrome, non-Hodgkin lymphoma and, in some populations (mainly patients originating from the Mediterranean basin or Japan), with lichen planus. Chronic HCV infection and sicca syndrome have an association with human leukocyte antigen (HLA)-DQB1*02.

Hepatitis D

General aspects

HDV (or delta agent) is an incomplete virus carried within the HBV particle and will only replicate in the presence of HBsAg. Therefore, there is no HDV without HBV infection. HDV spreads parenterally, mainly by shared hypodermic needles. Risk groups are as for HBV (see [Box 9.3](#)). HDV has been transmitted to patients and staff in health-care facilities.

HDV is endemic, especially in the Mediterranean littoral and among intravenous drug abusers, and is found worldwide. It is not endemic in northern Europe or the USA, but some haemophiliacs and others have acquired the infection and the prevalence is rising.

Clinical features

HDV infection may coincide with hepatitis B or may superinfect patients with chronic hepatitis B. Infection may produce a biphasic pattern with double rises in liver enzymes, and bilirubin. The incubation period of hepatitis D is unknown; 90% of infections are asymptomatic and HDV infection does not necessarily differ clinically from hepatitis B but can cause fulminant disease with a high mortality. About 70–80% of HBV carriers with HDV superinfection develop chronic liver disease with cirrhosis, compared with 15–30% with chronic HBV infection alone.

General management

Hepatitis D virus antigen indicates recent infection; delta antibody indicates chronic hepatitis or recovery. Drug treatment with interferon-alpha is effective. Vaccination against HBV protects indirectly against HDV.

Dental aspects

The same considerations apply as for hepatitis B.

Hepatitis E

HEV spreads mainly via the faecal–oral route and is responsible for large epidemics in India, South-East Asia, parts of the Commonwealth of Independent States (CIS; the old USSR) and Africa. HEV causes a disease similar to hepatitis A, but in pregnant women it has a high mortality rate (up to 40%).

Hepatitis E virus is not known to be transmitted during dentistry.

Hepatitis G

HGV may co-infect some patients infected with HCV or HBV. About 1.5% of healthy blood donors in the USA are infected with HGV and it is of high prevalence in intravenous drug users.

HGV infection, if it produces clinical hepatitis, tends to be less severe than hepatitis C but is followed by persistent infection in 15–30%. HGV appears to respond to interferon-alpha.

HGV is not known to be transmitted during dentistry. GB virus C is related to HGV.

Transfusion-transmitted virus (torque teno virus)

Transfusion-transmitted virus (TTV) has a single strand only of DNA and there is a high prevalence of chronic viraemia in apparently healthy people (up to nearly 100% in some countries). Like HGV, the pathogenicity of TTV has not been proven; it has not yet been aetio-logically linked to any other disease and the virus is not known to be transmitted during dentistry.

SEN viruses

SEN is named after the initials of the patient from whom the virus was isolated. SEN V-D and SEN V-H are DNA viruses that are transmitted parenterally and can cause post-transfusion hepatitis. These viruses are otherwise of unknown pathogenicity and not known to be transmitted during dentistry.

LEPTOSPIROSIS

The bacteria *Leptospira icterohaemorrhagiae*, associated with rats, and *Leptospira hardjo*, found in cattle, can be transmitted to humans by contact with the urine of rats, foxes or cattle, usually via contaminated water or soil. Leptospirosis is an occupational hazard for people who work outdoors or with animals (e.g. farmers and vets), and for sewer workers, and is a recreational hazard for those who participate in water sports and for campers. There is usually an influenza-like illness with severe headaches. The severe form (Weil disease), which affects only about 10–15%, causes liver damage and jaundice, and has a death rate between 4% and 40%. It may respond to penicillin or tetracycline.

ALCOHOLIC HEPATITIS

Alcohol is the major and increasing cause of hepatitis in developed countries. It injures the liver by blocking the metabolism of protein, fats and carbohydrates, and causes fatty change (alcoholic steatosis); in response there is inflammation (alcoholic hepatitis), which is probably

reversible initially. The amount of alcohol that can injure the liver varies greatly from person to person: in women, as few as 2–3 units per day may be responsible, and in men, as few as 3–4 units per day. Exposure to alcohol over long periods may cause liver fibrosis, which, in itself, is largely asymptomatic; as it progresses, however, it can turn into cirrhosis, where the fibrosis alters the architecture and impairs liver function. If cirrhosis progresses, the liver may fail.

NON-ALCOHOLIC STEATOHEPATITIS (NASH; MACROVESICULAR STEATOSIS; NON-ALCOHOLIC FATTY LIVER DISEASE, NAFLD)

Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease, strongly associated with obesity, the metabolic syndrome and type 2 diabetes. NASH is present in more than 25% of severely obese patients, 40% of whom have advanced fibrosis.

The histologic spectrum of NAFLD ranges from simple steatosis to non-alcoholic steatohepatitis (NASH), fibrosis and eventually cirrhosis. Patients with NASH and significant fibrosis seen on liver biopsy have an increased risk for liver-related morbidity and mortality compared to patients with simple steatosis. The only clinical evidence of hepatic steatosis and NASH may be mildly raised aminotransferase levels. Steatosis appears to have a benign course, whereas NASH can progress to cirrhosis.

Fatty infiltration of the liver can be identified by ultrasonography or computed tomography (CT).

Tests that can accurately predict the presence of advanced disease without the need for liver biopsy include those that predict NASH (such as markers of hepatocyte apoptosis, oxidative stress and inflammation) and those that predict fibrosis. Caspase-generated CK18 fragment levels can be measured in plasma using enzyme-linked immunosorbent assay (ELISA), and these levels have been found to be significantly higher in NASH patients than simple steatosis. Ferritin levels more than 1.5 times the upper limit of normal were associated with the diagnosis of NASH and advanced fibrosis.

Liver failure as a result of NASH is uncommon. Weight loss is the cornerstone of treatment in patients who are obese. Other treatments for NASH that are being studied include vitamin E and ursodiol.

DRUG-INDUCED HEPATITIS

Apart from alcohol, the main offender, many other drugs can cause hepatitis. These include halothane; some non-steroidal anti-inflammatory drugs (NSAIDs), antimicrobials, herbs and nutritional supplements; and paracetamol (acetaminophen) in overdose (Box 9.5). With some drugs, liver damage is a predictable dose-related effect, while with others the damage is unpredictable and may be immunologically mediated (Table 9.12).

Aspirin ingestion by children, during and after a viral illness (e.g. chickenpox, influenza or other respiratory tract illness), significantly increases the chance of developing Reye syndrome – liver damage with encephalopathy and abnormal accumulations of fat in the liver and other organs, along with a severe rise in intracranial pressure. Reye syndrome can follow several (1–14) days after aspirin use, usually in a viral infection, and generally progresses through two stages. The first includes persistent or continuous vomiting, severe tiredness, belligerence due to illness (moodiness), nausea and loss of energy. The second stage follows, with personality changes, bizarre mental and physical behaviour (confusion, restlessness and irrational behaviour), lethargy or inactivity, and sometimes coma and convulsions. There is a 90% chance of recovery for those diagnosed early but only 10%

Box 9.5 Hepatotoxic drugs, not including alcohol

- Allopurinol
- Amiodarone
- Amitriptyline
- Atomoxetine
- Azathioprine
- Erythromycin estolate
- Flucloxacillin
- Halothane
- Ibuprofen
- Indometacin
- Isoniazid (INH)
- Ketoconazole
- Loratadine
- Methotrexate
- Methyl dopa
- Minocycline
- Nifedipine
- Nitrofurantoin
- Oral contraceptives
- Paracetamol (acetaminophen)
- Phenytoin
- Pyrazinamide
- Rifampicin
- Sulphonamides
- Tetracyclines
- Valproic acid
- Zidovudine

Table 9.12 Drug and chemically related liver damage

Dose-related liver damage	Non-dose-related liver damage
Alcohol	Antithyroid drugs
Anabolic steroids	Erythromycin estolate
Isoniazid	Flucloxacillin
Ketoconazole	Halothane
Methyl dopa	Nitrofurantoin
Methyltestosterone	Phenylbutazone, phenothiazines, vinyl chloride and carbon tetrachloride
Paracetamol (acetaminophen)	Phenytoin
Tetracyclines	Sulphonamides

are likely to recover if diagnosed late. Treatment is typically provided in an intensive care unit for monitoring of fluids, electrolytes, blood gases, intracranial pressure and nutrition. About 90% of cases of Reye syndrome develop in the first 15 years of life, so aspirin or other salicylates are contraindicated for children under 16, except for certain specific diseases. Many over-the-counter medications, including mouth ulcer preparations, may contain salicylates and these must be avoided. Paracetamol (acetaminophen) in moderate dosage is now the preferred analgesic and antipyretic for children below the age of 16.

Antimicrobials that may sometimes cause liver problems include tetracyclines, erythromycin and flucloxacillin. Tetracyclines in massive doses can cause liver damage, especially if there is impaired urinary excretion. Erythromycin estolate is potentially hepatotoxic but the effect is reversible when the drug is stopped (erythromycin stearate, however, is not hepatotoxic). Flucloxacillin can be cholestatic.

Table 9.13 Autoimmune hepatitis

Clinical features	Type 1	Type 2	Type 3
Diagnostic autoantibodies	SMA ANA Anti-actin	Anti-LKM P450 IID6 Synthetic core motif peptides 254–271	Soluble liver–kidney antigen Cytokeratins 8 and 18
Age mainly affected	Any	Children	Adults
Concurrent autoimmune disease (%)	41	34	58
IgG raised	+++	+	++
HLA associations	B8, DR3, DR4	B14, Dw3, C4AQO	Uncertain
Progression to cirrhosis (%)	45	82	75

ANA = antinuclear antibody; IID = ???; LKM = liver–kidney microsomal; SMA = smooth muscle antibody.

Halothane can cause hepatitis, which may follow a single exposure in 1 in 35 000 cases. Transient impairment of liver function appears after halothane as after other anaesthetics, but hepatitis is more likely when anaesthetics are given repeatedly at intervals of less than 3 months, in middle-aged females, and in the obese. The reaction may be some form of hypersensitivity, but the precise mechanism is uncertain and pre-existing liver disease does not appear to be contributory. There also appears to be a genetic susceptibility. Clinically, halothane hepatitis causes pyrexia developing after a week post-operatively. Malaise, anorexia and jaundice may then appear, and if jaundice is severe the prognosis is very poor. Unfortunately, there are no dependable criteria or laboratory tests to indicate when halothane is truly contraindicated. Serum antibodies reacting with halothane-altered liver membrane determinants have been reported in about 75% of patients but, as with antibodies to penicillin, few of these patients have a reaction on a further exposure. Halothane should never be given repeatedly, or within a period of 3 months, and never to any patient who has had malaise, pyrexia or jaundice after exposure to it. Fortunately, newer halogenated anaesthetic agents, such as enflurane, isoflurane, desflurane and sevoflurane, do not induce hepatitis in those who have had an episode of halothane hepatitis. In many hospitals, these agents have, despite their cost, replaced halothane, particularly to carry out several operations on the same patient at short intervals.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis (autoimmune liver disease; autoimmune chronic active hepatitis) is associated with various autoantibodies and the complement allele C4AQO and with HLA haplotypes B8, B14, DR3, DR4 and Dw3; it often progresses to cirrhosis. Several types of autoimmune hepatitis are recognized (Table 9.13). Multisystem manifestations are common, especially in young women, and can include acne, arthralgia, amenorrhoea, haemolytic anaemia, nephritis, pulmonary fibrosis, thyroiditis and ulcerative colitis.

Diagnosis of autoimmune hepatitis is based on the presence of elevated aminotransferase levels. More than 80% of patients with autoimmune hepatitis have hypergammaglobulinaemia, antibodies against smooth muscle, and liver–kidney microsomal antibodies. Autoimmune hepatitis is typically responsive to immunosuppressants.

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure is a dangerous clinical syndrome characterized by rapid onset of hepatic encephalopathy and a marked decline

in hepatic synthetic function within 28 days of the onset of symptoms, in those without a history of chronic liver disease. The aetiology of fulminant hepatic failure, when known, is mainly paracetamol (acetaminophen) overdose, other drug reactions, hepatitis B or hepatitis A.

Hepatic encephalopathy and severe coagulopathy are the hallmarks of fulminant hepatic failure. Severe coagulopathy often precedes evolution of hepatic encephalopathy to coma. As soon as the diagnosis is made, it is important to establish the cause. Certain aetiologies demand immediate specific treatment, including *N*-acetylcysteine for paracetamol (acetaminophen) poisoning, penicillin for *Amanita* mushroom poisoning, delivery of the infant in acute fatty liver of pregnancy, or zinc and trientine therapy for Wilson disease.

Overall survival is poor without liver transplantation, with a mortality of up to 97%. Patients should be admitted to the intensive care unit and transferred for liver transplantation – the only effective therapy.

CIRRHOSIS

General aspects

Cirrhosis is characterized by liver cell necrosis and inflammation, followed by replacement with fibrotic tissue and regenerating nodules of hepatocytes, and vascular derangement. Liver function deteriorates and the blood flow becomes obstructed.

Clinical features

Cirrhosis is a potentially fatal disorder. Obstruction to the portal circulation can lead to portal hypertension, oesophageal varices, gastrointestinal haemorrhage and the risk of vomiting of blood (haematemesis), which can be fatal. Thrombocytopenia from splenomegaly, and low blood clotting factor levels, leads to a bleeding tendency that can worsen the haemorrhage. Anaemia may also result. Portal obstruction can also lead to portal–systemic (hepatic) encephalopathy and tremor (liver flap or asterix), due to failure to detoxify normal metabolites; this can be exacerbated by drugs, gastrointestinal haemorrhage or a high-protein diet and can lead to coma. Metabolism is disturbed, and sex-steroid accumulation can lead to gynaecomastia and testicular atrophy.

Spontaneous bacterial peritonitis is a potential and serious problem. Diabetes mellitus, peptic ulceration, renal dysfunction, gallstones, immune dysfunction and hepatoma are other potential complications.

The patient may develop (see Fig. 9.2): finger-clubbing, opaque nails (leukonychia), palmar erythema, asterix, spider naevi (angiomas; Fig. 9.6), scratch marks, purpura, gynaecomastia, scant body hair, testicular atrophy, hepatomegaly, splenomegaly, distended abdominal

Fig 9.6 Spider naevi.

Fig. 9.7 Ascites and finger-clubbing in chronic liver disease.

veins in which flow is away from the umbilicus (caput medusae), ascites (fluid in the peritoneal cavity) (Fig. 9.7) and ankle oedema. Alcoholic cirrhosis may have associated parotid swelling (sialosis) (Fig. 9.8), Dupuytren contracture (Fig. 9.9), gastric ulceration or pancreatitis.

General management

The diagnosis depends on the history, physical examination, evaluation of liver function tests (see Table 9.2) and other studies. Liver enzymes, especially aminotransferases, are raised. Values of bilirubin and alkaline phosphatase are variable. Serological markers are common in autoimmune hepatitis and include IgG elevations, antinuclear antibody, smooth muscle (anti-actin) antibody, LE (lupus erythematosus) cells, rheumatoid factor, and antibodies directed against liver and kidney microsomes. CT, ultrasound or other imaging may be indicated. Liver biopsy is essential for definitive diagnosis.

Autoimmune hepatitis generally improves with treatment with corticosteroids, with or without azathioprine. Treatment for chronic HBV and HCV with interferon-alpha suppresses viral replication. Treatment of chronic HBV infection with lamivudine gives results comparable to interferon and is well tolerated, but treatment for 1–3 years is usually needed and a mutant strain of the virus often emerges. Treatment with adefovir dipivoxil is another choice. Chronic HCV is treated with a combination of ribavirin plus interferon-alpha or PEG-IFN.

Prognosis is highly variable and patients with chronic hepatitis often survive years or decades, but often hepatocellular failure, cirrhosis or both eventually follow. Liver transplantation is fairly successful for HCV-related hepatitis and long-term survival rates are relatively high.

Fig. 9.8 Sialosis.

Fig. 9.9 Dupuytren contractures involve the fifth and fourth fingers in alcoholic liver disease. This may be also hereditary or have other causes.

Transplantation has not generally been effective for HBV end-stage liver disease because of aggressive disease recurrence in the graft, but treatment with lamivudine can now help ameliorate it.

In cirrhosis, laboratory tests for haemochromatosis or Wilson disease are specific but many others are non-specific. Serum albumin is often low but bilirubin, immunoglobulins, transaminases and alkaline phosphatase may be raised. Haematological abnormalities include a prolonged prothrombin time, thrombocytopenia, anaemia, macrocytosis and sometimes leukocytosis.

Treatments that can stop or delay further progression and complications include treatment of any viral cause, and interferon to inhibit activation of hepatic stellate cells and degradation of the collagenous matrix by metalloproteinases, activated by tissue inhibitor of metalloproteinases (TIMP). Adequate nutrition should be maintained and management is mainly directed towards prevention and treatment of complications. For example, for ascites and oedema, a low-sodium diet or the use of diuretics may help. For portal hypertension, beta-blockers may be needed. Varices are managed by ligation, beta-blockers and possibly transjugular intrahepatic portosystemic shunting. Encephalopathy can be managed with a low-protein diet supplemented with ornithine, aspartate, benzoate or phenylacetate. Lactulose plus neomycin may also be used.

The molecular absorbent recirculating system (MARS) removes water-soluble and protein-bound toxins that accumulate in liver

failure, based on an albumin-filled circuit recirculating through a charcoal and colestyramine column.

Liver transplantation is necessary when complications cannot be controlled, or when the liver becomes so damaged that it ceases functioning.

Dental aspects

Patients can present serious bleeding problems if surgery is needed. Certain drugs may be contraindicated. There may be a risk from transmission of infection. Surgery is hazardous also because of possible HCV or HBV carriage, or infection, diabetes, anaemia, drug therapy, poor wound healing and a liability to peritonitis. The hepatologist should be consulted if surgery, GA or drug therapy is needed. A clotting screen and prothrombin time may be indicated. If the prothrombin time is prolonged, vitamin K1 10mg parenterally (phytomenadione) should be given daily for several days preoperatively to improve haemostatic function. If there is an inadequate response, as shown by the prothrombin time, a transfusion of fresh blood or plasma may be required. Repeated gastrointestinal bleeding may cause anaemia (Ch. 8) or be fatal.

Routine dental treatment can usually be carried out without any particular problem, though alcoholism may influence treatment planning and procedures (Ch. 34).

Impaired drug detoxification and excretion mean that drug effects are not entirely predictable: age, gender, the type and severity of the liver disease, hypoalbuminaemia (depressed protein-binding of drugs) and the induction of hepatic drug-metabolizing enzymes by previous medication may influence outcomes of drug use. Especial care must be taken when considering the use of drugs, particularly some analgesics, antimicrobials and drugs exerting their effect on the central nervous system (CNS; see Table 9.7). Drugs that are hepatotoxic should obviously be avoided.

LA is safe given in normal doses, but prilocaine or articaine is preferred to lidocaine. Drugs liable to cause respiratory depression are dangerous and coma can be precipitated by sedatives, hypnotics or opioids. The doses of midazolam used for CS should thus be reduced. Inhalational sedation is preferable. Nitrous oxide with pethidine or phenoperidine appears to be suitable for GA but it is essential to avoid hypoxia; isoflurane or sevoflurane is preferable to halothane (see 'halothane hepatitis' earlier). Desflurane should be used in lower-than-normal doses. Suxamethonium is best avoided because of impaired cholinesterase activity.

Aspirin and most other NSAIDs, such as indometacin, should be avoided because of the risk of gastric haemorrhage in those with portal hypertension or peptic ulcers. Analgesia is best achieved with paracetamol (acetaminophen) or codeine used in lower-than-normal doses.

Antimicrobials that can usually be used safely in normal doses include penicillin, cefalexin, cefazolin and imipenem. Broad-spectrum antibiotics (at least in theory) should be avoided as they may further reduce vitamin K availability by destroying the gut flora.

If a jaundiced patient must undergo major surgery, aggressive treatment with intravenous fluids and diuresis with mannitol are indicated to avoid acute renal failure, which may complicate hepatic failure (hepatorenal syndrome; Ch. 12). There may also be considerations related to alcoholism (Ch. 34), autoimmune disease, hepatitis B, C or D antigen carriage or diabetes (Ch. 6).

Spontaneous bacterial peritonitis is a potential problem in cirrhosis with ascites. Though most infections are with normal gut aerobic bacteria or Gram-positive bacteria, invasive dental or oral surgical

procedures may increase the risk and, since the mortality approaches 30%, antibiotic prophylaxis must be considered. Amoxicillin orally 2–3g with metronidazole 1 hour preoperatively or intravenous imipenem is recommended.

Some patients have sialosis, or tooth erosion from gastric regurgitation. There is an association between liver cirrhosis and oral carcinoma.

PRIMARY BILIARY CIRRHOSIS

General aspects

Primary biliary cirrhosis (PBC) is an uncommon, progressive, autoimmune disorder with antibodies directed against mitochondrial pyruvate dehydrogenase complex, affecting small intrahepatic bile ducts; it is seen mainly in middle-aged women. PBC begins with non-suppurative destructive cholangitis and jaundice, and culminates in cirrhosis.

Clinical features

Patients with PBC may be asymptomatic for many years but, eventually, complaints of weakness, lethargy, weight loss, pale stools, dark urine, jaundice and pruritus emerge. Complications include xanthomas and skin pigmentation, or the complications of any chronic liver disease. Osteoporosis and connective tissue diseases, particularly systemic sclerosis (scleroderma) or Sjögren syndrome, may occur.

General management

PBC must be distinguished from other conditions with similar symptoms, such as *autoimmune hepatitis* or *primary sclerosing cholangitis*. The biochemical features of PBC resemble those of obstructive jaundice with raised serum alkaline phosphatase and elevated AST, ALT and GGT levels. Antibodies against mitochondria are found in about 90%. Approximately 50% have antinuclear antibodies, sometimes against proteins specific to nuclear components; the M2-IgG anti-mitochondrial antibody is the most specific test.

Antinuclear antibodies appear to be prognostic agents in PBC; *anti-glycoprotein-210 antibodies* and, to a lesser degree, *anti-p62 antibodies* correlate with progression toward end-stage liver failure. *Anticentromere antibodies* correlate with development of portal hypertension.

Abdominal ultrasound or a CT scan is usually performed to rule out blockage to the bile ducts. Previously, most suspected sufferers underwent a liver biopsy and – if uncertainty remained – endoscopic retrograde cholangiopancreatography (ERCP; an endoscopic investigation of the bile duct). Now most patients are diagnosed without invasive investigation since the combination of antimitochondrial antibodies and typical (cholestatic) liver function tests is considered diagnostic. Liver biopsy is still necessary to determine the stage of disease.

Medical treatment includes colestyramine to relieve pruritus, vitamins and calcium for osteoporosis prevention, and oral medium-chain triglycerides to improve nutrition. Ursodeoxycholic acid may help improve laboratory values but the effect on prognosis is unclear. Colchicine may play a role in inhibiting liver fibrosis and improves laboratory values but not signs or symptoms.

Orthotopic liver transplantation is highly successful for end-stage liver disease resulting from PBC.

Dental aspects

Patients with PBC may present similar management problems to those with other parenchymal liver diseases. Sjögren syndrome complicates 70% or more cases of PBC. Telangiectasias may be seen and oral lichen planus is an occasional complication. Penicillamine, once used for treatment, occasionally caused thrombocytopenia, polymyositis, pemphigus or myasthenia, and also caused lichenoid lesions, oral ulceration and loss of taste.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is an autoimmune form of cholangitis that leads to accumulation of bile; this damages the liver, leading in turn to jaundice and liver failure.

LIVER CANCER

General aspects

Cancer of hepatocytes is termed hepatocellular carcinoma (HCC) or malignant hepatoma. Common in Africa, South-East Asia, Japan and some Mediterranean countries (areas of high endemicity for HBV and HCV), it is uncommon in the USA and UK – where metastatic cancer to the liver from the colon, lungs, breasts, uterus or other parts of the body is far more common.

Risk factors for HCC include male gender, old age, a positive family history, chronic HCV or HBV, oral contraceptive use and cirrhosis. Aflatoxin, a mould that forms on peanuts, corn and other nuts and grains, is an important cause in Asia and Africa.

Clinical features

Liver cancer in the early stages often causes no symptoms. Later manifestations may include wasting, jaundice, pain or swelling in the abdomen, anorexia and fever.

General management

High alpha-fetoprotein serum levels can be a feature of liver cancer. Ultrasound, isotope and MRI scans, and biopsy are often needed for diagnosis.

Treatment usually consists of surgical resection (partial hepatectomy) but the prognosis is invariably poor. Liver transplantation may be required.

Radiotherapy, chemotherapy and targeted therapy may be used. Image-guided radiation therapy (IGRT) and respiratory gating may reduce toxicity. Doxorubicin alone or in combination with cisplatin, 5-fluorouracil and interferon (PIAF) is a chemotherapeutic approach that has improved survival for some. For HCC, anti-angiogenic drugs are the most common targeted therapy (sorafenib). More information on treatment options may be found at: <http://www.cancer.net/cancer-types/liver-cancer/treatment> (accessed 30 September 2013).

Dental aspects

There appear to be no significant dental considerations other than those applying to other types of severe liver disease.

EXTRAHEPATIC BILIARY OBSTRUCTION

General aspects

The main causes of extrahepatic biliary obstruction are gallstones and carcinoma of the pancreas (Ch. 7). Gallstones are common with advancing age, particularly in females. Around 10–20% of adults have gallstones but most are symptomless. About 80% of the stones contain cholesterol, while others are bile-pigment stones. The aetiology of cholesterol stones is usually unclear but some patients with Crohn disease or those on clofibrate, oral contraceptives or oestrogens appear to be susceptible. Pigment gallstones may complicate chronic haemolytic anaemias (hereditary spherocytosis, thalassaemia or sickle cell anaemia).

Clinical features

Gallstones are often asymptomatic but passage of the stones into the bile ducts can precipitate pain because of biliary colic, acute cholecystitis or acute pancreatitis. Extrahepatic biliary obstruction causes jaundice, pruritus, dark urine and pale stools with impaired absorption of fats and of vitamin K.

General management

There is usually a rise in serum bilirubin esters, alkaline phosphatase, 5'-nucleotidase, GGT and transaminases. Diagnosis may be by ultrasound and ERCP. Lithotripsy and medical treatment with chenodeoxycholic acid or ursodeoxycholic acid have a place in the treatment of asymptomatic stones. Cholecystectomy is usually indicated if obstructive jaundice develops.

Dental aspects

The main danger in surgery is excessive bleeding resulting from vitamin K malabsorption. Surgical intervention should therefore be deferred wherever possible in the presence of jaundice until haemostatic function returns to normal. If surgery is essential, vitamin K1 should be given parenterally for several days in an attempt to correct the bleeding tendency (Ch. 8).

GA in a severely jaundiced patient can lead to renal failure (hepatorenal syndrome).

POSTOPERATIVE JAUNDICE

Postoperative jaundice is discussed in Chapter 3 and its causes are listed in Table 9.14.

Table 9.14 Causes of postoperative jaundice

Excessive bilirubin load	Hepatocellular disease	Others
Haemolysis due to haemolytic anaemia or incompatible transfusions	Gilbert syndrome	Bile duct damage
Resorption of blood from large haematoma	Viral hepatitis	Obstructive jaundice
	Halothane and other drug-induced hepatitis	Sepsis
		Shock
		Gallstone disease
		Pancreatitis

LIVER TRANSPLANTATION

General aspects

Liver transplantation is provided for treatment of end-stage liver disease, such as from biliary atresia, metabolic disease, cirrhosis or malignancy. Usually, the liver is obtained from a cadaveric or brain-dead donor. Fortunately, even pieces of liver, when transplanted, will grow into a normal size. *Deceased organ transplantation* involves transplanting a liver that has been removed from a person who recently died. In *living donor liver transplantation*, a section of liver is removed from a living donor and used for transplant. *Split donation transplantation* is when a liver is removed from a person who recently died and then split into two pieces, each piece then being transplanted into a different patient.

The 1-year survival after liver transplantation is around 80% and, of survivors, 90% survive 5 years and 85% for 10 years. Graft-versus-host disease can follow liver transplantation (Ch. 35).

Several extracorporeal bioartificial liver devices are also undergoing clinical evaluation.

General management

All liver transplant recipients require lifelong immunosuppression with agents such as corticosteroids and calcineurin inhibitors to prevent a T-cell, alloimmune rejection response. TNF α inhibitors and other biological therapies may play an important role in solid-organ transplantation.

Liver transplant recipients may be susceptible to infections with viruses and/or fungi and to recurrence of their original disease; they may develop recurrence of hepatitis B or C, alcoholic liver disease, one of the autoimmune hepatitides, or diabetes, kidney disease, post-transplant lymphoproliferative syndrome or malignant neoplasms (Ch. 35).

The severity of hepatitis recurrence varies from mild to development of progressive allograft failure. Hepatitis B immunoglobulin is available for the prevention of hepatitis B reinfection in liver transplant patients. HCV recurrence after transplantation is almost universal but the extent of the graft damage is variable. The survival in the short term is not significantly affected, but concerns exist regarding long-term recurrence because the rate of developing cirrhosis at 5 years can be as high as 8–25%. Type 2 diabetes is a common and potentially serious complication of a liver transplantation, affecting about 1 in 5 people.

More information on liver transplantation may be found at: <http://www.nhs.uk/conditions/Liver-transplant/Pages/Introduction.aspx> (accessed 30 September 2013).

Dental aspects

In addition to those discussed in Chapter 35, dental aspects include:

- liver failure (bleeding tendencies, impaired drug metabolism)

- retarded tooth eruption and discoloured and hypoplastic teeth in children needing liver transplants
- gingival swelling in patients on ciclosporin or some other drugs.

APPENDIX 9.2 HEALTH PROTECTION AGENCY GUIDANCE

UK ADVISORY PANEL FOR HEALTHCARE WORKERS INFECTED WITH BLOODBORNE VIRUSES (UKAP)

Information on UKAP is available in the Infections A-Z under the 'Blood-borne viruses and occupational exposure' tab at: <http://www.hpa.org.uk/Topics/InfectiousDiseases/> (accessed 30 September 2013).

The panel is available for consultation:

- when advice is needed regarding restricting the practice of HCPs infected with blood-borne viruses
- when a lookback exercise may be needed as a result of exposure-prone procedures being undertaken on patients by an HCP infected with a blood-borne virus
- for general advice concerning the categorization of clinical procedures as exposure-prone.

The panel works within the framework of government guidance concerning HCPs and blood-borne viruses, and aims to interpret the guidance in relation to individual cases on a consistent basis.

UK DEPARTMENT OF HEALTH GUIDANCE

Hepatitis B infected healthcare workers and antiviral therapy (2007)

See http://www.dh.gov.uk/en/publicationsandstatistics/publications/publicationspolicyandguidance/dh_073164 (accessed 30 September 2013).

Health clearance for tuberculosis, hepatitis B, hepatitis C and HIV: new healthcare workers (2007)

See http://www.dh.gov.uk/en/publicationsandstatistics/publications/publicationspolicyandguidance/dh_073132 (accessed 30 September 2013).

Medical and dental students: health clearance for hepatitis B, hepatitis C, HIV and tuberculosis. Medical Schools Council (February 2008)

See <http://www.medschools.ac.uk/Students/howtoapply/publications/Pages/BBV.aspx> (accessed 30 September 2013).

Health service circular HSC 2000/020: hepatitis B infected health care workers

See http://www.dh.gov.uk/en/publicationsandstatistics/publications/publicationspolicyandguidance/dh_4008156 (accessed 30 September 2013).

Guidance extended the previous restrictions placed upon hepatitis B-infected HCPs. Both those who carry the e antigen (i.e. are HBeAg-positive) and those who are e-antigen-negative with a viral load

(hepatitis B virus [HBV] DNA level) that exceeds 10^3 genome equivalents per millilitre are restricted from performing exposure-prone procedures. The guidance names two dedicated laboratories in the UK where tests for HBV DNA are to be carried out using a specified assay and standardized controls.

Hepatitis B-infected HCPs who are HBeAg-negative and do not have an HBV DNA level exceeding 10^3 are not restricted from performing exposure-prone procedures but are subject to exposure-prone procedures.

Protecting health-care workers and patients from hepatitis B

The guidance recommends that carriers of the hepatitis B virus who are known to be e-antigen-positive must not carry out procedures where there is a risk that injury to themselves will result in their blood contaminating a patient's open tissues. Such procedures are termed 'exposure-prone procedures':

- Addendum to HSG(93)40: *Protecting health care workers and patients from hepatitis B* (April 2004)
- Addendum to HSG(93)40: *Protecting health care workers and patients from hepatitis B* (26 September 1996)
- *Protecting health care workers and patients from hepatitis B* (HSG[93]40)
- *Protecting health care workers and patients from hepatitis B* (Olive Book).

Health service circular HSC 2002/010: hepatitis C infected health care workers

Guidance recommends that HCPs known to be infected with hepatitis C and who are viraemic (i.e. HCV RNA-positive) should not perform exposure-prone procedures. The guidelines also recommend that HCPs intending to embark upon careers that rely upon the performance of exposure-prone procedures should be tested for hepatitis C (antibodies and, if positive, HCV RNA). This would mean prospective dental students before entry into dental schools. The guidelines are intended to apply to prospective students for undergraduate training, and not to those already qualified who are seeking postgraduate training. As in the HIV guidance, there is also a section about those at risk coming forward for testing for hepatitis C.

Guidance for clinical health care workers: protection against infection with blood-borne viruses (HSC 1998/063)

See http://www.dh.gov.uk/en/publicationsandstatistics/publications/publicationspolicyandguidance/dh_4002766 (accessed 30 September 2013). This booklet contains guidance on measures to protect clinical HCPs against occupational infection with blood-borne viruses. It is based on the recommendations of the Expert Advisory Group on AIDS and the Advisory Group on Hepatitis. It draws also on work done by the Advisory Committee on Dangerous Pathogens and the Microbiology Advisory Committee.

KEY POINTS

- Anxiety, phobias and depression are common, and can lead to misperceptions of disease or its severity
- Personality disorders can significantly disrupt team-working
- Substance abuse is common in mental disease

Mental health problems include mental illness; medically unexplained symptoms (MUS – formerly termed psychogenic problems); dementia, discussed in Chapter 13; and learning impairment, discussed in Chapter 28. The brain is a highly complex organ, the functions of many areas remaining unclear (Fig. 10.1). The rapid and widespread effects of mental reactions and emotions can readily be seen from the vasodilatation with blushing seen in anger, anxiety or embarrassment (Fig. 10.2).

All systems of mental disorders and diagnosis stem from the work of Kraepelin, who claimed that certain groups of symptoms often occur together, thus allowing us to call them *diseases* or *syndromes*.

Fig. 10.1 Brain structure.

Fig. 10.2 Blushing – an almost immediate vasodilatation emanating from a mental reaction to anxiety, anger or embarrassment.

He regarded each mental illness as distinct, with its own origins, symptoms, course and outcomes, and identified two major groups:

- *Dementia praecox* (schizophrenia)
- *Manic-depressive psychosis*.

This helped to establish the organic nature of mental disorders and formed the basis of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), the official classification system of the American Psychiatric Association (APA), and the World Health Organization's *International Classification of Diseases* (ICD; see below). The Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5; American Psychiatric Association [APA], 2013) is the most widely accepted up-to-date nomenclature used for the classification of mental disorders. Kraepelin's classification is also embodied in the Mental Health Act 1983, which contains three major categories of mental disturbances – mental illness, personality disorder and mental impairment.

Most disorders are caused by the interaction of:

- biological factors
- sociological factors
- psychological factors.

Genetics plays a role in shaping our personality and consequently our psychological status. The interactions of genetic and environmental factors are believed to cause a number of mental health problems ranging from autism (Ch. 28) to bipolar disorder.

Life stresses, such as bereavement and divorce, can play a significant role in mental health. Lifestyles can also influence mental health; brisk exercise can, by stimulating release of noradrenaline and endorphins, lift depression and create a sense of euphoria. Sunlight stimulates the pineal gland to release serotonin and melatonin, which influence mood. This is one reason why more people tend to be depressed during the darker winter months – seasonal affective disorder (SAD).

Although mental health and mental illness are related, they represent different psychological states.

Mental health is 'a state of well-being in which the individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community'. Indicators of mental health include the following:

- Emotional well-being – such as perceived life satisfaction, happiness, cheerfulness, peacefulness.
- Psychological well-being – such as self-acceptance, personal growth including openness to new experiences, optimism, hopefulness, purpose in life, control of one's environment, spirituality, self-direction and positive relationships.
- Social well-being: social acceptance, belief in the potential of people and society as a whole, personal self-worth and usefulness to society, sense of community. The social determinants of mental health include adequate housing, safe neighbourhoods, equitable jobs and wages, quality education, and equity in access to quality health care.

Good mental health is not just the absence of diagnosable mental health problems but is characterized by the ability to:

- learn
- feel, express and manage a range of positive and negative emotions
- form and maintain good relationships with others
- cope with and manage change and uncertainty.

Mental (psychiatric) illness is defined as ‘collectively all diagnosable mental disorders’ or ‘health conditions that are characterized by alterations in thinking, mood, or behaviour (or some combination thereof) associated with distress and/or impaired functioning’.

Depression is the most common type of mental illness and it has been estimated that depression will soon be the second leading cause of disability throughout the world, trailing only ischaemic heart disease. Evidence has shown that mental disorders, especially depressive disorders, are strongly related to the occurrence, successful treatment and course of many chronic diseases, including diabetes, cancer, cardiovascular disease, asthma, obesity and many risk behaviours for chronic disease, such as physical inactivity, smoking, excessive drinking and insufficient sleep.

When people experience severe and/or enduring mental health problems, they are sometimes described as mentally ill but there is no universally agreed cut-off point at which behaviour becomes abnormal enough to be termed mental illness. In any event, the term can imply that all such problems are caused solely by medical or biological factors, whereas most seem to result from complex interactions of medical, biological, social and/or psychological factors.

Personality disorder is defined as ‘an enduring pattern of inner experience and behaviours that deviates markedly from the expectation of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time and leads to distress or impairment’.

Mental health problems traditionally have been classified as *organic* (identifiable brain disease) or *functional* (no obvious brain structural abnormality); or as *neuroses* or *psychoses*. The term ‘neuroses’ covers those symptoms that can be regarded as severe forms of ‘normal’ emotional experiences, such as depression, anxiety or panic; they are now more often called ‘common mental health problems’ and include anxiety (with insight retained), depression, phobias, and obsessive–compulsive and panic disorders. Psychoses are less common and manifest with symptoms that constitute a severe distortion of a person’s perception of reality with loss of insight; they may include hallucinations such as seeing, hearing, smelling or feeling things that no one else can, and also severe and enduring mental health problems such as schizophrenia and bipolar affective disorder (manic depression).

Several diagnostic and classification frameworks have been developed to help identify mental health problems. As mentioned earlier, the two main ones are the ICD (the current one is version 10 – ICD-10) and the DSM (the latest is version 4 revised – DSM-IV-TR); these classify mental health problems in a series of families or categories (Box 10.1).

Therapies include psychotherapy and various psychoactive medications. Cognitive–behavioural therapy (CBT) is an increasingly used short-term, problem-focused psychosocial intervention. Evidence from randomised controlled trials and meta-analyses shows that CBT can be an effective intervention for depression, panic disorder, generalised anxiety and obsessive–compulsive disorder, and its usefulness in a growing range of other issues such as health anxiety/hypochondriasis, social phobia, schizophrenia and bipolar disorders. Most patients are

Box 10.1 International Classification of Diseases (ICD) 1 F00–F99: mental and behavioural disorders

- 1.1. (F00–F09) Organic, including symptomatic, mental disorders
- 1.2. (F10–F19) Mental and behavioural disorders due to psychoactive substance use
- 1.3. (F20–F29) Schizophrenia, schizotypal and delusional disorders
- 1.4. (F30–F39) Mood (affective) disorders
- 1.5. (F40–F48) Neurotic, stress-related and somatoform disorders
- 1.6. (F50–F59) Behavioural syndromes associated with physiological disturbances and physical factors
- 1.7. (F60–F69) Disorders of adult personality and behaviour
- 1.8. (F70–F79) Mental retardation
- 1.9. (F80–F89) Disorders of psychological development
- 1.10. (F90–F98) Behavioural and emotional disorders with onset usually occurring in childhood and adolescence
- 1.11. (F99) Unspecified mental disorder

cared for in the community, with rare recourse to ‘sectioning’ (admission to hospital against a patient’s will). In the UK, under the Mental Health Act 1983, intended to help doctors manage patients with a mental disorder, patients can be sectioned or detained against their will and given treatment. The types of defined ‘mental disorder’ include ‘severe mental impairment’, ‘psychopathic disorder’ or ‘mental illness’. Under the Act, patients can be sectioned if they are perceived to be a threat to themselves or others.

A patient can only be sectioned if an approved social worker or a close relative and two doctors believe it is necessary. One of these doctors is usually a psychiatrist, while the other knows the patient well, but in an emergency a single doctor’s recommendation may be sufficient.

If a patient is sectioned as an emergency case, they may then be detained under section 4 of the Mental Health Act for up to 72 hours. If doctors believe that further assessment or treatment is necessary, then the patient can be detained under section 2 of the Act, meaning that they can be admitted to hospital and detained for up to 28 days to undergo a full psychiatric assessment. At the end of the 28-day period, if the medical recommendation is for the patient’s stay in hospital to be extended, section 3 of the Act permits a further 6-month extension. A patient can be discharged from hospital at any time if doctors believe they are no longer a threat to themselves or anyone else.

LEGISLATION

Legislation and policy decisions affect individuals’ rights and, in particular, their entitlement to health-care provision, including oral health care. Legislation in the UK has evolved significantly over recent years to protect the rights of the individual, and a summary is presented below.

MENTAL HEALTH ACTS 1983 AND 2007

This Act is primarily concerned with the care and treatment of people with a mental health problem that requires that they be detained or treated in the interests of their own health and safety or with a view to protecting other people. It is now 30 years old and new legislation was passed through parliament in the form of the Mental Health Act 2007.

Table 10.1 Main parts and functions of the brain

Main part of brain (see Fig. 10.1)		Neurological functions	Mental and other functions
Supratentorial	Cerebrum	Initiation of movement, coordination of movement, temperature, touch, vision, hearing	Higher functions, memory, judgment, ideas, reasoning, problem-solving, emotions, learning Skilful intellectual tasks (e.g. reading, writing, mathematical calculations) Limbic system contains several nuclei of grey matter around the brainstem; it commands certain behaviours necessary for survival, e.g. distinction between agreeable and disagreeable; affective functions are developed, e.g. inducing females to nurse and protect their toddlers, or inducing playful moods. Emotions and feelings, like anger, fright, passion, love, hate, joy and sadness, originate in the limbic system, which is also responsible for aspects of personal identity and important functions related to memory
	Brainstem, including mid-brain, pons and medulla	Movement of eyes and mouth, relaying sensory messages (i.e. heat, pain, loudness), hunger, respiration, consciousness, cardiac function, body temperature, involuntary muscle movements, sneezing, coughing, vomiting, swallowing	Self-preservation. Mechanisms of aggression and repetitive behaviour. Instinctive reactions of the so-called reflex arcs and the commands that allow some involuntary actions and control of visceral functions (cardiac, pulmonary, intestinal, etc.)
Infratentorial	Cerebellum	Coordination of voluntary muscle movements and maintenance of posture, balance, equilibrium	–

MENTAL CAPACITY ACT 2005

This Act is relevant to everyone involved in the care, treatment or support of people aged 16 years and over in England and Wales who lack capacity to make all or some decisions for themselves. It also applies to situations where a person may lack capacity to make a decision at a particular time due to illness, drugs or alcohol. Assessments of capacity should be time- and decision-specific.

The Act clarifies the terms ‘mental capacity’ and ‘lack of mental capacity’, and says that a person is unable to make a particular decision if they cannot do one or more of the following:

- Understand information given to them
- Retain that information for long enough to be able to make the decision
- Weigh up the information available to make the decision
- Communicate their decision; this could be done, for example, by talking, using sign language or even simple muscle movements, such as blinking an eye or squeezing a hand.

The new criminal offence of ill treatment or wilful neglect of people who lack capacity also came into force in 2007. Within the law, ‘helping with personal hygiene’ (including tooth-brushing) attracts protection from liability as long as the individual giving this assistance has complied with the Act by assessing a person’s capacity and acting in their best interests. ‘Best-interest’ decisions made on behalf of people who lack capacity should place the fewest restrictions possible on their basic rights and freedoms.

Further changes within the Act include the introduction of *lasting powers of attorney* (LPA), which extend to health and welfare decisions. When a health professional has a significant concern relating to decisions about serious medical treatment taken under the authority of an LPA, the case can be referred for adjudication to the Court of Protection, which is ultimately responsible for the proper functioning of the legislation. The Act also created an *Office of the Public Guardian*, which has responsibility for the registration and supervision of both LPAs and court-appointed deputies. Furthermore, independent mental capacity advocates were introduced to support particularly vulnerable incapacitated adults – most often those who lack any other forms of external support – in making certain decisions.

DENTAL ASPECTS

Preventive dentistry is crucial in patients with mental health problems. The individual may neglect oral hygiene, dental appointments and instructions unless a caregiver or family member is also involved. Dental staff must use great tact, patience and a sympathetic, unpatronizing manner in handling patients with mental health problems. To avoid causing adverse drug interactions, special precautions should be taken when administering certain antibiotics, analgesics and sedatives. The treatment should be given in the morning, when cooperation tends to be best, with the usual caretakers present and in a familiar environment, and time must be allowed to explain every procedure before it is carried out. The patient should be treated while sitting upright in the dental chair or slightly reclined, to avoid aspiration and postural hypotension (Ch. 5).

Mental health is often affected by social, psychological, biological, genetic and environmental factors, as well as by changes in the brain neurotransmitters of the central nervous system (CNS) (Table 10.1).

Emotion is not a function of any specific brain area but of a circuit that involves interconnected basic structures: the hypothalamus, the anterior thalamic nucleus, the cingulate gyrus, the hippocampus, the prefrontal area, the parahippocampal gyrus and subcortical groupings like the amygdala, the medial thalamic nucleus, the septal area, the basal nuclei and a few brainstem formations (Table 10.2)

BIOLOGICAL ASPECTS

BRAIN NEUROTRANSMITTERS

Brain neurotransmitters include monoamines, acetylcholine (ACh), amino acids, gamma-aminobutyric acid (GABA), peptides, substance P and opioids (Table 10.3).

Monoamines include catecholamines (noradrenaline [norepinephrine], adrenaline [epinephrine] and dopamine), serotonin (5-hydroxytryptamine; 5-HT) and histamine. Noradrenaline is released by post-ganglionic neurons of the sympathetic branch of the autonomic nervous system. ACh mediates transmission at brain synapses involved in the acquisition of short-term memory. Amino acids such as glutamic

Table 10.2 Main parts and functions of the brain involved with emotion and mood

Brain area	Emotions/moods
Amygdala	Mediates and controls major affective activities like friendship, love and affection, expressions of mood and fear, rage and aggression
Cingulate gyrus	Coordinates smells and sights with pleasant memories of previous emotions and participates in the emotional reaction to pain and regulation of aggressive behaviour
Hippocampus	Responsible for long-term memory
Hypothalamus	Connects with other prosencephalic areas and the mesencephalus. Involved with several vegetative functions and some so-called motivated behaviours, like thermal regulations, sexuality, combativeness, hunger and thirst. Also plays a role in emotion, e.g. pleasure, rage, aversion and laughing
Nucleus accumbens	Responsible for pleasurable sensations, some of them similar to orgasm
Septal region	Associated with different kinds of pleasant sensations, mainly those related to sexual experiences. Anterior frontal lobe is important in the genesis and expression of affection, joy, sadness, hope or despair, as well as the capacity for concentration, problem-solving and abstraction
Thalamus	Associated with emotional reactivity due to connections with other limbic system structures. The medial dorsal nucleus connects with the frontal area and hypothalamus. The anterior nuclei connect with the mammillary bodies and, through them, via the fornix, with the hippocampus and cingulate gyrus

acid (Glu) are involved in transmission at excitatory synapses and are essential for long-term potentiation (LTP), a form of memory. GABA is released at inhibitory synapses to hyperpolarize the post-synaptic membrane, resulting in an inhibitory post-synaptic potential (IPSP). Peptides not only serve as brain neurotransmitters but some are also hormones; these include vasopressin (antidiuretic hormone; ADH), oxytocin, gonadotropin-releasing hormone (GnRH), angiotensin II and cholecystokinin (CCK). Other transmitters include substance P, which transmits pain impulses and opioids – a term used for all enkephalins, endorphins and morphine-like peptide chemicals, including dynorphin.

Enkephalins (from the Greek *kephale*, meaning head) are pentapeptides. One enkephalin, leu-enkephalin, terminates in a leucine; the other, met-enkephalin, terminates in a methionine. Enkephalins are released at synapses on neurons involved in transmitting pain signals to the brain and act as an intrinsic pain-suppressing system, hyperpolarizing the post-synaptic membrane and thus inhibiting pain signals.

Endorphins are small-chain peptides that activate opiate receptors, producing feelings of well-being, as well as tolerance to pain. These compounds are hundreds or even thousands of times more potent than morphine. Four groups of endorphins – alpha, beta, gamma and sigma – have been identified.

Dynorphins are other brain opioid peptides.

Factors that influence the production of enkephalins, endorphins and dynorphins include prolonged strenuous activity, transcutaneous electrical nerve stimulation (TENS), acupuncture and placebos. Enkephalins and endorphins bind to neuroreceptors in the brain to give relief from pain. This effect appears to be responsible for the so-called ‘runner’s high’, the temporary loss of pain after severe injury, and the analgesic effects that acupuncture and chiropractic adjustments of the spine can offer.

Enkephalins are found especially in the thalamus and in parts of the spinal cord that transmit pain impulses, and in the adrenal medulla.

They act as analgesics and sedatives, and appear to affect mood and motivation. Blood levels rise after exercise and sexual activity, and may explain how a severely wounded person can continue to function. Endorphins may act to prevent the release of substance P, which may account for the sedating effects of endogenous endorphins and of opioids given therapeutically. Endorphins also have anti-ageing effects by removing superoxide, anti-stress activity, pain-relieving effects and memory-improving activity. Endorphins may link the emotional state of well-being and the health of the immune system.

Once any neurotransmitter has acted, it must be removed from the synaptic cleft, usually by reuptake or breakdown, to prepare the synapse for the arrival of the next action potential. All the neurotransmitters except ACh do this via reuptake. ACh is removed from the synapse by enzymatic breakdown by acetylcholinesterase into inactive fragments.

OTHER FACTORS THAT AFFECT MENTAL HEALTH

These include the following:

- *Antidepressant drugs* include monoamine oxidase inhibitors (MAOIs), which block the breakdown of monoamines, such as noradrenaline and serotonin. Selective serotonin reuptake inhibitors (SSRIs) block the reuptake of serotonin only, but tricyclic antidepressants (TCAs) interfere with noradrenaline and serotonin reuptake from synapses and thus enhance their action.
- *Amino acids*, such as tyrosine, phenylalanine, methionine, tryptophan and GABA, are essential for the production of neurotransmitters and are, therefore, natural antidepressants. Organic sulphur in the form of methylsulphonylmethane (MSM) is needed for their production and utilization. Dietary supplementation with MSM may improve alertness and elevate mood.
- *Hormones* act indirectly via control of blood sugar, calcium and sodium balance, and affect behaviour in general – anger, love, anxiety, panic attacks and agitation. Hypoglycaemia can cause agitation, depression and poor mental concentration. Hypothyroidism can cause impotence and depression. Hyperthyroidism can cause agitation, irritability and lack of sleep. Addison disease can cause severe depression, while those treated with high corticosteroid doses can become euphoric or have hallucinations and psychoses. Sex steroids such as testosterone clearly affect mood and behaviour. The mood swings associated with premenstrual stress and menopause may be reduced with natural progesterone cream derived from wild yam – all sex steroids were originally produced from wild (elephant foot) yam. Melatonin may affect depression.
- *Drugs that bind to the GABA receptor* to enhance the inhibitory effect of GABA in the CNS include sedatives such as phenobarbital, alcohol, and anxiolytics such as benzodiazepines.
- *Drugs such as chlorpromazine and haloperidol bind to dopamine receptors*, leading to greater synthesis of dopamine at the synapse and easing some of the symptoms of schizophrenia.
- *Naloxone binds to the opioid kappa receptor*, and blocks both enkephalin-degrading enzyme inhibitors (enkephalinase inhibitors) and kappa antagonists.

NEUROIMMUNOLOGICAL MECHANISMS

There appears to be a relationship between mental health and the immune system, which can be either overactive or suppressed, leading to associated diseases. There is growing evidence that such

Table 10.3 *Some neurotransmitters, with their functions and associated disorders*

Neurotransmitter	Functions	Associated disorders
Acetylcholine (ACh)	Alertness, memory Muscle tone, learning, primitive drives, emotions, release of vasopressin (involved in learning and regulation of urine output). ACh-releasing neurons in the pons are active in rapid eye movement (REM) sleep (dreaming) Relation to sexual performance and arousal – helps control blood flow to genitals, heart rate and blood pressure during sexual intercourse	Alzheimer disease is associated with 90% loss of ACh in the forebrain and hippocampus
Adrenaline (epinephrine)	Physiological expressions of fear and anxiety (fright, fight and flight)	Adrenaline in excess is seen in anxiety disorders
Dopamine	Feelings of bliss ('the pleasure chemical'). More dopamine in the frontal lobe lessens pain and increases pleasure Regulation of information flow into the frontal lobe from other areas of brain Effect on voluntary movement, learning, memory and emotion	Parkinson disease is brought on when dopamine fails to reach the basal ganglia Relation to attention deficit hyperactivity disorder (ADHD) Schizophrenia is associated with the inability of dopamine to reach the frontal lobe Excess dopamine in the limbic system and not enough in the cortex may produce paranoia or inhibit social interaction A shortage of dopamine in the frontal lobes may cause poor memory Cocaine, opiates and alcohol produce their effects in part via dopamine release
Endorphins and enkephalins	Involvement in pain reduction, pleasure (enhance release of dopamine) and hibernation, as well as a number of other behaviours Endorphins block pain at receptor sites and facilitate the dopamine pathway that feeds into the frontal lobe, thereby replacing pain with pleasure Also produced by the pituitary gland and released as hormones	Opiates (natural and synthetic) bind to endorphin and enkephalin brain receptors and alter behaviour
Gamma-aminobutyric acid (GABA)	Major inhibitory neurotransmitter lessening anxiety. Brain produces substances that enhance anxiety (beta-carbolines), as well as substances that lower anxiety (e.g. allopregnanolone). All modify GABA brain receptors to produce effects	Anxiolytic drugs, such as benzodiazepines, act by enhancing effects of GABA at synapses
Glutamate	The main brain excitatory neurotransmitter, with actions mediated at NMDA and AMPA receptors involved in memory formation	Involvement in a 'suicidal' response when the brain is damaged, as in stroke. Excess glutamate is neurotoxic and neurons are damaged by the excessive calcium that enters the cell due to glutamate-binding. Glutamate is produced excessively in amyotrophic lateral sclerosis
Neuropeptide Y/polypeptide YY (NPY/PPYY)	Effect on hypothalamus and stimulation of excessive food intake and fat storage	Link with anxiety and eating disorders
Noradrenaline (norepinephrine)	Stimulant to the body and mind. Causes some of the physiological expressions of fear and anxiety (fright, fight and flight response). Modulation of heart rate, blood pressure, learning, memory, waking, emotion	Most forms of depression are associated with a deficiency of noradrenaline High levels can cause aggression Stress in children can lead to permanently high levels of noradrenaline, creating the potential for violent behavior Raised levels of norepinephrine mixed with dopamine and phenylethylamine produce feelings of infatuation High levels contribute to multiple orgasms in women
Oxytocin	Raised levels give mothers an impulse to cuddle their newborns	
Phenylethylamine	In the limbic system gives feelings of bliss A natural ingredient in chocolate	Low levels in ADHD
Serotonin (5-hydroxytryptamine, 5-HT)	The 'feel-good' hormone that enables relaxation and enjoyment of life Synthesized from the amino acid l-tryptophan Also a precursor for the pineal hormone melatonin, which regulates the body clock: sleep, appetite, sensory perception, temperature regulation, pain suppression and mood	Most forms of depression are associated with a deficiency of serotonin at functionally important serotonergic receptors
Substance P	A neurotransmitter that mediates pain; found throughout the pain pathway Release can be blocked by enkephalins and endorphins	–

neuroimmunological mechanisms might influence immunological and inflammatory disorders and defence against infection. It has, for example, been suggested that stress might underlie some periodontal and other oral diseases. The major route identified for neuroimmunomodulation is via the neuroendocrine system.

In addition to recognizable neurotransmitters, the nervous system contains significant levels of cytokines and their receptors. Thus the possibility of a two-way exchange of information is clearly present. Immune cells possess a host of receptor profiles for modulatory substances and many of these are common to the nervous system. Two different pathways and effects of immediate stress can be demonstrated:

- The endocrine path, in which the CNS is central to the control of release of glucocorticosteroids such as cortisol, which have an immunosuppressive effect and temporary adverse effects on cognitive functions, such as learning and memory.
- The second, direct neural pathway to the adrenal medulla releases other transmitters, particularly catecholamines, which depress chemotaxis and phagocytosis, and beta-adrenergic agonists, which have general effects on white blood cells.

In severe long-term stress, natural opioids are released; the adrenals release met-enkephalin and the hypothalamus releases beta-endorphin, which leads to enhanced anti-tumour activity of natural killer (NK) cells and proliferative response of lymphocytes.

Inflammatory cytokines – interleukin (IL)-1b, IL-6 and tumour necrosis factor alpha (TNF α) – activate the hypothalamo–pituitary–adrenal (HPA) axis. IL-1 modulates brain catecholamine activity; depletion of central catecholamines potentiates severity of inflammation and also affects the release of corticotropin-releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH). IL-1, IL-6 and nitric oxide modulate brain serotonin activity, depletion of which enhances the inflammatory response.

Under stress conditions, if immune activity is not controlled, it may reach a state of activation in which host injury and tissue destruction can take place (autoimmunity).

ANXIETY AND STRESS

Anxiety disorders are characterized by excessive and unrealistic worry about everyday tasks or events, or may be specific to certain objects or rituals. Stress keeps people alert and ready to avoid danger, but when it persists, illness can result.

ANXIETY DISORDERS

Clinical features

Anxiety can cause several physical effects as a result of overwhelming autonomic activity. Sympathetic activity via the release of catecholamines causes apprehension, tachycardia, hyperventilation, hypertension, sweating, tremor and dilated pupils. Parasympathetic activity may lead to involuntary defecation and urinary incontinence. These changes may be recognized by features such as those listed in Table 10.4.

Pathological anxiety may be difficult to diagnose and requires careful consideration of an individual's personal history and presenting clinical features. A thorough history and perhaps psychiatric assessment may be appropriate, but underlying organic causes such as hyperthyroidism and mitral valve prolapse should be excluded first.

Anxiety can be classified into the following diagnostic categories:

- Panic disorder – discrete attacks with no external stimulus
- Phobias – discrete attacks with stimuli

Table 10.4 Features suggesting anxiety

Physiological	Behavioural	Cognitive
Child		
Pallor	Crying	Being scared
Increased pulse rate	Being uncooperative, restless or disruptive	Anxiety
Tension	Silence or sullenness	Negative thoughts
Hyperventilation		
Adult		
Dry mouth	Verbal abuse	Negative thoughts
	Excessive talking	
	Cancelling appointments, arriving late or not at all	

- Generalized anxiety disorder (GAD) – a generalized persistent state of anxiety
- Anxiety as a manifestation of other psychiatric disease such as depression.

General management

Treatment of anxiety and stress may require:

- appropriate management of any underlying organic disease
- lifestyle changes – to reduce stressors and avoid precipitating factors
- behavioural techniques
- pharmacotherapy (anxiolytics and beta-blockers)
- psychotherapy – this may be used to aid adjustment of lifestyle (supportive) or to explore patient conflicts and secondary gain (psychodynamic).

Psychotherapy involves talking with a mental health professional, such as a psychiatrist, psychologist, social worker or counsellor, to learn how to deal with problems. Cognitive behavioural therapy (CBT) and behavioural therapy are effective for several anxiety disorders, particularly panic disorder and social phobia. There are two components to CBT: the cognitive component helps to change thinking patterns that keep people from overcoming their fears, while the behavioural component seeks to change reactions to anxiety-provoking situations. Anxiety disorders may be addressed by exposure (to the object or event of concern) and response prevention – not permitting the compulsive behaviour, to help the individual learn that it is not needed. A key element of this component is exposure, in which people have to confront the things they fear. Behavioural therapy alone, without a strong cognitive component, has been used effectively to treat specific phobias. Here, persons are gradually exposed to the objects or situations that are feared. Often the therapist will accompany them to provide support and guidance. After treatment, the beneficial effects of CBT may last longer than those of medication for people with panic disorder; the same may be true for obsessive–compulsive disorder (OCD), post-traumatic stress disorder and social phobia.

Drugs can play a part in the treatment of some people with anxiety or phobias. Anti-anxiety medications (anxiolytics) either alter or inhibit the amount or action of a targeted neurotransmitter. Anxiolytics include benzodiazepines (BZPs – which enhance GABA inhibitory activity), serotonin selective reuptake inhibitors (SSRIs), and azapirones such as buspirone (which act on 5-HT [serotonin]1A receptor). Other drugs, like beta blockers, are used as anxiolytics since they can inhibit some of the physical manifestations, such as rapid heartbeat and sweating. BZPs relieve symptoms quickly with few side-effects, except often for some drowsiness. BZPs include clonazepam,

which is used for social phobia and GAD; alprazolam, which is helpful for panic disorder and GAD; and lorazepam, which is also useful for panic disorder. BZPs should be prescribed for short periods of time because of development of tolerance (rising doses to achieve the same effect) and dependence. Panic disorder is an exception, for which BZPs may be used for 6 months to a year. Those who abuse drugs or alcohol are not usually good candidates for BZPs because they can become dependent. Withdrawal symptoms, and in certain instances rebound anxiety, can follow after stopping BZPs. They should not be given to children, the elderly, alcoholics (except to treat withdrawal), or pregnant or lactating women. Temazepam is particularly prone to becoming abused and is a controlled drug. Azapirones (AZPs) are used to treat a range of mental health problems, including anxiety disorders, depression and psychosis. Adverse effects may include drowsiness, dizziness, nausea, weakness, insomnia and lightheadedness.

Beta-blockers, such as propranolol, are helpful in certain anxiety disorders, particularly social phobia. Antidepressants can help to relieve anxiety.

Dental aspects

Anxiety can be generated by dental or medical appointments, even amongst normal patients, and is a perfectly natural reaction to an unpleasant experience. A total of 65% of patients report some level of fear of dental treatment. It is essential, therefore, not to dismiss patients who will not accept a proposed treatment as being 'phobic' or 'uncooperative', though a small number will require psychological or even psychiatric assessment and/or treatment. Younger patients have significantly more fear of treatment than older patients. Among fearful patients, changes in pulse rate (>10 beats/min) and blood pressure are detectable.

Quantification of anxiety levels can be achieved using a modified dental anxiety scale (see Box 2.2). Other scales and a range of techniques to manage such patients are outlined by Rafique et al. (2008).

Dental 'phobia' is more extreme than straightforward anxiety, and previous frightening dental experiences are often cited as the major factor in their development. Patients fear the noise and vibration of the drill (56%), the sight of the injection needle (47%) and sitting at the treatment chair (42%) especially. Effects include muscle tension (64%), faster heart beat (59%), accelerated breathing (37%), sweating (32%) and stomach cramps (28%). Patients with a true phobic neurosis about dental treatment are uncommon but, when seen, demand great patience. Phobic patients, who may genuinely want dental care but are unable to cooperate, are often unaware of their anxiety and, as a consequence, may be hostile in their responses or behaviour. Some individuals are difficult or even impossible to manage because of anxiety, phobia or personality disorders.

Patients who apply for treatment at a dental fear clinic are not just dentally anxious; they often show a wide range of other complaints. Persons with clinically significant fear tend to have poorer perceived dental health, a longer interval since their last dental appointment, a higher frequency of past fear behaviours, more physical symptoms during dental injections, and a higher percentage of symptoms of anxiety and depression. They may chatter incessantly, have a history of failed appointments, and appear tense and agitated ('white knuckle syndrome').

Dental treatment in anxiety states is usually straightforward. Early morning appointments, with pre-medication and no waiting, can help. The main aids are careful, painlessly performed dental procedures, psychological approaches, confident reassurance, patience and, sometimes, the use of pharmacological agents – for example, anxiolytics such as oral diazepam, supplemented if necessary with

intravenous, transmucosal or inhalational sedation during dental treatment. General techniques to help overcome anxiety include relaxation techniques (e.g. deep breathing), distraction (e.g. watching TV), control strategies (e.g. 'put your hand up if you wish me to stop') and positive reinforcement (e.g. praise). Other measures include systematic desensitization, biofeedback, modelling and hypnosis, and may need support from a psychologist.

Symptoms such as agitation, slight tachycardia and dry mouth, mainly caused by sympathetic overactivity, are usually controllable by reassurance and possibly a very mild anxiolytic or sedative, such as a low dose of a beta-blocker or a short-acting (temazepam) or moderate-acting (lorazepam or diazepam) BZP, provided the patient is not pregnant and does not drive, operate dangerous machinery or make important decisions for the following 24 hours. Temazepam 10mg orally on the night before and 1 hour before dental treatment can be used to supplement gentle sympathetic handling and reassurance of the anxious patient. Intravenous or intranasal sedation with midazolam, or relative analgesia using nitrous oxide and oxygen, is also useful. BZP metabolism is impaired by azole antifungals, and by macrolide antibiotics such as erythromycin and clarithromycin. Alcohol, antihistamines and barbiturates have additive sedative effects with BZPs. The analgesic dextropropoxyphene should be avoided in patients taking alprazolam, as it may cause toxicity.

Difficulties may also result from alcoholism or drug dependence, or drug treatment with major tranquillizers, MAOIs or TCAs. Oral manifestations, such as facial arthromyalgia, dry mouth, lip-chewing or bruxism, may be complaints in chronically anxious people. Cancer phobia is also an indication of an anxiety.

STRESS

General aspects

The brain areas involved in regulation of stress responses include the prefrontal cortex, amygdala, hippocampus and nucleus accumbens. Acute stress enhances immune function whereas chronic stress suppresses it.

Besides the hypothalamus and brainstem, which are essential for autonomic and neuroendocrine responses to stressors, higher cognitive areas of the brain play a key role in memory, anxiety and decision-making, and are targets of stress and stress hormones. The effects of glucocorticoids on the hippocampus and other brain regions are regulated by: corticosteroid-binding globulin (CBG), multiple drug resistance P-glycoprotein (MDR1), and metabolism by 11-hydroxysteroid dehydrogenase type 1 (11-HSD-1). Four peptide/protein hormones – IGF-1, insulin, ghrelin and leptin – affect the hippocampus.

Different alleles of commonly occurring genes determine how individuals will respond to stress. For example, the serotonin transporter is associated with alcoholism, and individuals who have one allele are more likely to respond to stress by developing depression. Individuals with an allele of the monoamine oxidase A gene are more vulnerable to abuse in childhood and more likely to become abusers themselves and to show antisocial behaviours. Stress begins in and affects the brain, as well as the rest of the body. Acute stress responses promote adaptation and survival via neural, cardiovascular, autonomic, immune and metabolic responses. Chronic stress can promote and exacerbate pathophysiology through the same systems. The burden of chronic stress and accompanying changes in personal behaviours (smoking, eating too much, drinking, poor-quality sleep – otherwise referred to as 'lifestyle') is called allostatic overload. Brain regions such as the hippocampus, prefrontal cortex and amygdala respond to acute

and chronic stress and show changes in morphology and chemistry that are largely reversible if the chronic stress lasts only for weeks. However, it is not clear whether prolonged stress for many months or years may have irreversible effects.

In obese individuals, the final common pathway of the stress response – the HPA axis – is altered, and concentrations of cortisol are raised in adipose tissue due to raised activity of 11 β -HSD-1. Short sleep and decreased sleep quality are also associated with obesity. In addition, sleep curtailment induces HPA-axis alterations that, in turn, may negatively affect sleep.

CRH plays a central role in the regulation of the HPA axis. CRH action on ACTH release is potentiated by vasopressin, whereas oxytocin inhibits it. ACTH release results in the release of corticosteroids from the adrenals, which subsequently, through mineralocorticoid and glucocorticoid receptors, exert negative feedback on the hippocampus, the pituitary and the hypothalamus. The most important glucocorticoid in humans is cortisol. Vasopressin production is increased in depression. The suprachiasmatic nucleus, the biological clock of the brain, shows lower vasopressin production and a smaller circadian amplitude in depression, which may explain the associated sleep problems. The hypothalamo–pituitary–thyroid (HPT) axis is inhibited in depression. Although cortisol and CRH may well be causally involved in depression, there is no evidence for any major irreversible damage in the hippocampus in depression.

The stress response is mediated by the HPA system and reliant on activity of the CRH neurons in the hypothalamic paraventricular nucleus (PVN). The CRH neurons co-express vasopressin (ADH), which potentiates the CRH effects. CRH neurons regulate the adrenal innervation of the autonomic system and affect mood. Both centrally released CRH and increased levels of cortisol contribute to the features of depression. Depression is also a frequent side-effect of steroid treatment and is one of the symptoms of Cushing syndrome. The ADH neurons in the hypothalamic PVN and supraoptic nucleus are also activated in depression, which contributes to the increased release of ACTH from the pituitary. Increased levels of circulating ADH are also associated with the risk for suicide. The prevalence, incidence and morbidity risk for depression are higher in females than in males and fluctuations in sex hormone levels are considered to be involved.

Causes of stress

The causes of stress can be different for each person and individuals vary in their ways of coping.

Common causes of stress include:

- accidents
- confrontations
- crowds
- deadlines
- death of a loved one
- divorce
- examinations
- financial problems
- heavy traffic
- house-moving
- illness
- job change or loss
- legal problems
- marriage
- pregnancy
- retirement
- separation.

Clinical features of stress

Signs include the following:

- Emotional
 - ◆ Anger
 - ◆ Inability to concentrate
 - ◆ Mood swings
 - ◆ Sadness
 - ◆ Unproductive worry
- Physical
 - ◆ Chronic fatigue
 - ◆ Sweaty palms
 - ◆ Tremors
 - ◆ Weight changes
 - ◆ Headaches
- Mental/behavioural
 - ◆ Acting on impulse
 - ◆ Changing jobs frequently
 - ◆ Over-reacting
 - ◆ Using alcohol or drugs
 - ◆ Withdrawing from relationships.

Stress is a reaction caused by anything that requires adjustment to a change in the environment. The reactions can be physical, mental/behavioural and/or emotional. Emotional stress can release chemicals that provoke brain blood vessel changes, which in turn can trigger tension (stress) headaches. The sympathetic nervous system turns on the fight or flight response with adrenaline (epinephrine) release; the brain limbic system immediately responds. Cortisol secretion rises but other hormones shut down; growth, reproduction and the immune system are suppressed. Later, the tranquillizing parasympathetic nervous system activates to calm things down.

Tension headaches can be either episodic or chronic. Episodic tension headache is usually triggered by an isolated stressful situation or a build-up of stress; it can usually be treated by analgesics. Daily stress, such as from a high-pressure job, can lead to chronic tension headaches. Treatment for chronic tension headaches usually involves counselling, stress management and possibly anxiolytics or antidepressants.

Coping with stress

The key to coping with stress is identifying stressors, learning ways to reduce stress and managing stress. Coping is a process, not an event.

Helpful advice includes the following measures:

- Lower your expectations; accept that there are events beyond your control
- Ask others to help
- Take responsibility for the situation
- Problem-solve
- Be assertive rather than aggressive
- Maintain emotionally supportive relationships
- Maintain emotional composure
- Try to change the source of stress and distance yourself from it
- Learn to relax
- Eat and drink sensibly
- Maintain a healthy self-esteem
- Exercise regularly
- Avoid smoking or other bad habits.

Stress may play a greater role in health and disease than formerly supposed. Humans are sensitive to stressors (e.g. operations) and even visits for health care can activate the HPA system. Anxiety generated

Table 10.5 *Some possible effects of acute and chronic stress*

	Mild stress	Acute stress	Chronic stress
Central nervous system	Mood change	Improved concentration and clarity of thought	Anxiety, loss of sense of humour, depression, fatigue, headaches, migraines, tremor
Cardiovascular	Rise in pulse rate and blood pressure	Tachycardia, arrhythmias	Hypertension, chest pain, ischaemic heart disease
Respiratory	Raised respiratory rate	Hyperventilation	Cough, asthma
Mouth	Slight dryness	Dry mouth	Dry mouth, ulcers
Gastrointestinal	Raised bowel activity	Impaired digestion	Peptic ulceration, irritable bowel syndrome
Sexual	Male impotence, female irregular menstruation	Male impotence, female irregular menstruation	Male impotence, female amenorrhoea

by such ordeals as dental or medical appointments, or by public speaking, solo musical performances, examinations or interviews, is normal. Stress is also fairly common in dental students and staff. Work stressors may include examinations, fear of failure, difficulties with accommodation or study facilities, inadequate holidays or relaxation time, financial difficulties, criticism, and time and scheduling demands. Stress can lead to reactions affecting a wide range of functions (Table 10.5).

Fear, an emotion that deals with danger, causes an automatic, rapid protective response in many body systems, coordinated by the amygdala. Emotional memories stored in the central amygdala may play a role in disorders involving very distinct fears, such as phobias, while different parts may be involved in other forms of anxiety.

The hippocampus – an area of the brain critical to memory and emotion – is involved in intrusive memories and flashbacks typical of post-traumatic stress disorder, and results in raised levels of stress hormones – cortisol, adrenaline (epinephrine) and noradrenaline (norepinephrine).

Danger induces high levels of enkephalins and endorphins, natural opioids, which can temporarily mask pain, and in some anxiety states higher levels persist even after the danger has passed.

Cortisol is the major steroid hormone produced in the adrenal glands and is essential for the body to cope with stress. Cortisol levels exhibit a natural rise in the morning and fall at night. If this rhythm is disturbed, mineral balance, blood sugar control and stress responses are affected. Lack of cortisol can lead to fatigue, allergies and arthritis, while excess cortisol can have an even greater negative effect on the body. While short-term elevations of cortisol are important for dealing with the stress of life-threatening issues, illness and wound-healing, chronically elevated levels can result in tiredness, depression and accelerated ageing with hypertension, muscle loss, bone destruction, obesity and diabetes. Prolonged stress or prolonged exposure to glucocorticoids can also have adverse effects on the hippocampus to cause atrophy, and memory deficits such as have been demonstrated in Cushing syndrome, depression and post-traumatic stress disorder.

Dehydroepiandrosterone (DHEA), the most abundant steroid hormone in the body, appears to counter the effects of high levels of cortisol and improves the ability to cope with stress. Low levels of DHEA have been associated with impaired immunity, cardiovascular disease, Alzheimer disease, hypothyroidism and diabetes.

Anxious or stressed patients may require drugs to control the anxiety but they respond better to beta-blocking agents (such as propranolol) than to BZPs, and with less impairment of performance. Stress may lead to substance abuse (Ch. 34). Anxiety may be caused or aggravated by using caffeine or street drugs like amphetamines, LSD or ecstasy.

Stress in dental staff

Dentistry can be a stressful occupation for both the dentist and the ancillary staff. There appears to be a significant level of dissatisfaction amongst dental nurses and hygienists in general practice, in terms of working conditions, relations with other staff and management skills of the dentist.

Increasingly, dentists in general practice appear concerned about the business aspects of practice, and seem to experience more physical and mental ill-health compared with other health professionals. In contrast, community dentists may be more worried about clinical matters, such as treating medical emergencies or difficult patients.

POST-TRAUMATIC STRESS DISORDER (PTSD)

General aspects

Post-traumatic stress disorder is an anxiety state that can follow exposure to a terrifying event where victims can see danger, where life is threatened, or where they see other people dying or being injured. Traumatic events that can trigger PTSD include personal assaults, such as rape or mugging, disasters, accidents or military combat.

Many people with PTSD repeatedly re-experience the ordeal in the form of flashback episodes, memories, nightmares or frightening thoughts, or being 'on guard', especially when exposed to events or objects reminiscent of the trauma. Anniversaries of the event can also trigger symptoms. Most people with PTSD thus try to avoid any reminders or thoughts of the ordeal (avoidance and numbing).

Clinical features

Symptoms of PTSD typically begin within 3 months of the traumatic event but occasionally not until years later. Headaches, gastrointestinal complaints, dizziness, chest pain or discomfort elsewhere can be disabling. Emotional numbness and sleep disturbance, depression, anxiety, irritability, outbursts of anger and feelings of intense guilt are common.

Associated depression, alcohol or other substance abuse, or another anxiety disorder is also common.

General management

CBT, group therapy, eye movement desensitization and reprocessing (EMDR) and exposure therapy, in which patients gradually and repeatedly relive the frightening experiences under controlled conditions to help them work through the trauma, can be effective. Medications, particularly SSRIs, are frequently prescribed (TCAs are as effective),

and help to ease associated symptoms of depression and anxiety and to promote sleep.

Dental aspects

Frightening though dentistry may be, it is not known to have precipitated PTSD. However, patients who are suffering from PTSD may present with a variety of unexplained pain problems.

GENERALIZED ANXIETY DISORDER (GAD)

General aspects

Generalized anxiety disorder differs from normal anxiety in that it is chronic and fills the day with exaggerated and unfounded worry and tension. GAD is twice as common in women as in men.

Clinical features

People with GAD are always anticipating disaster, often worrying excessively about health, money, family or work; they may have physical symptoms, such as fatigue, headaches, muscle tension, muscle aches, difficulty in swallowing, trembling, twitching, irritability, sweating and hot flushes, and trouble falling or staying asleep. Unlike individuals with other anxiety disorders, people with GAD do not characteristically avoid certain situations. GAD is often accompanied by other conditions associated with stress, such as irritable bowel syndrome. GAD may be accompanied by another anxiety disorder, depression or substance abuse.

General management

Generalized anxiety disorder is diagnosed when someone spends at least 6 months worrying excessively about everyday problems. GAD is commonly treated with CBT and BZPs such as clonazepam or alprazolam. Venlafaxine, a drug closely related to the SSRIs, is also useful. Buspirone, an azapirone, is also used: it must be taken consistently for at least 2 weeks to achieve effect, and possible adverse-effects include dizziness, headaches and nausea.

PANIC DISORDER

General aspects

Panic disorder is the term given to recurrent unpredictable attacks of severe anxiety with physical symptoms such as palpitations, chest pain, dyspnoea, paraesthesiae and sweating ('panic attacks'). There are associations with mitral valve prolapse in 50%.

Clinical features

Panic attacks can come at any time, even during sleep. In a panic attack, there are features of catecholamine release – the heart pounds and the patient may feel sweaty, weak, faint or dizzy. The hands may tingle or feel numb, and there may be nausea, chest pain, a sense of unreality or fear of impending doom.

Many or most of the symptoms may result from hyperventilation. An attack generally peaks within 10 minutes but some symptoms may last much longer. Many individuals suffer intense anxiety between episodes, worrying when and where the next attack will strike.

Panic disorder is often accompanied by other conditions such as depression, drug abuse or alcoholism, and may lead to a pattern of avoidance of places or situations where panic attacks have struck.

General management

Panic disorder is one of the most readily treatable disorders and usually responds to psychotherapy or medication with alprazolam or lorazepam. Fluoxetine or another SSRI is frequently prescribed but TCAs are as effective. Hyperventilation is effectively treated by rebreathing into a paper bag.

SOCIAL PHOBIA (SOCIAL ANXIETY DISORDER)

General aspects

Social phobia involves overwhelming anxiety and excessive self-consciousness in normal social situations, resulting in a persistent, intense and chronic fear of being watched and judged by others and being embarrassed or humiliated by one's own actions. Women and men are equally likely to develop social phobia, usually beginning in childhood or early adolescence.

Clinical features

Accompanying physical symptoms may include blushing, profuse sweating, trembling, nausea and difficulty in talking. Anxiety disorders and depression are common and substance abuse may develop.

General management

Social phobia can usually be treated successfully with psychotherapy or medications. Beta-blockers, such as propranolol or clonazepam, are helpful. Fluoxetine or other SSRIs are frequently prescribed but TCAs are as effective.

SPECIFIC PHOBIAS (PHOBIC NEUROSES)

General aspects

A phobia is a morbid fear or anxiety out of all proportion to the threat, an intense irrational fear of something that poses little or no actual danger. Twice as common in women as in men, phobias usually appear first during childhood or adolescence and tend to persist into adulthood.

Clinical features

Phobic neuroses differ from anxiety neuroses in that the phobic anxiety arises only in specific circumstances, whereas patients with anxiety neuroses are *generally* anxious. Claustrophobia (fear of closed spaces) is probably the most common phobic disorder. Magnetic resonance imaging (MRI) is sometimes impossible to carry out because of claustrophobia.

Some of the other more common specific phobias are centred around heights, tunnels, driving, water, flying, insects, dogs and injuries involving blood. When phobias are centred on threats such as flying, anaesthetics or dental treatment, normal life is possible if such threats are avoided. Phobias may also be a minor part of a more severe disorder, such as depression, obsessive neurosis, anxiety state, personality disorder or schizophrenia.

General management

Specific phobias are highly treatable with carefully targeted psychotherapy. Behaviour therapy aims at desensitization by slow and gradual exposure to the frightening situation. Implosion is a technique in which

patients are asked to imagine a persistently frightening situation for 1 or 2 hours. Phobias can sometimes be controlled by anxiolytic drugs. Buspirone is particularly useful, since it lacks the psychomotor impairment, dependence and some other effects of BZP use. Antidepressants, especially TCAs, are used if there is a significant depressive component.

PERSONALITY DISORDERS

In mental health, the word ‘personality’ refers to the collection of characteristics or traits that makes each of us an individual, including the ways that we think, feel and behave.

Personality may develop in a way that makes it difficult for us to live with ourselves and/or other people – traits or disorders usually noticeable from childhood or early teens. Personality disorders are chronic abnormalities of character or maladjustment to life that shade into neuroses or psychoses and may make it difficult to make or keep relationships, get on with friends and family or with people at work, keep out of trouble or control feelings or behaviour. However, insight is retained and most patients manage to pursue a relatively normal life. Personality disorders are shown in Table 10.6.

Causes include upbringing (neglect, physical or sexual abuse, violence in the family, parents who drink too much alcohol), early problems (childhood severe aggression, disobedience and temper tantrums) or brain problems (these remain to be defined). Personality disorders may be aggravated by drugs or alcohol, interpersonal conflicts, financial problems or other mental health problems.

People with personality disorders are often made unhappy by poor relationships or frequent conflicts, and severe antisocial personality disorders can lead to criminal behaviour. Dangerous and severe personality disorders are the subject of a recent review of the Mental Health Act; these patients may be detained under the Act, regardless of the absence of treatable disease.

Handling patients with personality disorders requires enormous patience and tolerance, and the exercise of tact and skills. These skills only come with appreciation of the existence of these disorders and with experience, but are difficult to acquire. Even with such skills, little progress may still be possible. Antipsychotics or antidepressant or mood-stabilizing drug therapy may be helpful.

BORDERLINE PERSONALITY DISORDER (BPD)

General aspects

Borderline personality disorder is characterized by pervasive instability of mood, interpersonal relationships, self-image and behaviour. It frequently disrupts family and work, long-term planning and the individual's sense of self-identity. BPD affects 2% of adults, mostly young women.

Brain imaging studies in BPD show that individual differences in the ability to activate regions of the prefrontal cerebral cortex thought to be involved in inhibitory activity predict the ability to suppress negative emotion.

Clinical features

A person with BPD may experience intense bouts of anger, depression and anxiety that may last only hours, or at most a day, while a person with depression or bipolar disorder (see below) typically endures the same types of mood for weeks. Bouts of BPD may be associated with episodes of impulsive aggression, self-injury, and drug or alcohol

Table 10.6 *Types of personality disorder*

Personality disorder	Features
Cluster A	Paranoid
Paranoid	Suspicious, distrustful, litigious, lacking humour, blaming others Feeling that other people are being unpleasant (even when evidence shows this is false), sensitive to rejection, tending to hold grudges
Schizoid	Socially distant, detached, secretive, isolated, lacking friends Emotionally ‘cold’, disliking contact with other people, preferring own company; having a rich fantasy world
Schizotypal	Odd, eccentric, having difficulties with thinking, lacking emotion or appropriate emotional reactions, seeing or hearing strange things, related to schizophrenia
Cluster B	Emotional and impulsive
Antisocial or dissocial	Impulsive, aggressive, manipulative, selfish, callous, disloyal, in conflict with everyone and everything, not caring about the feelings of others, easily frustrated Tending to be aggressive, committing crimes, finding it difficult to make intimate relationships, not feeling guilty or learning from unpleasant experiences
Borderline	Impulsive, self-destructive, unstable, finding it hard to control emotions Feeling bad about self, often self-harming, feeling ‘empty’, making relationships quickly but easily losing them, possibly feeling paranoid or depressed When stressed, possibly hearing noises or voices
Histrionic	Emotional, dramatic, theatrical, immature, manipulative, attention-seeking, having shallow interpersonal relationships, over-dramatizing events, self-centred Showing strong emotions that change quickly and do not last long Can be suggestible, worrying a lot about appearance, craving new things and excitement, can be seductive
Narcissistic	Boastful, egotistical, ‘superiority complex’, strong sense of own self-importance Dreaming of unlimited success, power and intellectual brilliance, craving attention but showing few warm feelings in return, exploiting others, asking for favours but not returning them
Cluster C	Anxious
Avoidant	Shy, timid, ‘inferiority complex’, very anxious and tense, worrying a lot Feeling insecure and inferior, having to be liked and accepted Extremely sensitive to criticism
Dependent	Dependent, submissive, clinging, passive, relying on others to make decisions for them, finding it hard to cope with daily chores, feeling hopeless and incompetent Easily feeling abandoned by others
Obsessive–compulsive (anankastic)	Perfectionist, rigid, controlling, chronically worried about standards and self-image; unable to relax, often depressed Cautious, preoccupied with detail, worrying about doing the wrong thing, finding it hard to adapt; often having high moral standards Judgmental; sensitive to criticism; possibly having obsessional thoughts and images (although not as bad as in obsessive–compulsive disorder)

abuse. People with BPD may exhibit other impulsive behaviours, such as excessive spending, binge eating or risky sex. Distortions in cognition and sense of self can lead to frequent changes in long-term goals, career plans, jobs, friendships, gender identity and values.

BPD is often associated with other psychiatric problems, particularly bipolar disorder, depression, anxiety disorders, substance abuse and other personality disorders. Thus BPD often causes highly unstable patterns of social relationships.

General management

Dialectical behaviour therapy, developed specifically to treat BPD, involves four primary modes of treatment: individual therapy, group skills training, telephone contact and therapist consultation. Antidepressants and antipsychotic drugs may also be used.

Dental aspects

Persons with personality disorders may make unreliable patients. They are unlikely to have any conscience about missing appointments or to pay much attention to oral health-care instructions. Treatment plans may be argued about or frankly refused. Payment may be withheld and litigation threatened.

Dental staff may also have personality disorders and find themselves in conflict with others, including colleagues – often to the dental staff's disadvantage, and may find it difficult not to antagonize patients and colleagues.

OBSESSIVE–COMPULSIVE DISORDER (OCD)

General aspects

Obsessional personality traits are common, especially amongst dental and medical personnel, and are often salutary. Many healthy people have features of obsessive–compulsive disorder with secondary ritualistic behaviours, such as checking that the door is locked several times before or after leaving the house. In true OCD, the urge to do or think certain things repeatedly can dominate life unhelpfully, with obsessive activities consuming at least 14 hours a day and causing significant disruption of normal life. For example, one dental surgeon felt compelled to telephone his patients late at night because he was obsessed with the notion that, having prepared the cavity, he might have forgotten to place the restoration. The basal ganglia and striatum appear to be involved in OCD. OCD strikes males slightly more commonly and usually starts in childhood, adolescence or early adulthood.

OCD is the fourth most common mental disorder, affecting 1–2% of the population, and it appears to be increasing.

Clinical features

OCD is comprised of thoughts (obsessions) that create anxiety, and things the patient does to reduce the anxiety (compulsions). Obsessional patients are often intelligent, many are unmarried and many have a pre-morbid state, such as an uncertain and vacillating – or alternatively, a stubborn, rigid, morose and irritable – personality. Obsessional thoughts are those that come repeatedly into consciousness against the patient's will; they are usually unpleasant but always recognized as the patient's own thoughts. Typical obsessions are the repeated checking, questioning of decisions, hoarding, counting, religious compulsions, the fear of harm or harming, or the fear of dirtiness or contamination. This may manifest with repeated hand-washing, for example (Fig. 10.3).

Fig. 10.3 Effects of repeated hand-washing in obsessive–compulsive disorder.

However, the thoughts are not accepted by the patient as harmless or inevitable, and an internal struggle against them leads to secondary ritualistic thought or behaviour patterns (compulsions). The compulsions may include rituals, checking, avoidance, hoarding and reassurance. A prominent example was the millionaire Howard Hughes, who was so severely affected that he eventually ended up sitting naked in the middle of his hotel room, obsessed with concerns about 'contamination' and with six aides 'cleaning' him.

The obsessional thoughts may also in turn generate depression or other anxiety disorders, and some people with OCD also have eating disorders. Obsessional features can also be associated with disorders such as depression, schizophrenia or, rarely, organic brain disease.

The course of OCD is variable. Symptoms may come and go, may ease over time or can grow progressively worse.

General management

Treatment is often difficult, though OCD may respond to psychotherapy or to medication with antidepressants, especially SSRIs, clomipramine and the TCAs, which are useful when there is also depression. The BZPs may be useful when anxiety is predominant.

Dental aspects

It is questionable whether true obsessions often become centred on the mouth but they may, for example, result in compulsive tooth-brushing or excessive use of antiseptic mouthwashes. Occasional patients become obsessed with the possibility of infections or cancer in the mouth (as, for example, one man who was obsessed with the idea that his Fordyce spots were thrush) and refuse to be reassured. Some individuals become obsessed with the notion that they have oral malodour.

CHILDHOOD DISORDERS

These include attention-deficit/hyperactivity disorder, conduct disorder (the antisocial personality disorder of childhood) and oppositional defiant disorder (not only in children).

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER (ADHD)

This is a disorder that interferes with the ability to persist in a task and to exercise age-appropriate inhibition. ADHD is usually diagnosed in childhood, but the condition can continue into the adult years. It manifests with a failure to listen to instructions, inability to organize oneself, fidgeting with hands and feet, talking too much, leaving projects and work unfinished, and having trouble paying attention to and responding to details.

ADHD types include:

- a predominantly inattentive subtype
- a predominantly hyperactive–impulsive subtype
- a combined subtype.

General aspects

Mischievous children are not abnormal. Overactivity or hyperactivity applies to gross misbehavior, such as reckless escapes from parents while on public transport. Hyperactive children always seem to be in motion and seem unable to curb their immediate reactions or think before they act. Although parents not infrequently describe their badly behaved child as ‘overactive’, the term should be limited to those who demonstrate gross behavioural abnormalities, including uncontrolled activity, impulsiveness, impaired concentration, motor restlessness and extreme fidgeting. These activities are seen particularly when orderliness is required – for example, in the dental waiting room or surgery. Deficit in attention and motor control and perception may be a variant.

Once called *hyperkinesis* or *minimal brain dysfunction*, ADHD is characterized by inattention and hyperactivity and/or impulsivity, which are excessive, long-term and pervasive. It is one of the most common of childhood mental disorders, affecting 3–5% of children; it is twice as common in boys as in girls and often continues into adolescence and adulthood.

Commonly associated disorders may include:

- oppositional defiant disorders – these affect nearly half of all children with ADHD, who overreact or lash out when they resent anything
- developmental language disorders
- motor and coordination difficulties
- specific learning disabilities
- Tourette syndrome.

Overactivity can be caused by minor head injuries, undetectable brain damage or refined sugar and food additives. It is also caused by factors affecting the parents, the child or the child–parent relationship, or by external factors (Table 10.7).

Table 10.7 Causes of hyperactivity in a child

Child	Parental	External
Hyperkinetic syndrome	Child–parent relationship	Institutionalization
Brain damage	Rejection or overprotection	Excessive demands at school
Low intelligence	Inconsistent discipline	
Tartrazine sensitivity	Lack of parental love	
Anxiety states	Marital disharmony	
Drug abuse	Depression	

Clinical features

To make a diagnosis of ADHD, the abnormal behaviours listed above must be severe, appear before the age of 7 years, and continue for at least 6 months. Signs of inattention include becoming easily distracted by irrelevant sights and sounds, failing to pay attention to details and making careless mistakes, rarely following instructions carefully and completely, or losing or forgetting things such as toys, pencils, books and tools needed for a task.

Signs of hyperactivity and impulsivity include feeling restless, often fidgeting with hands or feet, squirming, running, climbing or leaving a seat, in situations where sitting or quiet behaviour is expected, blurting out answers before hearing the whole question, and having difficulty waiting in a queue or for a turn.

General management

Behavioural therapy, emotional counselling and practical support, including structured classroom management and tutoring, are required for the child, along with parent education. Sedatives and tranquillizers should be avoided, as they may impair learning ability or cause paradoxical reactions – such as aggressive behaviour. Stimulants surprisingly seem to be the most effective treatment in both children and adults, and treatment may include methylphenidate (Ritalin), atomoxetine and dexamfetamine (dextroamphetamine; Dexedrine); in the USA, Adderall – a ‘cocktail’ of four different amphetamine salts – is also available. The non-stimulant antihypertensive agent guanfacine may also have a role.

Dental aspects

- Overactive children can often be almost impossible to manage in the dental surgery and frequently succeed in frustrating all concerned.
- ‘Tell–show–do’ may be of value.
- Tranquillizers such as diazepam should be avoided, as they usually exacerbate rather than depress overactivity.
- Dental treatment may not be possible without conscious sedation (CS) or general anaesthesia (GA). Such patients are, therefore, often referred to hospital for dental care. The drug treatment may create resistance to CS. Local anaesthesia (LA) containing adrenaline (epinephrine) may interact with atomoxetine to increase blood pressure.

SOMATIZATION DISORDERS

General aspects

Many people suffer inner anxieties and some are prone to turn these into symptoms; these individuals are termed ‘somatizers’. They typically develop inappropriate health-seeking behaviours, with multiple consultations and investigations, and use of many conventional and alternative therapies, and may accumulate huge medical records (‘fat folder syndrome’). *Somatic disorders* are those that are thought to be initiated or aggravated by psychological factors and that persist for over 2 years. Typical examples are unexplained breathlessness, chest pain, fatigue, dizziness, paraesthesiae or chronic facial pain. Allergies, migraine, anorexia nervosa, psychogenic vomiting and, sometimes, obesity may also have a psychogenic basis. In addition, psychological factors may contribute to factitious injuries.

Psoriasis from head to inbetween toes
 Perpetual scream in left ear
 Spasmodic pressure above left ear
 Constant ulcers in mouth and on tongue
 Asthma, bronchitis, severe bouts of indigestion
 Sore mouth due to grinding of bottom right molar
 Severe pain under crutch after any exertion
 Constant irritation around back passage
 Spasmodic bleeding piles

Medicines taken internally
 Prednisolone
 Ventolin
 Asilone suspension
 Bronchipax

Fig. 10.4 Note as presented by a patient. Such histories vary in length, detail and imagination, and sometimes suggest that the patient is disturbed (*maladie du petit papier*).

Features that may suggest that symptoms are related to somatization, but not necessarily depressive, may include any of the following:

- *Absence of organic cause or physical signs.* The affected area typically appears normal and if, for example, a putatively diseased tooth is extracted, symptoms are unaffected. The symptoms cause real enough suffering to the patient and this must be acknowledged while emotional factors are explored.
- *Persistence of symptoms for very long periods, sometimes for years.* Clearly, after such periods any organic cause would have become apparent.
- *Bizarre symptoms.* The may include 'drawing' or 'gripping' sensations or apparently exaggerated 'unbearable' pain in spite of normal physical health or often sleep.
- *Vague localization of symptoms.* The distribution of pain, for example, may not follow an anatomical pattern, and the patient may be unable to put a finger precisely upon the painful area.
- *Unrecognizable stimuli.* Symptoms are usually not provoked by recognizable stimuli such as hot or cold foods, or mastication.
- *Multiple physical disorders.* Patients may have several chronic physical complaints at the same time.

In contrast to patients with severe organic disease, who typically reach for medication, many patients with chronic pain make little attempt to seek relief from them. After a brief trial, drugs are frequently said to be totally ineffective.

Patients' personality and manner are highly variable. Some appear obviously neurotic but few are overtly depressed. Indeed, the organic symptoms can be regarded as more acceptable substitutes ('depressive equivalents') for more typical manifestations of depression. These varied clinical pictures are discussed more fully below.

Sometimes the patients bring notes (Fig. 10.4) or drawings (Fig. 10.5) to illustrate their problems. These may reflect genuine disease, or may indicate the emotional nature of the complaint(s) (*la maladie du petit papier*). However, increasingly, informed patients who have no mental health problems bring notes or computer print-outs to consultations.

In some patients, the response to antidepressant drugs is dramatic, with relief of symptoms and striking general improvement in mood, sometimes before the drug has had time to produce a true antidepressant effect. However, effective dosage varies widely and, in the case of TCAs, the response is generally related to the plasma levels achieved. Thus doses may sometimes have to be very high before an effect is evident.

Fig. 10.5 Drawing produced by a patient.

Many patients go from specialist to specialist (doctor-shopping) over the course of years, with negative results from innumerable investigations or no response to any form of treatment. Indeed, the patient persistently refuses to accept advice or reassurance, and may even seem to take a sort of perverse pride in the resistance of the pain to the challenge of medical science.

Conflict between patient and carer is not uncommon, and patients may believe they are not receiving proper care.

Chronic physical symptoms can generally be regarded as a plea for help or attention. This occasionally becomes distressingly apparent in a patient who, at the start, appears well-balanced and self-controlled – even occasionally joking about symptoms – but after a little while is crying uncontrollably. At the other extreme, many patients reject the possibility of mental illness and aggressively assert that 'It's not my nerves' (even if no such suggestion has been made) and typically also reject the idea of psychiatric help, however obliquely and sympathetically suggested.

Examples of these varied clinical pictures therefore include the following:

- The patient may be overtly depressed and cries readily or is obviously having difficulty in restraining tears. Alternatively, initial self-control is followed by unrestrained crying.
- The patient may complain (in effect) of depression by saying that the pain or other symptom makes them miserable.
- Some, when allowed to discuss their symptoms, relate them to 'stress' or trouble with the family or at work.
- A few are already taking, or have taken, antidepressant drugs but the symptoms have not been controlled.
- A few have associated bizarre (delusional) symptoms, such as 'powder' or 'slime' coming out of the painful area, as mentioned earlier.
- A few, given the chance of a sympathetic hearing, gratefully expand on their problems and welcome the suggestion of help.

- The most difficult and relatively common group is the ‘rejectors’, who will not accept the idea of mental disturbance, refuse to have the possibility investigated and are unwilling to accept that any drugs (which they equate with drugs of dependence) may be helpful.

It should not need to be emphasized that, where psychological problems are suspected, discussion with the patient must be conducted patiently, gently and sympathetically. Surprisingly, this may perhaps be the first opportunity that patients have had to unburden themselves. Listening, tolerance, empathy and compassion are required. Unfortunately, some doctors are at least as intolerant of such ‘neurotic’ patients as some members of the public. This is not to suggest that the dentist should attempt to be an amateur psychiatrist but an effort must be made to understand the nature of the symptoms. It is probably unnecessary to enquire into full details of family relationships or broken homes. If a patient is depressed, the cause is often as much the patient’s susceptibility to depression as the so-called life situation. In any case, improvement in the life situation is unlikely to be feasible, and it is only too common for those so affected to be unable to overcome their difficulties without help from drugs or other sources. It is important to stress to the patient that we now understand that damage to the periphery, perhaps from unnecessary dental treatment, causes wind-up and central sensitization so that the brain becomes hypervigilant. Such an explanation allows both doctor and patient to understand how the pain changes and moves around; the problem is not some localized pathology but a disorder of pain signalling requiring both pharmacological and cognitive help.

The key feature is the fact that the presenting complaint cannot be explained by any known medical condition and there appears to be unconscious/involuntary symptom production; these are sometimes termed medically unexplained symptoms (MUS).

Careful investigation is therefore essential to exclude possible organic causes; however, the dentist must be careful not to over-investigate the patient, as this has been shown to make problems more difficult to treat. It is important to achieve a shared understanding and management plan. Try diaries to record the problems; avoid manipulation by the patient; and minimize involvement of other health-care professionals (‘doctor-shopping’).

The concurrence of emotional and physical disease is one of the most common problems in medicine that require a mature clinical understanding.

Types of disorder previously termed ‘psychosomatic’ include those shown in [Box 10.2](#).

SOMATIZATION DISORDER

This consists of complaints of multiple unexplained symptoms, which rarely remit completely but are presented in colourful, exaggerated terms.

Box 10.2 Types of somatization disorder

- Somatization disorder
- Hypochondriasis
- Conversion disorder
- Somatoform pain disorder
- Body dysmorphic syndrome
- Malingering
- Factitious disorders
- Hysterical states

Patients are rarely men but rather are inconsistent historians with depressed mood and anxiety symptoms. Diagnostic criteria include:

- four pain symptoms, *plus*
- two gastrointestinal symptoms, *plus*
- one sexual/reproductive symptom, *plus*
- one pseudoneurological symptom
- if within a medical condition, excessive symptoms
- absence of laboratory abnormalities
- symptoms that cannot be intentionally feigned or produced.

HYPOCHONDRIASIS

Health anxiety (hypochondriasis) is obsessive worrying about health, often to the point where it causes great distress and affects the ability to function properly. Some people with health anxiety have unexplained physical symptoms, e.g. chest pain, abdominal pain, facial pain or headaches, which they assume are a sign of disease despite reassurance. Hypochondriasis neurosis (health anxiety) is a morbid preoccupation with physical symptoms or bodily functions, in which minute details are related incessantly; there is excessive preoccupation with fear of disease or a strong belief in having disease due to false interpretation of a trivial symptom. The condition may be graphically described as ‘illness as a way of life’. Minor degrees of hypochondriasis are common, especially among older people, particularly (and quite understandably) if they are living alone. Features include:

- presentation of the medical history in excessive detail
- absence of organic disease or physiological disturbance
- unwarranted fears or ideas persisting despite reassurances
- clinically significant distress
- complaints not restricted to appearance or delusional intensity
- negative physical examination and laboratory results.

General management

Organic disease should always be excluded, as should depression and schizophrenia. Most patients with hypochondriasis are depressed and some are deluded.

Reassurance, CBT and supportive care are then needed, and anti-depressant drugs may be helpful. Unnecessary interventions must also be avoided.

Dental aspects

The common oral symptoms are dry or burning mouth, disturbed taste and oral or facial pain.

Other syndromes related to dentistry include the so-called but unproven chronic candidosis (‘candidiasis’) syndromes and mercury allergy syndrome.

CONVERSION DISORDER (‘HYSTERIA’)

In conversion disorder, the patient complains of isolated symptoms that appear to be motivated by the desire to achieve a gain of some sort and have no physical cause (e.g. blindness, deafness, stocking anaesthesia and features that do not conform to known anatomical pathways or physiological mechanisms).

Diagnostic criteria include:

- symptoms preceded by stress
- no neurological, medical, substance abuse or cultural explanation
- severe distress
- absent or insufficient significant laboratory findings.

Nevertheless, in 10–50% of these patients, a physical disease process will ultimately become apparent.

SOMATIZATION PAIN DISORDER (BRIQUET SYNDROME)

Somatization disorder is characterized by physical symptoms that mimic disease or injury, for which there is no identifiable physical cause, but that are not the result of conscious malingering or factitious disorders (Ch. 13).

BODY DYSMORPHIC DISORDER (BDD; DYSMORPHOPHOBIA)

In BDD, the affected person is excessively concerned and preoccupied by a perceived defect in their physical features, causing psychological distress that impairs occupational and/or social functioning, sometimes to the point of depression, anxiety or social withdrawal. BDD affects men and women equally, with the onset of symptoms generally in adolescence or early adulthood. BDD is characterized by an unusually exaggerated degree of worry or concern about a specific part of the face or body, rather than the general size or shape of the body. The most common area of focus is the face (size, shape or lack of symmetry).

BDD is distinguished from anorexia nervosa and bulimia nervosa, as those patients are generally preoccupied with their overall weight and body shape. About 50% of patients with BDD, however, also meet the criteria for a delusional disorder, which is characterized by beliefs that are not based in reality. The defect in BDD exists only in the eyes of the beholder, and others can rarely agree that anything is defective. Thus the patient may adopt compulsive behaviour, which can include:

- compulsive checking in mirrors, windows and other reflective surfaces
- attempts to camouflage the imagined defect
- excessive grooming
- compulsive skin-touching
- reassurance-seeking
- compulsive information-seeking
- obsession with cosmetic procedures, such as orthognathic or plastic surgery, with few satisfactory results for the patient; with the number of elective cosmetic dentistry procedures being performed, the dentists may be the first health-care provider to notice BDD.

Patients with BDD may well be unrealistically dissatisfied with results of treatments and procedures, or unable to verbalize expectations. BDD has a high rate of comorbidity, most commonly with major depression, social phobia or OCD. BDD patients can also be self-destructive, and may even perform surgery on themselves (e.g. sawing down teeth or removing facial scars with sandpaper) and attempt or complete suicide. There is a completed suicide rate double that of major depression and so BDD is a major risk factor for suicide. CBT and SSRIs are indicated.

MALINGERING

Malingering is the deliberate simulation or exaggeration of symptoms for obvious and understandable gain. The gain can be monetary (e.g. compensation or incapacity benefit), or to avoid work or other unpleasant tasks (e.g. service in the armed forces) or criminal prosecution. True malingering is rare. Diagnosis can be difficult but a key is whether the symptoms persist when the patients believe they are not being watched.

Fig. 10.6 Self-induced burns from cigarettes as an attention-seeking device.

Fig. 10.7 Self-harm.

FACTITIOUS INJURIES

Factitious (self-induced) disorders are distinguished from somatoform disorders by the voluntary production of symptoms, and distinguished from malingering by the lack of external incentive. Physical or psychological symptoms are intentionally produced to assume a sick role. They are more common in men than women, and seen most frequently in health-care professionals (HCPs), who intentionally produce signs of medical and/or mental disorders.

Serious and deliberate self-inflicted lesions in the mouth are considerably less common than on the skin. This may be due to an underlying need or desire for attention, and oral lesions are insufficiently obvious.

Factitious disorders are not uncommon in depressed patients and in those with schizophrenia and learning disability. Examples include self-induced cigarette burns (Fig. 10.6) or cuts (Fig. 10.7). Rare causes of self-injury also include any cause of sensory loss or pain insensitivity, such as the Riley–Day syndrome, Lesch–Nyhan syndrome (Ch. 23) and Gilles de la Tourette syndrome – multiple tics and coprolalia (involuntary uttering of obscenities).

Clinical features

Minor, subconsciously self-induced oral lesions are common, the classic examples being bruxism and cheek-biting (*morsicatio buccarum*) and exfoliative cheilitis (*‘tic de lèvres’*; Fig. 10.8). Other lesions may be accidentally self-inflicted when the oral mucosa is anaesthetized, after a local anaesthetic, surgery or damage to the trigeminal nerve.

The most commonly reported type of self-inflicted oral injury has been so-called self-extraction of teeth. Soft-tissue lesions can also be produced, typically by picking at the gingivae with the fingernails. In

Fig. 10.8 Exfoliative cheilitis.

adults, injuries may be produced by use of the pointed end of a nail file, often also at the gingival margins.

Other types of injury include the application of caustic substances to the lips or injuries from attempts at suicide.

General management

Self-inflicted lesions should be suspected when they do not correspond with those of any recognized disease; are of bizarre configuration with sharp outlines; are found in an otherwise healthy patient; are in sites accessible only to the patient; or if the patient shows signs that suggest emotional disturbance, is under stress, is known to be under psychiatric treatment, or has a learning impairment.

Few patients will admit to injuring themselves. More frequently, the diagnosis can be confirmed only by discreet observation after admission of the patient to hospital. However, even when seen to cause the injuries, the patient may still deny having made them. Once the diagnosis has been made, the family doctor or specialist psychiatrist should see the patient.

HYSTERICAL STATES

Hysterical personality disorders, neuroses and acute psychoses are recognized.

Hysterical neuroses

Hysterical neuroses mainly affect females – sometimes those working in medical or paramedical occupations – as conversion neurosis or as a dissociative state. Hysterical conversion neurosis is characterized by physical complaints that have no demonstrable organic basis, such as pain, anaesthesia, dysphagia, fainting, fits, paralysis or tremor, but frequently result in patients submitting to repeated operations; there may, as a result, be multiple scars (see ‘Munchausen syndrome’). Dissociative states are characterized by disturbances of consciousness or identity (but no physical symptoms) in the absence of demonstrable organic disease. Amnesia, states of fugue (when the patient wanders aimlessly away), or (rarely) multiple personalities are examples.

It is often difficult to establish that the patient is gaining something by the illness, although in compensation neurosis the nature of the potential gain is easily recognized.

Dental aspects

Patients who aggressively insist on their symptoms and demand surgery for undetectable lesions are fortunately rare.

Munchausen syndrome

Munchausen syndrome is a disorder in which patients go to considerable length to fabricate histories and simulate symptoms without an external incentive (compare malingering) but apparently for the sake of undergoing operations. This may be done repeatedly, even occasionally by assuming false names and travelling to many hospitals scattered about the country. Patients are often intelligent and resourceful. Common complaints are of acute abdominal pain; fever; haematuria; or infected wounds. Ultimately, the patient may become extensively scarred and develop complications from the repeated operations.

Munchausen syndrome-by-proxy is the term given to a parent or other carer who invents symptoms in, and demands unnecessary medical or surgical treatment for, a child.

Treatment is difficult and often fails; the main aims should be to avoid unnecessary drug use (especially opiates) and surgery.

Compensation neurosis

Compensation neurosis usually follows an accident (especially a head injury) or operation, and is characterized by paralysis, chronic pain (often headache) or other symptoms of obscure origin and of no obvious organic cause. Men and women are equally susceptible, there is no previous history, and the lack of insight is less convincing than in hysteria.

Settlement of the claim for compensation typically results in rapid disappearance of the symptoms.

SELF-HARM

Self-harm (SH) or deliberate self-harm (DSH) includes self-injury (SI) and self-poisoning, and is defined as the intentional, direct injuring of body tissue. Discrete from most body art such as piercings/tattoos, SH is most common in adolescence and young adulthood, usually first appearing between the ages of 12 and 24.

The most common form of SH is skin-cutting but there is a wide range of behaviours including, but not limited to, burning, scratching, banging or hitting body parts, interfering with wound healing, hair-pulling (trichotillomania) and ingestion of objects (pica) or toxic substances. It is not intended to be suicidal but that might result.

Connotations include:

- neurotic – nail-biting, picking, extreme hair removal and unnecessary cosmetic surgery
- religious – self-flagellation and other forms
- cultural – such as the Shi’ite ritual of self-flagellation, Mayan self-cutting/piercing
- psychotic – eye or ear removal, genital self-mutilation, autocastration and extreme amputation
- organic brain diseases – repetitive head-banging, hand-biting, finger-fracturing or eye removal.

SH is classed as a borderline personality disturbance or a coping mechanism which provides temporary relief of intense feelings such as anxiety, depression, stress, emotional numbness or a sense of failure. Munchausen syndrome, war avoidance behaviour and attention-seeking may be involved. DSH is especially prevalent in prison populations.

SH may also feature in:

- genetic disorders: e.g. Lesch–Nyhan syndrome
- mental issues: bipolar disorder, schizophrenia, depression
- substance abuse or withdrawal.

Box 10.3 Some possible behavioural reactions to organic disease

- Denial
- Anger
- Frustration
- Aggression
- Anxiety
- Fear
- Withdrawal
- Apathy
- Dependency
- Depression

Care plans should be multidisciplinary and developed collaboratively with the person who self-harms and, provided the person agrees, with their family, carers or significant others. Psychological, pharmacological and psychosocial interventions may be needed (see <http://www.nice.org.uk/newsroom/pressreleases/LongerTermManagementOfSelfHarmGuidance.jsp>).

PSYCHIATRIC DISORDERS

Psychiatric disorders are common; perhaps one-third of the population suffer at some time during their life. These disorders are often under-diagnosed, and what may appear simply to be unusual behaviour may actually be a manifestation. Psychiatric illnesses cause significant incapacity but, equally, organic illness can cause major behavioural changes and sometimes precipitate psychiatric disease (Box 10.3). Mental disorders underlie many complaints and extend the recovery time from many others.

Mental disorders frequently coexist with diverse other illnesses. Depression, for example, may be associated with a high prevalence (around 65%) of common chronic medical conditions, such as hypertension, coronary artery disease, diabetes, arthritis and chronic lung disorders. About 15% of people with a mental disorder also indulge in substance abuse.

Diagnostic criteria for the most common mental disorders are outlined in DSM-IV (American Psychiatric Association, 1994; revised 2000; Table 10.8 and Box 10.4). The most significant psychiatric disorders are shown in Table 10.9.

Dental aspects

Mental disorders can significantly influence oral health care, not least because of behavioural disorders or interpersonal difficulties. Patients with mental disease may be unable to cooperate. Drug misuse may explain abnormal behaviour in some patients:

- Compliance with appointments or treatment is often poor.
- There may be difficulties in gaining informed consent to treatment.
- There may also be oral neglect with a high prevalence of caries and periodontal disease, difficulties coping with dental prostheses, and self-induced lesions or other oral symptoms caused by the psychiatric illness or its treatment.
- Some of the more severely ill or neglected patients with mental disorders are at high risk from diseases of deprivation and lifestyle, such as tuberculosis.
- Drugs such as antidepressants, phenothiazines, lithium or barbiturates can cause xerostomia or other orofacial disorders, or otherwise influence dental care.

Table 10.8 Classification of psychosocial health

Axis	Description
I	Clinical disorders (see Box 10.4)
II	Personality disorders
III	General medical conditions
IV	Psychosocial and environmental problems
V	Global assessment of functioning

Box 10.4 Axis I

- Disorders first diagnosed in infancy
- Delirium, dementia, and amnesic and other cognitive disorders
- Mental disorders caused by a general medical condition
- Substance-related disorders
- Schizophrenia and other psychotic disorders
- Mood disorders
- Anxiety disorders
- Somatoform disorders
- Factitious disorders
- Dissociative disorders
- Sexual and gender identity disorders
- Eating disorders
- Sleep disorders
- Psychological factors affecting medical conditions
- Impulse control disorders not classified elsewhere
- Adjustment disorders
- Other conditions that may be the focus of medical attention

Table 10.9 The most common mental disorders

Condition	Anxiety disorders	Depression	Schizophrenia
Prevalence (approximate)	1 in 10 people	1 in 10 people	1 in 100 people

MOOD DISORDERS

Depression

General aspects

Depression is more than just a 'bad day'; diagnostic criteria established by the APA dictate that five or more symptoms must be present for a continuous period of at least 2 weeks. Depression is characterized by depressed or sad mood, diminished interest in activities that used to be pleasurable, weight gain or loss, psychomotor agitation or retardation, fatigue, inappropriate guilt and difficulties concentrating, as well as recurrent thoughts of death.

Major depression frequently goes unrecognized and untreated, and may foster tragic consequences, such as suicide and impaired interpersonal relationships at work and at home. The use of medications and/or specific psychotherapeutic techniques has proven effective in the treatment of major depression.

Dysthymia, a depressive disorder characterized by low-grade mood impairment of at least 2 years that commonly has an initial presentation in childhood or young adulthood, has been likened to a less severe major depression, but one more likely to assume a chronic course.

Depression is a common emotion which all of us experience at some time. It becomes a disorder of emotion when it is characterized by a

persistent lowering of mood and negative patterns of thinking, and may impact significantly on an individual's quality of life. Depression is also often a feature of a medical problem but is sometimes so severe and enduring that it becomes an illness in itself.

Depression as an illness, involves mood and thoughts, and affects the way persons eat and sleep, feel about themselves and think about things. Although depression alone may be seen (unipolar disorder), about 1 in 10 people who suffer from serious depression will also have periods when they are too happy and overactive (bipolar disorder – which used to be called manic depression).

The lifetime risk for depression is approximately 10%, with rates being doubled in women; hormonal factors may contribute, particularly menstrual cycle changes, pregnancy, miscarriage, the postpartum period, pre-menopause and the menopause. Depression may be genetic and can often run in families; onset may be at any stage from childhood onwards. Episodes can be triggered by adverse life events, such as a serious loss, difficult relationships, financial problems or any stressful (unwelcome or even desired) change in life patterns.

Some cases are precipitated by serious medical illnesses such as stroke, heart attack, cancer, Parkinson disease, hormonal disorders, or illnesses that are long and uncomfortable or painful, such as arthritis or bronchitis. Some people become depressed after viral infections like influenza or glandular fever.

The main effects of depression appear to relate to changes in hypothalamic centres that govern food intake, libido and circadian rhythms; various hormones, particularly serotonin, dopamine and noradrenaline (norepinephrine), are implicated and hypercortisolism is common. Antidepressants increase concentrations of these chemicals at brain nerve endings and so seem to boost the function of those parts of the brain that use serotonin and noradrenaline.

The danger in depression is of suicide; death from suicide in men is four times that of women, though more women attempt it.

In addition to being a chronic disease in its own right, depression appears to be associated with behaviours linked to other chronic diseases:

- *Smoking.* Depression is a risk factor for smoking, with nicotine stimulating receptors in the brain that may improve mood in certain types of depression; furthermore, depression may impede smoking cessation efforts.
- *Alcohol consumption.* Early onset of drinking is associated with a range of problematic outcomes, including depressive symptoms.
- *Physical inactivity.* Physical inactivity and obesity are modifiable risk factors for depression.
- *Sleep disturbance.* Depression appears to be associated with poor sleep.

Clinical features

Features of major depression (Box 10.5) include: a persistently sad, anxious or 'empty' mood; feelings of hopelessness and pessimism; of guilt, worthlessness and helplessness; loss of interest or pleasure in hobbies and activities that were once enjoyed, including sex; lack of energy, fatigue and a feeling of being 'slowed down'; difficulty concentrating, remembering, and making decisions; insomnia, early-morning awakening or oversleeping; appetite and/or weight loss, or overeating/weight gain; and restlessness and irritability. A depressive episode is diagnosed if five or more of the following symptoms last most of the day, nearly every day, for a period of 2 weeks or longer:

- feeling unhappy most of the time (but may feel a little better in the evenings)
- loss of interest in life and inability to enjoy anything

Box 10.5 Features of depression

- Sadness
- Hopelessness
- Pessimism
- Lack of pleasure
- Irritability
- Fatigue
- Sleep disturbance
- Loss of libido and appetite

- finding it harder to make decisions
- inability to cope with things that the patient used to be able to deal with
- feeling utterly tired
- feeling restless and agitated
- loss of appetite and weight (some people find they do the reverse and put on weight)
- taking 1–2 hours to get off to sleep, and then waking up earlier than usual
- loss of interest in sex
- loss of self-confidence
- feeling useless, inadequate and hopeless
- avoidance of other people
- feeling irritable
- feeling worse at a particular time each day, usually in the morning
- thoughts of suicide.

Patients may exhibit: lack of energy, fatigue, reduced concentration, insomnia, early-morning awakening, oversleeping, loss of appetite and weight loss or gain. Depression may also manifest as chronic pain; 50% of patients who are depressed have pain as their presenting complaint. Chronic pain or other persistent bodily symptoms that are not caused by physical illness or injury are common.

Men are less likely to admit to depression and doctors are less likely to suspect it. It is often masked in men by manifesting, not as feeling hopeless and helpless, but as being irritable, angry and discouraged. Alternatively, depression may be suppressed by alcohol or drugs, or by the socially acceptable habit of working excessively long hours.

There may be thoughts of death or suicide, and suicide attempts. Warning signs include: talking about feeling suicidal or wanting to die; feeling hopeless, that nothing will ever change or get better; feeling helpless, that nothing the patient does makes any difference; feeling a burden to family and friends; abusing alcohol or drugs; putting affairs in order (e.g. organizing finances or giving away possessions to prepare for death); writing a suicide note; and putting themselves in harm's way, or in situations where there is a danger of being killed. Risks for suicide appear to be higher earlier in the course of the illness.

Dysthymic disorder is a chronic, less intense form of depression but may progress to major depression. It involves long-term, chronic symptoms that do not disable patients, but keep them from functioning well or from feeling happy. Many dysthymics also experience major depressive episodes at some time.

Seasonal affective disorder (SAD) is a chronic cyclical form of depression that appears as daylight hours shorten and is related to melatonin and serotonin production. Its features also include winter somnolence and a craving for carbohydrates. Light therapy may be beneficial.

Involuntal melancholia is characterized by severe anxiety and hypochondriasis, beginning in later life and mainly affecting women.

Bipolar disorder is the term given to depression alternating with mania, which may amount to a psychosis. The various mood states in bipolar disorder may be regarded as a spectrum with severe depression at one end and mania at the other. Bipolar I disorder consists of alternating depression and mania; bipolar II disorder is alternating depression with hypomania; while mixed bipolar disorder is when depression and mania occur concurrently – usually as aggression plus depression.

General management

Diagnosis of depression is dependent upon identifying:

- a persistent lowering of mood
- alterations of biological function (as outlined above)
- altered thought content – patients have negative pessimistic thoughts about themselves, the world and the future (Beck cognitive triad).

It is important to remember that depressed patients often present with other symptoms, such as pain, and questionnaires to screen for thought and biological disturbances are therefore useful diagnostically.

Anyone thinking about committing suicide needs immediate attention, preferably from a psychiatrist. Important measures, if there is an attempt, are calling a doctor or emergency services to seek immediate help; ensuring that the suicidal person is not left alone; and denying access to medications, weapons or other items that could be used for self-harm.

Treatment of depression is by psychotherapy and medication. (Fig. 10.9) Psychotherapy involves talking with a mental health professional, such as a psychiatrist, psychologist, social worker or counsellor, to learn how to deal with problems.

The majority of patients with depression can be managed in the primary health-care setting by using the following measures:

- Appropriate risk assessment for suicide, self-neglect and danger to others. Psychiatric referral is needed if suicide risk is high or the depression is severe and unresponsive to initial treatment. Following the recent review of the Mental Health Act 2008 in the UK, all doctors are required to be able to judge a patient's capacity to make decisions; psychiatrists are further required to assess dangerousness.
- Psychological techniques (cognitive behavioural and supportive therapy).
- Pharmacotherapy (Tables 10.10 and 10.17).
- Electroconvulsive therapy (ECT) for very severe cases, where significant physical retardation or delusions (fixed unshakeable false beliefs) are present.

Antidepressants

Antidepressant drugs raise brain levels of serotonin and noradrenaline (norepinephrine). None of them is perfect and all suffer from at least one of the following drawbacks:

- Delayed onset of action from 7 to 28 days – although some improvements may be seen in the first few weeks, most antidepressant medications must be taken regularly for 3–4 weeks (in some cases, as many as 8 weeks) before the full therapeutic effect starts
- Anticholinergic effects
- Sedation
- Agitation
- Cardiotoxicity
- Weight gain.

Fig. 10.9 Depression, CBT, tricyclic antidepressants and electroconvulsive therapy (ECT).

Table 10.10 Classification of antidepressants^a (see Table 10.16)

Class	Examples
Tricyclic antidepressant (TCA)	Amitriptyline
Serotonin noradrenaline (norepinephrine) reuptake inhibitor (SNRI)	Venlafaxine
Selective serotonin reuptake inhibitor (SSRI)	Fluoxetine
Noradrenaline (norepinephrine) reuptake inhibitor (NRI)	Reboxetine
Noradrenaline (norepinephrine) and specific serotonergic agonist	Mirtazapine
Serotonin reuptake inhibitor (SRI)	Nefazodone
Reversible inhibitor of monoamine oxidase A (RIMA)	Moclobemide
Monoamine oxidase inhibitor (MAOI)	Phenelzine

^aSee Table 10.16.

Table 10.11 Monoamine oxidase inhibitors (MAOIs)

MAOI	Special comments (see text about food reactions)
Isocarboxazid	Contraindicated in liver or cardiovascular disease
Phenelzine	Contraindicated in liver or cardiovascular disease
Tranylcypromine	The most dangerous MAOI
Moclobemide	Less reactive with foods or drugs

Patients often are tempted to stop medication too soon but they should continue for at least 4–9 months to prevent recurrence.

Monoamine oxidase inhibitors (MAOIs) These were the first effective antidepressants but are now rarely prescribed because of their adverse effects (Table 10.11). Dry mouth and hypotension are common side-effects of MAOIs. The most serious adverse effects of the earlier and non-selective irreversible MAOIs, such as phenelzine, isoniazid and tranylcypromine, are drug or food interactions.

Table 10.12 Monoamine oxidase inhibitors: possible adverse effects and interactions

Possible adverse effects	Possible interactions
Hyposalivation	Hypertensive reactions with noradrenaline (norepinephrine), ephedrine or phenylephrine, or with tyramine-containing foods
Hypotension	
Anorexia	
Nausea	Adrenaline (epinephrine) can be used safely
Constipation	Enhanced action of respiratory depressants such as general anaesthetic agents, sedatives, antihistamines, opioids
Sexual dysfunction	Risk of seizures with tramadol

Hypertensive crises have resulted from interaction of these MAOIs with foods containing tyramine, particularly cheese, and also with yeast products, chocolate, bananas, broad beans, some red wines and beer, pickled herring or caviar. However, the frequency of such reactions has been greatly overestimated. Selective MAOIs, such as selegiline, used mainly in parkinsonism rather than depression, can also provoke similar reactions contrary to earlier beliefs. Interactions of MAOIs with pethidine and other opioids are the most dangerous reactions and have sometimes been fatal (Table 10.12). Interactions with TCAs are also dangerous. Ephedrine and similar drugs, which are often present in nasal decongestants or cold remedies, may cause severe hypertension.

The most commonly used MAOIs are phenelzine and isocarboxazid; phenelzine, for example, is helpful for people with panic disorder and social phobia.

Tricyclic antidepressants (TCAs) These are probably the most effective antidepressants, which have stood the test of time, despite their undesirable adverse effects (Table 10.13); they are useful when there is associated anxiety. Their most common adverse effects, and ways to deal with some of them, are:

- dry mouth – it is helpful to drink sips of water, chew sugarless gum and clean teeth daily
- constipation – bran, prunes, fruit and vegetables should be in the diet
- bladder difficulties – emptying the bladder may be troublesome and the urine stream may be weak
- sexual difficulties – sexual function may deteriorate
- blurred vision
- dizziness – rising from the bed or chair slowly is helpful
- drowsiness as a daytime problem (see Table 10.13) – the more sedating antidepressants are generally taken at bedtime to help sleep and minimize daytime drowsiness. A person feeling drowsy or sedated should not drive or operate dangerous equipment.

The onset of action of TCAs is slow and they may take 4 weeks to exert their full effect. The action is dose-dependent and lack of effect is often the result of failure to achieve adequate plasma levels. TCAs are contraindicated in patients with cardiac disorders (recent myocardial infarct, arrhythmias, heart block, cardiac failure), epilepsy, liver dysfunction, blood dyscrasias, glaucoma and urinary obstruction (e.g. prostatic hypertrophy). They should only be given after a full blood count and liver function tests; if the patient is over 45, an ECG is also indicated. TCAs should not be given within 2 weeks of the use of MAOIs.

The most commonly used TCAs are amitriptyline, dosulepin and imipramine. Sedation is a common side-effect, particularly with amitriptyline, but this may be an advantage if the patient is agitated

Table 10.13 Some possible adverse effects and interactions of tricyclic antidepressants

	Possible adverse reactions	Possible interactions
Cardiovascular	Arrhythmias Cardiotoxicity Postural hypotension Tachycardias	Hypertensive reaction with noradrenaline (norepinephrine)
Neurological	Agitation Ataxia Dizziness Drowsiness Insomnia Seizures Tremor	Potential of CNS depressants Risk of seizures with tramadol
Liver	Jaundice	
Blood	Leukopenia	
Others	Blurred vision Constipation Dry mouth Nausea Sexual dysfunction Urinary retention	

Table 10.14 Tricyclic and related antidepressants

Drug	Special comments ^a
Tricyclic antidepressant (TCA)	
Amitriptyline	More cardiotoxic, sedative and antimuscarinic than many TCAs; caution with general anaesthesia
Amoxapine	May cause tardive dyskinesia
Clomipramine	Possibly low sedative activity
Dosulepin	Sedative
Doxepin	Sedative; fewer cardiac effects
Imipramine	Less sedative than most but more antimuscarinic and cardiac effects
Lofepamine	Avoid in renal or hepatic disease
Nortriptyline	Possibly low antimuscarinic effects
Trimipramine	Photosensitive rashes
Related drugs	
Maprotiline	Less antimuscarinic but more epileptogenic than TCAs
Mianserin	Possible hepatic and haematological reactions
Trazodone	Fewer antimuscarinic and cardiac effects

^aUp to 4 weeks are required before symptom control can be expected. Reduced doses should be used in the elderly. Arrhythmias and heart block may be seen, as well as drowsiness, dry mouth, urinary retention and constipation (antimuscarinic actions). Contraindicated after myocardial infarction. Cardiotoxic in overdose.

(Table 10.14). Side-effects of the TCAs are more serious in older people. Various other TCAs have particular advantages: imipramine, for example, is mildly stimulating and clomipramine appears to be useful where there are obsessional or phobic problems. Lofepamine has fewer antimuscarinic effects than some others and is less dangerous in overdose. Doxepin (similar to imipramine) is the drug of choice if there is cardiovascular disease. Clomipramine is the only tricyclic prescribed for OCD, while imipramine may be given for panic disorder and GAD.

Selective serotonin reuptake inhibitors (SSRIs) These are newer antidepressants, and have the advantage over older antidepressants of

less severe antimuscarinic activity, weight gain or cardiac conduction effects. SSRIs do not interact with alcohol and are thus often preferred by both patients and practitioners; however, gastrointestinal effects are common.

Adverse effects of SSRIs include anorexia, nausea, anxiety, diarrhea, sexual dysfunction, and rarely mania, paranoia or extrapyramidal features (Table 10.15). Fluoxetine (Prozac) has been hailed as a valuable antidepressant (makes you feel 'better than well!'), but in the USA has allegedly been associated with aggressive behaviour, including murders. More recently, the same allegations have been made against paroxetine.

SSRIs may interact with TCAs or neuroleptics to cause a rise in plasma concentration and exaggerated effects of these drugs. SSRIs may interact with MAOIs, TCAs, carbamazepine or lithium to produce the serotonin syndrome (see Table 10.15), which comprises CNS irritability, hyper-reflexia and myoclonus, and is occasionally fatal. SSRIs should not therefore be used with TCAs or within 2 weeks of MAOIs. They are also contraindicated in epilepsy, cardiac disease, diabetes, glaucoma, bleeding tendencies, pregnancy, liver or renal disease.

They may have other adverse effects:

- Arrhythmias if the patient is using terfenadine
- Headache

Table 10.15 Selective serotonin reuptake inhibitors: possible adverse effects and drug interactions

Possible adverse effects	Possible interactions	
	Drug	Effect
Xerostomia	Carbamazepine	Serotonin syndrome
Arrhythmias	Lithium	Serotonin syndrome
Gastrointestinal upsets	Monoamine oxidase inhibitors	Serotonin syndrome
	Terfenadine	Arrhythmias
	Tramadol	Risk of seizures
	Tricyclics	Serotonin syndrome

- Nausea
- Nervousness and insomnia (trouble falling asleep or waking often during the night) – dosage reductions or time will usually resolve these complaints
- Agitation
- Dry mouth.

SSRIs such as fluoxetine or sertraline are commonly prescribed for panic disorder, OCD, PTSD and social phobia, and may be preferred for anxiety disorders. SSRIs can inhibit cytochrome P450 enzymes and thus impair the metabolism of BZPs, carbamazepine, codeine and erythromycin.

Newer antidepressants These include agomelatine, a melatonin receptor agonist; ketamine-like N-methyl-D-aspartate receptor (NMDA) antagonists; and vortioxetine – a SSRI variant which has antagonistic properties at 5-HT_{3A} and 5-HT₇ receptors, partial agonistic properties at 5-HT_{1B} receptors, agonistic properties at 5-HT_{1A} receptors, and potent inhibition of the serotonin reuptake transporter.

Summary of antidepressants (see Appendix 10.1) The SSRIs and other newer antidepressants (Table 10.16) that affect neurotransmitters, such as dopamine or noradrenaline (norepinephrine), generally have fewer adverse effects than TCAs, and both SSRIs and TCAs are safer overall than MAOIs, which can interact, even fatally, with some foods and drugs. Other agents used in severe depression may include some antipsychotics such as quetiapine and aripiprazole.

Herbal therapy

St John's wort (*Hypericum perforatum*) has been shown to be effective in mild depression but it may interact with SSRIs to produce the serotonin syndrome. It also stimulates cytochrome P450, and thus impairs the activity of drugs such as chemotherapeutic drugs (e.g. irinotecan, the vinca alkaloids, etoposide, teniposide, anthracycline, paclitaxel, docetaxel and tamoxifen), ciclosporin, digoxin, warfarin, indinavir (a protease inhibitor used in human immunodeficiency virus [HIV] infection), oral contraceptives, opioids and general anaesthetic agents.

Table 10.16 Antidepressants and their actions^a

Class	Abbreviation	Actions	Examples
Monoamine oxidase inhibitors	MAOIs	Inhibit monoamine oxidase A (MAO-A)	Moclobemide
Noradrenergic and specific serotonergic antidepressants	NASSAs	Block noradrenaline (norepinephrine), 5HT ₂ and 5HT ₃ reuptake	Mirtazapine
Noradrenaline (norepinephrine) reuptake inhibitors	NRIs	Block noradrenaline (norepinephrine) reuptake	Reboxetine
Selective serotonin reuptake inhibitors	SSRIs	Block 5HT (serotonin) reuptake	Citalopram Fluoxetine Fluvoxamine Paroxetine Sertraline
Serotonin noradrenaline (norepinephrine) reuptake inhibitors	SNRIs	Block noradrenaline (norepinephrine) and 5HT reuptake	Duloxetine Venlafaxine
Serotonin reuptake inhibitors	SRI	5HT antagonists	Nefazodone
Tricyclic antidepressants	TCAs	Block noradrenaline (norepinephrine) and 5HT reuptake	Amitriptyline Clomipramine Dosulepin Doxepin Lofepamine Nortriptyline Protriptyline

^aSee Table 10.10. For adverse effects, see Tables 10.11–10.15.

Electroconvulsive therapy (ECT)

ECT is sometimes given for severe depression, where drugs have been ineffective or where there is a strong risk of suicide. A muscle relaxant is given before treatment, which is delivered under GA. Electrodes are placed at precise locations on the head to deliver electrical impulses. The stimulation causes a brief seizure. The patient does not consciously experience the electrical stimulus. Amnesia is the main side-effect.

Dental aspects of depression

The features aiding recognition of depression have been suggested above. Dental staff should be alert to this possibility, particularly where the patient appears withdrawn, difficult or aggressive, or where there are oral complaints of the types described earlier. Great tact, patience and a sympathetic, friendly manner are needed. Dental treatment is preferably deferred until depression is under control but preventive programmes should be instituted at an early stage.

In patients taking TCAs, adrenaline (epinephrine) in local anaesthetics has not been shown clinically to cause hypertension (despite statements to the contrary). However, severe hypertension has resulted from high concentrations of noradrenaline (norepinephrine) in local anaesthetics, whether or not the patient was receiving antidepressants. Noradrenaline has no advantages as a vasoconstrictor and noradrenaline preparations have been withdrawn.

Paracetamol (acetaminophen) can inhibit the metabolism of TCAs, and atropinics are potentiated by TCAs.

Patients on MAOIs are at risk from GA, since prolonged respiratory depression may result. Any CNS depressant, especially opioids and phenothiazines, given to patients on MAOIs (or within 21 days of their withdrawal) may precipitate coma. Pethidine is particularly dangerous.

Indirectly acting sympathomimetic agents, such as ephedrine or cocaine, can interact with MAOIs to cause hypertension, and must therefore not be used. There is no evidence of any danger to patients on MAOIs from adrenaline (epinephrine) in LA solutions.

Tricyclics and MAOIs can cause postural hypotension. Dental patients using these drugs should not be stood immediately upright if they have been recumbent during treatment and the chair should be brought upright slowly.

Some depressed patients resort to drug misuse, and this must be considered (Ch. 34).

BZPs, carbamazepine, codeine and erythromycin may be potentiated by SSRIs.

The most common oral complaint of depressed patients under treatment is that of a dry mouth, especially as a result of the use of TCAs, MAOIs or lithium. This may even predispose to oral candidosis and accelerated caries. Taste sensation may also be disturbed and patients tend to eat more sugar. The effect of xerostomia can occasionally result in ascending suppurative parotitis. The most effective treatment is to change the antidepressant to another that has little anticholinergic activity. If this is not acceptable, the dry mouth should be managed as in Sjögren syndrome (Ch. 16). Smoking, and other drugs that may add to the xerostomia, such as antihistamines, hyoscine (scopolamine) or other atropine-like drugs, or SSRIs, should therefore be avoided. Both MAOIs and TCAs have also been reported occasionally to cause facial dyskinesias, and prolonged use of flupentixol can lead to intracetable tardive dyskinesia.

Bodily complaints, often related to the mouth, are common in depression and the dental surgeon should appreciate the possibility of a psychological basis for such oral disorders. Depression is associated especially with the following painful disorders of the orofacial region:

- Chronic facial pain
- Burning mouth or sore tongue (oral dysaesthesia)
- Occasionally temporomandibular pain dysfunction syndrome
- Other oral complaints, which may be delusional and include:
 - discharges (of fluid, slime or powder coming into the mouth)
 - dry mouth or sialorrhoea despite normal salivary flow
 - spots or lumps
 - halitosis
 - disturbed taste sensation.

Depression may also accompany: other mental diseases, such as schizophrenia; viral infections (e.g. influenza, hepatitis or infectious mononucleosis); drugs (particularly reserpine, methyl dopa, fenfluramine and corticosteroids) or their withdrawal (e.g. of amphetamines, BZPs or antidepressants); and serious medical disorders such as parkinsonism, stroke, myocardial infarction, malignant diseases or endocrinopathies, like diabetes.

Chronic fatigue syndrome (myalgic encephalitis/encephalomyopathy [ME])

General aspects

Chronic fatigue syndrome (CFS) is not a mental disorder but the cause is still unclear. It is a disorder characterized by lack of energy, tiredness, muscle and joint pains after minimal effort, emotional lability, poor concentration and memory, and often other symptoms. This clinical picture was described in 1867 and termed 'neurasthenia'. CFS is under-diagnosed in more than 80% of the people who have it; at the same time, it is often misdiagnosed as depression.

CFS often begins after an infection such as influenza or infectious mononucleosis, or after a period of high stress. Since the symptoms may resemble those of the recovery phase of a viral infection, the complaint is termed 'post-viral fatigue syndrome', but claims for Epstein-Barr virus, herpes virus 6 and Coxsackie B having a causative role have not been substantiated. Parvovirus has been implicated in some patients. Xenotropic murine leukaemia virus-related virus (XMRV), a human retrovirus apparently first identified in tissue samples from prostate cancer, was also reported to have been detected in two-thirds of patients with CFS. However, evidence of XMRV in these conditions was controversial and the suggested links have since been disproved.

Genetic, immunological, infectious, metabolic and neurological aetiologies have been suggested to explain CFS. Several mechanisms have been proposed, such as excessive oxidative stress following exertion, immune imbalance characterized by decreased natural killer cell and macrophage activity, immunoglobulin G subclass deficiencies (IgG1, IgG3), and decreased serum concentrations of complement component. Autoantibodies have also been suggested as a possible factor; recent studies indicate that antiserotonin, anti-microtubule-associated protein 2 and antimuscarinic cholinergic receptor 1 antibodies may play a role. It has been demonstrated that impairment in vasoactive neuropeptide metabolism may explain the symptoms of CFS. Genes for haematological disease and function, immunological disease and function, cancer, cell death, immune response and infection have altered expression. Increases in elastase activity and protein kinase and ribonuclease (RNase) L enzymes support the clinical importance of these immune dysfunctions in CFS.

Clinical features

Unlike most post-viral symptoms, which usually abate in a few days or weeks, CFS symptoms, particularly fatigue, either persist or fluctuate,

frequently for more than 6 months. CFS also has eight other possible primary symptoms, which include: loss of memory or concentration, sore throat, painful and mildly enlarged lymph nodes in the neck or axilla, myalgia, polyarthralgia without swelling or redness, headache of a new type, pattern or severity, sleep disturbance; or extreme exhaustion after normal exercise or exertion. A person meets the diagnostic criteria of CFS when unexplained fatigue persists for 6 months or more with at least 4 of the above 8 primary symptoms are also present.

Similar features may be seen in infection with:

- Epstein–Barr virus
- human herpesvirus 6
- enterovirus
- rubella
- *Candida albicans*
- bornaviruses
- mycoplasma
- Ross River virus
- *Coxiella burnetii*
- human retroviruses, such as HIV or XMRV.

CFS is a post-infective condition in approximately 10–12% of cases.

Neurally mediated hypotension (NMH) or postural orthostatic tachycardia syndrome (POTS) have been incriminated in some CFS patients.

General management

Tests showing any disorders of muscle function or any other organic lesion have not been substantiated. By contrast, those with organic neuromuscular diseases do not have the mental symptoms characteristic of CFS.

Management of CFS aims to relieve symptoms by using gradual but steady exercise and treatment of symptoms. CFS may respond to antidepressant drugs.

Dental aspects

Unexpectedly, perhaps, atypical (idiopathic) facial pain has not been reported as a feature of CFS. The only oral symptom reported has been dry mouth.

PSYCHOSES

Psychotic disorders are serious conditions characterized by dysregulation of thought processes, in which insight is often lacking (Table 10.17). In particular, schizophrenia has hallmark symptoms of delusions (false, strongly held beliefs not influenced by logical reasoning or explained by a person's usual cultural concepts) and hallucinations (hearing and/or seeing sensory information which is not actually present and is not apparent to others). Typically, psychotic disorders are treated with antipsychotic medications and psychosocial interventions.

Bipolar disorder

Bipolar disorder (formerly known as 'manic–depressive psychosis') is a major mood disorder in which the individual most commonly experiences episodes of depression and episodes of mania (a clearly elevated, unrestrained or irritable mood that may manifest in an exaggerated assessment of self-importance or grandiosity, sleeplessness, racing thoughts, pressured speech, and the tendency to engage in activities

Table 10.17 Main psychoses: features

Bipolar disorder (manic depression)	Mainly severe depression but there may be manic episodes for weeks, months or years
Schizophrenia	Severe disorder of thought, behaviour and affect, with hallucinations, delusions and illusions
Korsakoff syndrome	Recent amnesia and confabulation
Brief psychotic disorder	Short, non-recurrent psychosis
Delusional disorder	One or more fixed beliefs
Shared psychotic disorder	'Folie à deux' – a delusional disorder shared by two people

Table 10.18 Bipolar disorders

Terminology	Comments
Bipolar I	At least one high, or manic episode, lasting longer than 1 week. Some people with bipolar I will have only manic episodes, although most will also have periods of depression Untreated, manic episodes generally last 3–6 months Depressive episodes last rather longer – 6–12 months without treatment
Bipolar II	More than one episode of severe depression but only mild manic episodes – 'hypomania'
Cyclothymia	Mood swings not as severe as in full bipolar disorder but can be longer. May develop into full bipolar disorder
Rapid cycling	More than four mood swings in a 12-month period

that appear pleasurable but have a high potential for adverse consequences). Medications and psychotherapy are effective treatments of bipolar disorder.

Mu-opioids (endorphins), CRH, noradrenaline (norepinephrine), dopamine and serotonin appear to be altered in depression.

General aspects

Bipolar disorder is characterized by cycling mood changes of severe highs (mania) and lows (depression). Hypomania with major depression is termed bipolar I disorder (Table 10.18). Sometimes the mood switches are dramatic and rapid, but most often they are gradual.

About 1 in every 100 adults has bipolar disorder. Men and women are affected equally. It usually starts in late adolescence or early adulthood. It is unusual for it to start after the age of 40. However, symptoms may sometimes start during childhood, or alternatively in later in life, when they may indicate organic disease: for example, a neoplasm or an effect of drugs such as corticosteroids, alcohol or another drug of dependence.

When in the manic cycle, the person may be overactive and over-talkative, and have excessive energy. In the depressed cycle, any or all of the symptoms of a depressive disorder are prominent.

Mania

Mania, left untreated, may worsen to a psychotic state. It is characterized by:

- abnormal or excessive elation, 'high', excessively euphoric mood
- unusual irritability
- less need for sleep
- grandiose notions and unrealistic beliefs in abilities and powers

- excessive talking
- racing thoughts, jumping from one idea to another ('butterfly mind')
- distractibility
- excessive sexual desire
- greatly increased energy and provocative, intrusive or aggressive behaviour
- poor judgment
- inappropriate social behaviour
- spending sprees
- abuse of drugs, particularly cocaine, alcohol and sleeping medications
- denial that anything is wrong.

A manic episode is diagnosed if elevated mood comes with three or more of the other symptoms for most of the day, nearly every day, for 1 week or longer.

Mania often affects thinking, judgment and social behaviour in ways that can cause serious problems and embarrassment. The individual in a manic phase may feel elated and full of grand schemes that might range from unwise business decisions to romantic sprees. Frequently, therefore, the family rather than the patient feel the ill-effects and complain accordingly.

A mild to moderate level of mania is called hypomania and it may be enjoyed by the patient; it may even be associated with good functioning and enhanced productivity. Thus, even when family and friends learn to recognize the mood swings as possible bipolar disorder, the person may deny that anything is wrong. Alternation between mild mania and depression is termed cyclothymia.

Sometimes, severe episodes of mania or depression include psychotic symptoms, such as hallucinations and delusions. Psychotic symptoms in bipolar disorder tend to reflect the extreme mood state at the time. For example, delusions of grandiosity, such as believing one is the president or has special powers or wealth, may be experienced during mania. Delusions of guilt or worthlessness, such as believing that one is ruined and penniless or has committed some terrible crime, may appear during depression. People with bipolar disorder who have these symptoms are sometimes incorrectly diagnosed as having schizophrenia.

General management of mania

CBT may be effective. Psychoeducation involves teaching people with bipolar disorder about the illness and its treatment, and how to recognize signs of relapse so that early intervention can be instituted before a full-blown episode. Lithium, carbamazepine and valproate are the main mood-stabilizing drugs. 'Atypical' antipsychotic medications (such as olanzapine) may help.

Lithium can have several adverse effects. It affects thyroid function and the ECG, and can produce nephrogenic diabetes insipidus. It is also a teratogen. It must only be used where blood levels can be monitored, as overdose can cause tremor, ataxia, convulsions and renal damage. Patients with cardiovascular, renal or thyroid disorders are at risk. Side-effects include thirst, dry mouth and nausea. Povidone-iodine is contraindicated.

Carbamazepine has fewer adverse effects than lithium and is given when the latter is not tolerated. An important adverse effect is ataxia.

Valproate may lead to adverse effects. It depresses platelet numbers and function to produce a bleeding tendency. Valproate may lead to adverse hormone changes in teenage girls and polycystic ovary syndrome in women who start taking the medication before age 20, so

Table 10.19 Potential drug interactions with lithium

Drug interacting with lithium	Consequences
Carbamazepine	Lithium toxicity
Diazepam	Hypothermia
Droperidol and other neuroleptics	Facial dyskinesias
Non-steroidal anti-inflammatory drugs (NSAIDs)	Lithium toxicity
Metronidazole	Lithium toxicity
Phenytoin	Lithium toxicity
Selective serotonin reuptake inhibitors (SSRIs)	Serotonin syndrome
Suxamethonium and other muscle relaxants	Prolonged muscle relaxation
Tetracyclines	Lithium toxicity

young female patients who are prescribed valproate should be monitored carefully by a physician. NSAIDs, erythromycin and BZPs are also contraindicated.

Newer anticonvulsant medications, including lamotrigine, gabapentin and topiramate, are being studied for their effect in stabilizing mood. Atypical antipsychotic medications, including clozapine, olanzapine, risperidone and ziprasidone, are also possible treatments.

If insomnia is a problem, a high-potency BZP, such as clonazepam or lorazepam, may help. These medications may be habit-forming and should be prescribed in the short term only; therefore other types of sedative medication, such as zolpidem, are sometimes used instead.

Treatments of unproven worth in mania include St John's wort (*Hypericum perforatum*) and omega-3 fatty acids found in fish oil.

Dental aspects

An excited manic patient can be difficult to manage and treatment may have to be delayed until after stabilization. Lithium treatment should be monitored by regular assay of plasma levels. Arrhythmias may be precipitated, particularly during GA. Lithium can interact with many drugs, and it may be advisable to stop lithium treatment 2–3 days before GA (Table 10.19).

Most NSAIDs and metronidazole should be avoided, as they can induce toxicity, but aspirin, paracetamol (acetaminophen) and codeine are safe to use.

Manic-depressive patients may be treated with lithium and also antidepressant drugs – with oral side-effects such as xerostomia.

Schizophrenia

The term 'schizophrenia' covers a number of chronic conditions of complex aetiology that are characterized by dopamine overactivity in the mesolimbic pathways of the brain. It is a disabling condition and has a lifetime prevalence of approximately 1%, although in recent years prevalence figures are falling for reasons that are not clear.

There is a significant genetic component in the aetiology, probably related to chromosomes 13 and 6. Schizophrenia appears to be due to some imbalance of the complex interrelated chemical systems of the brain, involving dopamine and glutamate; many studies have found abnormalities in brain structure, and suggest it may be a developmental disorder leading to neurons forming inappropriate connections during fetal development. Marijuana use may precipitate schizophrenia and abuse of phencyclidine (PCP), crack cocaine, LSD and amphetamines

can cause a similar picture (Ch. 34). There is a high prevalence in the socially deprived and in penal institutions. It may also be common in some people of African heritage.

Clinical features

Acute schizophrenia typically presents in young individuals with positive symptoms (hallucinations, delusions and thought disorder). The person generally lacks insight and concern is initially raised by a friend or relative. Acute schizophrenia may develop in previously normal individuals, is often precipitated by organic disorders or external stress, and affective symptoms such as depression may be associated. Chronic schizophrenia is more common and characterized by inappropriate affect (mood), disordered thought processes, delusions and hallucinations. Some patients are strikingly paranoid, while others have mainly motor symptoms (catatonia), a bizarre mixture of emotional, behavioural and thought disturbances, or neuroses. Chronic schizophrenia may present insidiously with negative symptoms (apathy, loss of affect and social withdrawal) and thus be misdiagnosed.

Intelligence is unimpaired and insight may even be retained. Occasionally, as a result, patients may be aware that their behaviour is bizarre and even realize the consternation that such behaviour creates in others.

Mood, thoughts and behaviour are disorganized and appear irrational and exaggerated. Disorders of perception (hallucinations) and thought (delusions) are common. Disintegration of the individual's personality results in social isolation and withdrawal. Some patients are strikingly paranoid whilst others exhibit motor impairment (catatonia) or a mixture of emotional, behavioural and thought disturbances (hebephrenia). Thoughts and behaviour can be totally inappropriate and incomprehensible.

The first signs of schizophrenia often appear as confusing, or even shocking, changes in behaviour. Schizophrenics frequently suffer terrifying symptoms, such as hearing internal voices not heard by others, or believing that other people are reading their minds, controlling their thoughts or plotting to harm them. Such symptoms may leave them fearful and withdrawn.

Schizophrenics often suffer a severely impaired emotional expressiveness – a 'blunted' or 'flat' affect. Signs of normal emotion are diminished or missing, the voice monotonous and facial expressions mask-like; the person may appear apathetic. Schizophrenics may withdraw socially, avoiding contact with others; when forced to interact, they may have nothing to say ('impoverished thought').

Disordered thinking is common. Schizophrenics may not be able to sort out what is relevant and what is not relevant to a situation. Thoughts may come and go rapidly. The patient may not be able to concentrate on one thought for very long and may be easily distracted and unable to focus attention. Schizophrenic thought disorder causes loss of cohesion between logical thought sequences, with thoughts becoming disorganized and fragmented. Speech and behaviour can be so disorganized as to be incomprehensible or frightening to others. Speech may include non-existent words (neologisms) or be inconsequential ('word salad'). There may be disruption of the stream of speech (thought-blocking), which can make conversation very difficult.

If people cannot make sense of what an individual with schizophrenia is saying, they are likely to become uncomfortable and tend to leave that person alone, and this, together with inappropriate affect and withdrawal from social contact, leads to isolation. Motivation can thus be greatly weakened, as can interest in or enjoyment of life. In some severe cases, a person can spend entire days doing nothing at all, even neglecting basic hygiene. These problems with emotional expression and motivation may

be extremely troubling to family members and friends, but are symptoms of schizophrenia, not character flaws or personal weaknesses.

Hallucinations and delusions have no connection to an appropriate source and can involve any sensory form – auditory, visual, tactile, gustatory and olfactory. However, hearing voices that other people do not hear is the most common type of hallucination. Such voices may describe the patient's activities, carry on a conversation, warn of impending dangers or even issue orders. Schizophrenics live in a world distorted by hallucinations and delusions, and may feel frightened, anxious and confused; they may behave very differently at various times. Sometimes they may seem distant, detached or preoccupied, and may even sit as rigidly as a stone, not moving for hours or uttering a sound. At other times they may move about constantly – always occupied, appearing wide awake and alert. The bizarre nature of the disorder may be made obvious when they shout back at the unheard voices.

Delusions, on the other hand, describe a sensory stimulus that is present but is incorrectly interpreted by the individual. As we have seen, delusions are false personal beliefs not subject to reason or contradictory evidence, and are not explained by a person's usual cultural concepts. Delusions may take on different themes. For example, patients suffering from paranoid-type symptoms – roughly one-third of schizophrenics – often have delusions that they, or a member of the family or someone close to them, are the focus of persecution. Alternatively, they may have false and irrational beliefs that they are being cheated, harassed, poisoned or conspired against. Delusions of grandeur, in which the individual believes that he or she is a famous or important figure, are common. The best-known schizophrenic delusion, in the past, was that of being Napoleon! Sometimes the delusions are quite bizarre: for instance, believing that a neighbour is controlling their behaviour with magnetic waves; that people on television are directing special messages to them, or that their thoughts are being broadcast aloud to others. Murderous attacks on others are sometimes ordered by the illusory inner voices.

Paranoia is a projection of the patient's internal disturbance, which, as a consequence, is believed to be the result of the hostility of others, such as neighbours, secret agents or foreign powers, who may be projecting mysterious rays to achieve their malign objectives, for example.

Catatonia, with abnormalities of movement, posture and speech, negativism, echolalia, mannerisms and stereotypia, may also be a feature.

General management

Diagnosis is not easy at times, since even normal individuals may feel, think or act in ways that resemble schizophrenia. At the same time, people with schizophrenia do not always act abnormally. Indeed, some people with the illness can appear completely normal and be perfectly responsible, even while they experience hallucinations or delusions. An individual's behaviour may change over time, seeming close to normal when appropriate treatment is being received, but becoming bizarre when medication is stopped.

The diagnosis should thus only be made by an experienced psychiatrist. The diagnostic criteria for schizophrenia vary but include the recognition of Schneider's first-rank symptoms:

- Auditory hallucinations – thought echo or voices talking about the patient in the third person
- Passivity – the feeling of being controlled by external forces
- Thought insertion or withdrawal
- Thought broadcasting
- Delusions
- Hallucinations.

Some people with symptoms of schizophrenia exhibit prolonged extremes of elated or depressed mood, mimicking a manic–depressive (or bipolar) disorder or major depressive disorder. When such symptoms cannot be clearly categorized, a diagnosis of ‘schizoaffective disorder’ is sometimes made.

It is important to rule out other illnesses, as sometimes similar symptoms are due to undetected underlying medical conditions or drug abuse; for this reason, a medical history should be taken and a physical examination and laboratory tests should be done to rule out other possible causes.

Coping with the symptoms of schizophrenia can be especially difficult for family members who remember how involved or vivacious a person was before they became ill.

Treatment of schizophrenia includes:

- early active intervention before the illness becomes chronic
- assessment of the risk a patient poses to themselves or others (individuals may require acute psychiatric admission under the Mental Health Act [“sectioning”])
- family therapy
- CBT
- long-term psychotherapy and antipsychotic drug therapy (Table 10.20)
- supportive therapy via community psychiatric services.

A person with schizophrenia can be more sensitive to stress, so it is best to avoid arguments and keep calm.

Treatment with individual psychotherapy is of questionable value. Rehabilitation, family education and self-help groups can help. Treatment usually includes drugs, which can be the older (typical) antipsychotics that work by reducing brain dopamine but can cause side-effects, such as stiffness and shakiness, feeling slow, restlessness, sexual difficulties and unwanted movements, mainly of the mouth and tongue. Some of these antipsychotic medications, including haloperidol, fluphenazine, perphenazine and others, are available in long-acting injectable forms that eliminate the need to take pills every day. The newer (atypical) antipsychotics are less likely to produce unwanted movements but can cause weight gain, diabetes, tiredness and sexual problems (see Table 10.20).

Antipsychotic medications alter the dopamine/cholinergic balance in the basal ganglia so that extrapyramidal and anticholinergic effects are common and can be disabling. All may variably produce weight

gain, extrapyramidal side effects, prolactin increase, prolonged QT interval (Ch. 5) and sedation. The long-term side-effects of antipsychotic drugs, especially drowsiness, hypotension, xerostomia, interference with temperature regulation and extrapyramidal symptoms, may pose particularly serious problems. Extrapyramidal features from medication are most common with the piperazine phenothiazines, butyrophenones and depot preparations, and include:

- dystonia and dyskinesia (abnormal movements)
- akathisia (restlessness)
- Parkinsonism; anti-parkinsonian drugs, such as benztropine or orphenadrine, are required to control extrapyramidal symptoms, which sometimes develop after only a few doses. L-dopa is contraindicated.

Maintenance therapy is conveniently carried out with long-acting preparations such as fluphenazine or flupentixol, but these can cause intractable tardive dyskinesia. Phenothiazines can also cause the neuroleptic malignant syndrome, dose-related impaired temperature regulation, obstructive jaundice, leukopenia or ECG changes.

Most schizophrenic patients need and show substantial improvement with antipsychotic drugs but there have been sudden deaths in asthmatics. Some people have only one such psychotic episode; others have many episodes during a lifetime but lead relatively normal lives during the interim periods; but those with ‘chronic’ schizophrenia, or a continuous or recurring pattern of illness, typically require long-term treatment. Schizophrenia can be remarkably disturbing for patients and for those in contact with them; hospitalization may therefore be necessary in severe cases. Overall, about 10% remain hospitalized and a further 30% remain seriously handicapped.

ECT may be given if there is a poor response to medication or if there is catatonia.

Tardive dyskinesia Tardive dyskinesia (TD) is characterized by involuntary movements, most often involving the mouth, lips and tongue, and sometimes the trunk or other parts of the body, such as arms and legs. It affects about 15–20% of patients who have been receiving phenothiazines for many years, but sometimes only for short periods. The symptoms of TD are usually mild so that the patient may be unaware of the movements. TD does not respond to withdrawal of the causative drug or to any other medication.

Table 10.20 Important drugs used to treat schizophrenia

Class	Examples	Features
Phenothiazines		
Phenothiazines with pronounced sedative effects, but moderate antimuscarinic and extrapyramidal effects	Chlorpromazine, promazine	If there is considerable anxiety or hyperactivity, chlorpromazine is most commonly used but parenteral fluphenazine enanthate or decanoate, pipotiazine palmitate and zuclopenthixol decanoate by biweekly injection overcome compliance difficulties
Phenothiazines with low extrapyramidal effects, and moderate sedative and antimuscarinic effects	Pericyazine, pipotiazine, thioridazine	Fewer extrapyramidal effects than other phenothiazines Thioridazine may be cardiotoxic
Piperazine phenothiazines, with low sedative and antimuscarinic activity	Fluphenazine, perphenazine, prochlorperazine, trifluoperazine	May be given if no sedation is needed, but may have pronounced extrapyramidal effects and may worsen depression
Butyrophenones		
Thioxanthenes		
Atypical antipsychotics		
	Benperidol, droperidol, haloperidol	Useful mainly for violent patients
	Flupentixol, zuclopenthixol	Extrapyramidal effects common
	Clozapine, amisulpride, olanzapine, quetiapine, risperidone, sertindole, zotepine	All apart from clozapine are first-line treatment for newly diagnosed schizophrenia. Clozapine is used for resistant cases; it does not cause tardive dyskinesia but has significant antimuscarinic effects and can cause agranulocytosis
		All can cause long QT syndrome
Diphenylbutylpiperidines		
	Fluspirilene, pimozide	Danger of sudden unexplained, probably cardiac, death

Neuroleptic malignant syndrome Neuroleptic malignant syndrome (NMS) is a rare but potentially life-threatening drug-induced disorder associated with the use of antipsychotic medications. It is characterized by disturbances in mental status, hyperpyrexia, and disturbed autonomic and extrapyramidal functions. Laboratory findings include leukocytosis, raised creatine phosphokinase and metabolic acidosis. Treatment of NMS consists primarily of early recognition, discontinuation of triggering drugs, management of fluid balance, cooling, and monitoring for complications. Use of dopamine agonists or dantrolene, or both, should be considered and may be indicated in more severe, prolonged or refractory cases.

Dental aspects

Mild schizophrenic features (which are often unrecognized) include loss of social contact, flatness of mood or inappropriate social behaviour, which may appear at first as mere tactlessness or stupidity. Thus the patient, when asked to sit down in the surgery, may sit in the operator's rather than the dental chair. Attempts at communication are met by a response that indicates a failure to get through or are interrupted by totally irrelevant remarks. Such patients may have delusional oral symptoms, the treatment of which is beyond the expertise of dental staff, and then psychiatric help must be sought.

Phenothiazines can cause adrenaline (epinephrine) reversal in patients given a LA; there is vasodilatation instead of the anticipated vasoconstriction because of the alpha-adrenergic blocking activity of phenothiazines. Any practical importance of this in relation to LA is unclear:

- Conscious sedation is safe.
- With tramadol, there is a risk of seizures.
- Haloperidol and phenothiazines may cause orthostatic hypotension. Patients should be raised slowly and carefully assisted from the dental chair.
- Haloperidol and droperidol reportedly block the vasoconstrictor activity of adrenaline (epinephrine).
- GA, especially with intravenous barbiturates, can lead to severe hypotension and should therefore be avoided if possible.
- The long-term use of neuroleptics can lead to xerostomia (with susceptibility to candidosis and caries, and, occasionally, ascending parotitis), oral pigmentation and severe extrapyramidal symptoms.
- Muscular rigidity or tonic spasms (facial dyskinesias), frequently involving the bulbar or neck muscles, with subsequent difficulties in speech or swallowing. Alternatively, there may be uncontrollable facial grimacing (orofacial dystonia), which may start after only a few doses. This may be controlled by stopping the neuroleptic and giving anti-parkinsonian antimuscarinic drugs.
- Haloperidol and clozapine can cause hypersalivation.

Korsakoff psychosis

Korsakoff psychosis is characterized by amnesia for recent events, impaired ability to learn new facts and fabricated descriptions of recent events (confabulation). Nevertheless the patient is alert, responsive and behaves in an otherwise normal manner.

The disease results from a symmetrical lesion in the periaqueductal area, thalamus, mammillary bodies and cerebellar vermis; chronic alcoholism associated with thiamine deficiency is an important cause, though

Table 10.21 Some drug-induced mental states

Mental State	Drugs sometimes responsible	
	Used in medicine mainly	Used in dentistry too
Confusion	Antihypertensives Antihistamines Tricyclic antidepressants	Benzodiazepines
Aggressive behaviour	Dopa derivatives	Benzodiazepines (in children)
Nightmares or hallucinations	Some antihypertensives	Pentazocine or ketamine
Mania	L-dopa	Corticosteroids
Depression	Antihypertensives Contraceptive pill	Pentazocine Corticosteroids
Delirium	Antihypertensives Antitubercular drugs Anticonvulsants	Procaine penicillin Sulphonamides
Paranoia	Oral hypoglycaemics Antihypertensives Anticonvulsants Amphetamines	Ephedrine Corticosteroids

relatively few alcoholics develop the syndrome. Other possible causes include cerebrovascular disease, tumours or degenerative disorders.

Other psychoses

Psychoses can complicate various endocrine disturbances, the puerperium, or the use of drugs such as alcohol, amphetamine, cannabis or psychotomimetics (Table 10.21).

SYSTEMIC DISEASE CAUSING MENTAL DISORDERS

Many endocrine diseases can be complicated by mental disturbances, as may alcoholism, drug abuse or drug treatment. Major trauma, surgery or severe life-threatening disease can also frequently cause emotional reactions, such as anxiety or depression, or conditions such as compensation neurosis.

APPENDIX 10.1 WORLD HEALTH ORGANIZATION'S NOMENCLATURE FOR ANTIDEPRESSANTS, WITH EXAMPLES

NON-SELECTIVE MONOAMINE REUPTAKE INHIBITORS

- Tricyclic antidepressants: imipramine, amitriptyline*, clomipramine, lofepramine, amoxapine
- Noradrenaline reuptake inhibitors: desipramine, nortriptyline, maprotiline

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

- Fluoxetine*, fluvoxamine, zimelidine, paroxetine, sertraline, citalopram, escitalopram

MONOAMINE OXIDASE INHIBITORS (NON-SELECTIVE)

- Phenelzine, tranylcypromine, isocarboxazid

MONOAMINE OXIDASE A INHIBITORS

- Moclobemide, toloxatone

OTHER ANTIDEPRESSANTS

- Serotonin noradrenaline reuptake inhibitors: venlafaxine, duloxetine
- Noradrenaline dopamine reuptake inhibitors: nomifensine, bupropion
- Noradrenaline and selective serotonin antagonists: mirtazapine
- Serotonin antagonist and reuptake inhibitor: trazadone
- Melatonin receptor agonist with 5-HT_{2C} receptor antagonist properties: agomelatine
- Serotonin partial agonist: gepirone

*Listed in the WHO's list of essential medicines for use in depressive disorders; adapted from Hatcher S, and Arroll B. *BMJ* 2012; 344 doi: <http://dx.doi.org/10.1136/bmj.d8300>.

KEY POINTS

- Rashes can be genetic or acquired (infective, autoimmune, inflammatory, allergic)
- Epidermolysis bullosa and pemphigus can be life-threatening
- Stratified squamous epithelium is the common origin of dental, oral mucosal and cutaneous tissues, and there are close associations between disorders affecting these

SKIN DISEASES

The common and more important skin diseases only are discussed here.

ACNE

General aspects

Acne is a common skin disorder in which hair follicles become blocked with oil and hypertrophied epithelium; it is characterized by clogged pores and pimples. More than 4 out of 5 people, particularly adolescent males, develop acne. Several factors – including hormones, bacteria, medications such as corticosteroids, heredity and stress – play a role. Many adult women experience mild to moderate acne due to hormonal changes associated with menstrual cycles, starting or stopping oral contraceptives, or pregnancy.

Clinical features

Pimples appear as hair follicles and become plugged with oil and dead skin cells, causing the follicle wall to bulge and produce a 'whitehead'. If the pore stays open and traps dirt, the plug surface oxidises and darkens, causing a 'blackhead'. Blockages and inflammation deep inside hair follicles can produce scarring and cysts. Acne is rarely serious but it often causes emotional distress.

General management

Effective lotions generally contain benzoyl peroxide or azelaic acid. Topical erythromycin and clindamycin are effective treatments for inflamed lesions. Systemic acne treatment should start with antimicrobials (tetracyclines or erythromycin). Options for scarring cystic acne or acne that fails to respond to other treatments are, in women, cyproterone acetate or isotretinoin (vitamin A analogue, only prescribable by consultant dermatologists). For men, only isotretinoin is available. Oral contraceptives, including a combination of norgestimate and ethinylestradiol, can improve acne in women. Maternal use of vitamin A congeners must be avoided since birth defects similar to those in Di George syndrome can result – the *fetal isotretinoin syndrome*.

Dermabrasion (removing the top skin layers with a rapidly rotating wire brush) may help more severe scarring. Laser resurfacing can achieve the same effect.

CANCER

General aspects

The three major types of skin cancer, all on the increase, are (see also Ch. 22):

- basal cell carcinoma (BCC; rodent ulcer; Fig. 11.1)
- squamous cell carcinoma (SCC; Fig. 11.2)
- melanoma.

All are on the increase; nearly half of all men over 65 years will develop a skin cancer. Risk factors are shown in Box 11.1.

Clinical features and general management

Skin cancer develops mainly on areas of sun-exposed skin: the scalp, face, lips, ears, neck, chest, arms and hands, and on the legs in women. BCC is superficial and highly treatable, especially if found early. It appears as a pearly or waxy lump on the face, ears or neck, or a flat,

Fig. 11.1 Basal cell carcinoma.

Fig. 11.2 Squamous cell carcinoma.

Box 11.1 Risk factors for skin cancer

- Fair skin – patients with blond or red hair and light-coloured eyes, who freckle or contract sunburn easily, are 20–30 times more prone
- Sunburn increases the risk – people who live in areas of strong sunshine are at greatest risk; immigrants to Australia and the southern USA, or at high elevations, are frequent victims. Severe sunburn as a child or teenager is a particular risk. Overuse of sunbeds for tanning is another cause
- Moles – people who have >20 naevi are at greater risk of skin cancer
- Pre-cancerous skin lesions (e.g. actinic keratoses) – can increase the risk of developing skin cancer
- A family history of skin cancer
- A personal history of skin cancer
- An immune defect
- Exposure to environmental hazards, such as chemicals (including some herbicides) or psoriasis treatments

flesh-coloured or brown scar-like lesion on the chest or back, typically in persons after middle age, but responds to excision. In Gorlin syndrome, BCC can start to form in childhood.

SCC is superficial, slow-growing and highly treatable, especially if found early. It presents as a firm, red nodule on the face, lip, ears, neck, hands or arms, or a flat lesion with a scaly, crusted surface on the face, ears, neck, hands or arms. It usually responds to wide excision.

Melanoma has the greatest potential to spread and may be fatal. It typically appears as: a large brownish spot with darker speckles, anywhere; a simple mole anywhere that changes in colour or size or consistency, or that bleeds or exhibits new growth; a small lesion with an irregular border and red, white, blue or blue-black spots on the trunk or limbs; shiny, firm, dome-shaped nodules anywhere; dark lesions on palms, soles, tips of fingers and toes, or on mucous membranes; or a red flat lesion (amelanotic melanoma). Malignant melanomas can also form in the retina or, rarely, even in areas protected from sunlight such as the mouth.

Treatment of melanoma is usually excision, and if the tumour is superficial (Breslow depth <1.5 mm) the prognosis is excellent at 90% 5-year survival. The prognosis of malignant melanoma is usually poor as a consequence of late diagnosis and rapid spread: survival averages only 2 years.

Dental aspects

Dentists are a risk group for skin cancers (from excess vacation sun exposure!).

ECZEMA**General aspects**

Eczema is a term describing a range of persistent skin conditions that include dryness and recurring rashes characterized by redness, itching, crusting, flaking, blistering, cracking, oozing or bleeding.

Clinical features

Common types of eczema include the following:

- *Atopic eczema* is believed to have a hereditary component (often runs in families whose members also have asthma and/or hay fever). It is particularly noticeable on face and scalp, neck, inside of elbows, behind knees and buttocks.

- *Contact dermatitis* is irritant (resulting from direct reaction to a solvent) or allergic.
- *Seborrhoeic dermatitis* causes dry or greasy scaling of scalp and eyebrows, scaly pimples and red patches.

General management

Patch-testing, raised serum immunoglobulin E (IgE), eosinophilia, radioallergosorbent test (RAST) or paper radioimmunosorbent test (PRIST; Ch. 17) may be diagnostically helpful. There is no known cure. Treatments, which aim to control symptoms, reduce inflammation and relieve itching, include topical emollients, corticosteroids, or calcineurin inhibitors. Ciclosporin, azathioprine or methotrexate may rarely be needed.

PSORIASIS**General aspects**

Psoriasis is a common chronic skin disease characterized by scaling and inflammation. It has a strong genetic background with human leukocyte antigen (HLA)-Cw6 and HLA-DR7. T cells trigger inflammation, and excessive skin cell reproduction underlies the pathogenesis. There are sometimes associations with stress and alcoholism.

Clinical features

Psoriasis causes thick pruritic erythematous plaques covered with silvery scales (Fig. 11.3), predominantly on scalp, elbows and knees, lower back, face, palms, and soles of feet, and ‘ice-pick’ pitting or onycholysis of fingernails and toenails (Fig. 11.4). About 15% have joint inflammation (psoriatic arthropathy).

Fig. 11.3 Psoriasis. Silvery flaky rash on the elbows.

General management

Treatment of psoriasis initially is with topical agents – corticosteroids, vitamin D3, vitamin A analogues (retinoids), coal tar or dithranol (anthralin). Failing this, light (phototherapy) is used. Sunlight often helps but more controlled artificial light treatment may be used in mild psoriasis (ultraviolet B phototherapy), or psoralen and ultraviolet A (PUVA) therapy in more severe or extensive psoriasis.

Severe cases of psoriasis may need systemic treatment with methotrexate, ciclosporin or retinoids.

Dental aspects

Local anaesthesia (LA) is safe. Conscious sedation (CS) can be given if required.

Fig. 11.4 Psoriasis affecting nails.

Oral lesions, such as white or reddish mucosal plaques, are rare. There may be a higher prevalence of erythema migrans and fissured tongue, particularly in pustular psoriasis. The temporomandibular joint is involved in up to 60% of patients with psoriatic arthropathy.

Oral complications of the treatment of psoriasis, such as gingival swelling from ciclosporin, or ulceration from methotrexate, may be seen.

ACQUIRED MUCOCUTANEOUS DISORDERS

Several mucocutaneous diseases can involve the mouth or may influence dental treatment. The most common is lichen planus. The most serious are pemphigus (which is potentially fatal), erythema multiforme and mucous membrane pemphigoid (which may involve other mucosae). Oral lesions herald some mucocutaneous diseases or may be the main manifestation. Immunostaining can often help the diagnosis (Table 11.1).

Many of the mucocutaneous diseases are treated with corticosteroids (topically or systemically), which may, if used for prolonged periods, cause adrenocortical suppression (Ch. 6).

LICHEN PLANUS

General aspects

Lichen planus (LP) is a common skin and mucosal disease. The immunopathogenesis includes a dense T-lymphocyte infiltrate, to an unidentified provoking antigen.

Lesions clinically and histologically similar or identical to LP (lichenoid lesions) can be related to dental restorations, particularly amalgam and drugs, especially to non-steroidal anti-inflammatory drugs (NSAIDs), gold, antimalarials and beta-blockers. Reported associations of oral LP with diabetes mellitus and hypertension have not been confirmed, and the so-called Grinspan syndrome of LP, diabetes mellitus and hypertension is probably related to drug treatment.

Table 11.1 Immunostaining in skin and oral mucosal diseases

Disease	Direct immunofluorescence	Epithelial location	Indirect immunofluorescence	Type of antibody ^a	Main epithelial antigen
Pemphigus vulgaris	Yes	Intercellular	Yes	IgG	Desmoglein
Paraneoplastic pemphigus	Yes	Intercellular ^b	Yes	IgG	Desmoplakin
IgA pemphigus	Yes	Intercellular	Yes	IgA	?Desmocollin
Bullous pemphigoid	Yes	Basement membrane area	Yes	IgG	BP1
Mucous membrane pemphigoid	Yes	Basement membrane area	Rarely	IgG	BP2
Angina bullosa haemorrhagica	No	–	No	–	–
Dermatitis herpetiformis	Yes	Basement membrane area	No	IgA	Transglutaminase
Linear IgA disease	Yes	Basement membrane area	No	IgA	Laminin
Systemic lupus erythematosus	Yes	Basement membrane area	Yes	ANA	NR
Chronic discoid lupus erythematosus	Yes	Basement membrane area	No	ANA	NR
Lichen planus	Often	Basement membrane area	No	(Usually fibrin)	?
Chronic ulcerative stomatitis	Yes	Basal cell layer	No	IgG/ANA	?

ANA = antinuclear antibody; BP = bullous pemphigoid; Ig = immunoglobulin; NR = not relevant.

^aUsually with complement deposits.

^bTransitional epithelium.

Fig. 11.5 Lichen planus rash.

Fig. 11.7 Wickham striae in lichen planus.

Fig. 11.6 Lichen planus rash.

Fig. 11.8 Lichen planus on lips.

Similar lesions may be reactions to chemicals, such as photographic developing solutions, graft-versus-host disease (Ch. 35), chronic liver disease and virus infections – hepatitis C or human immunodeficiency virus (HIV).

Approximately 1% of cases of oral LP may develop malignant change after 10 years.

Clinical features

Skin lesions are usually small polygonal purplish or violaceous itchy papules, particularly affecting the flexor surfaces of the wrist (Fig. 11.5), and also elsewhere such as the shins (Fig. 11.6) or periumbilically, but rarely, if ever, on the face. Examination with a lens may show a fine lacy white network of striae (Wickham striae) on these papules (Fig. 11.7). Mouth and genital lesions in LP include white striae, papules, plaques, or red atrophic areas or erosions (Fig. 11.8). The nails or hair may be affected (Fig. 11.9).

General management

A drug history should be taken in order to exclude possible reactions. If there is any doubt about the diagnosis, a biopsy is needed, particularly to differentiate LP from lupus erythematosus, chronic ulcerative stomatitis or keratoses. Topical corticosteroids or tacrolimus can be useful to control symptomatic LP, especially severe erosive lesions. Aloe vera reportedly gives effective symptomatic relief.

Exceptionally severe LP sometimes responds only to systemic corticosteroids. Other drugs, such as vitamin A analogues (etretinate), dapsone, ciclosporin or alefacept, are used only rarely.

Fig. 11.9 Lichen planus affecting nails.

Dental aspects

Oral lesions in LP can persist for years, although the skin lesions frequently resolve within a few months. Oral lesions characteristically are bilateral and sometimes strikingly symmetrical; they affect particularly the posterior buccal mucosa but may also involve the tongue, gingivae or other sites. Gingival lesions are usually atrophic and red ('desquamative gingivitis').

Replacement of amalgam with non-metallic alternatives may sometimes cause lesions to resolve, but relapse is possible. LA is safe. CS can be given if required.

PEMPHIGUS

Pemphigus is a potentially fatal autoimmune reaction against proteins, usually within the stratified squamous epithelium; it is characterized

Table 11.2 Pemphigus variants

Pemphigus variant	Desmosomal antigens	Serum antibodies	Oral lesions	Comments
Pemphigus vulgaris localized to mucosae (mucosal)	Desmoglein 3	IgG	Common	Fatal
Pemphigus vulgaris also involving skin/ other mucosae (mucocutaneous)	Desmoglein 3 Desmoglein 1	IgG	Common	Fatal
Pemphigus vegetans	Desmoglein 1	IgG	Uncommon	Variant of vulgaris
Pemphigus foliaceus	Desmoglein 1	IgG	Uncommon	–
Pemphigus erythematosus	Desmoglein 1	IgG	Uncommon	Variant of foliaceus
Drug-induced pemphigus	Desmoglein 3	IgG	Common	–
Paraneoplastic pemphigus	Desmoplakin 1 Desmoplakin 2	IgG or IgA	Common	Rare. Associated with lymphoproliferative disorders
IgA pemphigus	Desmocollin 1 Desmocollin 2 Desmoglein 3	IgA	Common	Rare

by widespread formation of skin vesicles and bullae. The mouth is frequently the first site of attack. Variants include those listed in Table 11.2.

Pemphigus vulgaris

General aspects

Pemphigus vulgaris is an uncommon disease, which mainly affects middle-aged women. Pemphigus may occasionally be associated with other autoimmune diseases, such as lupus erythematosus, inflammatory bowel disease, or thymoma and myasthenia gravis. Rarely, it is induced by a drug such as rifampicin, penicillamine or captopril. The main immunological finding is circulating antibodies to desmogleins of intercellular attachments (desmosomes) of epithelial cells of stratified squamous epithelia. These IgG antibodies, and complement components, are deposited (and can also be localized by immunostaining) around the epithelial cells, and result in loss of adherence of the cells to one another (acantholysis). Pemphigus is characterized by widespread formation of intraepithelial vesicles and bullae.

Clinical features

Pemphigus vulgaris is characterized by thin-roofed vesicles or bullae, followed by ulceration (Fig. 11.10). It frequently appears in the mouth first. Stroking the skin or mucosa with a finger may induce vesicle formation in an apparently unaffected area or cause a bulla to extend (Nikolsky sign). If untreated, pemphigus vulgaris is usually fatal, as a result of extensive skin and mucosal damage leading to fluid and electrolyte loss, and often infection.

General management

Rapid and precise diagnosis of pemphigus vulgaris is essential since acute cases need immediate immunosuppressive treatment. Diagnosis is confirmed by biopsy. The specimen should be halved to enable both light and immunofluorescent microscopy to be carried out. Light microscopy on a paraffin section is usually distinctive and shows supra-basal cleft formation and intraepithelial vesicles containing free-floating acantholytic cells. Immunofluorescence examination shows IgG and C3 deposits intercellularly. It can be carried out by the direct method using fluorescein-conjugated anti-human IgG and anti-complement (C3) sera

Fig. 11.10 Pemphigus.

on the frozen specimen or on exfoliated cells. In the indirect method, the patient’s serum is incubated with normal animal mucosa, which is then labelled with fluorescein-conjugated antihuman globulin (see Table 11.1). Antibodies to desmoglein 1 may be found in pemphigus vulgaris with cutaneous lesions, or in pemphigus foliaceus; antibodies to desmoglein 3 may herald oral involvement in pemphigus vulgaris.

The usual treatment of pemphigus vulgaris is with high doses of systemic corticosteroids plus a steroid-sparing agent such as azathioprine. Gold may sometimes be used. Cyclophosphamide, methotrexate or mycophenolate mofetil also appear to be effective. With current methods of treatment, the mortality may be reduced to about 8% but is often a complication of immunosuppressive treatment. Long-term remission has been reported but many require prolonged therapy.

Dental aspects

LA and CS can be given as required. Orofacial manifestations are as described above. However, blisters are so fragile as rarely to be seen intact in the mouth. They leave painful erosions.

Mucous membrane pemphigoid

General aspects

Mucous membrane pemphigoid is a group of subepithelial immune blistering diseases with autoantibodies directed to different epithelial

basement membrane proteins. Oral pemphigoid-like lesions have occasionally been reported in association with internal cancers or the use of certain drugs, such as penicillamine. Autoantibodies against basement membrane proteins cause loss of attachment of the epithelium to the connective tissue and blister formation. The common variant of mucous membrane pemphigoid has antibodies against bullous pemphigoid antigen 2 (BP2) but the types that mainly affect the mouth have antibodies against integrin or epiligrin. Serum autoantibodies are demonstrable by conventional techniques in relatively few patients.

Clinical features

Mucous membrane pemphigoid predominantly affects women between 50 and 70 years of age. Intact vesicles or bullae are frequently visible. Sometimes the blisters fill with blood and then must be distinguished from generalized or localized oral purpura. The gingivae may be particularly affected and pemphigoid is an important cause of so-called 'desquamative gingivitis'. Progress is typically indolent and lesions may remain restricted to one site, such as the mouth, for several years or possibly never develop elsewhere, depending on the type.

Scarring after healing of the bullae is a serious complication in sites such as the eyes, larynx, oesophagus or genitalia. Ocular involvement is the most common dangerous manifestation since it can impair or destroy sight (Fig. 11.11). Laryngeal or oesophageal stenosis secondary to scarring is also possible.

General management

The diagnosis of pemphigoid must be confirmed by biopsy. The section should be halved and a frozen section tested for localization of immunoglobulins or complement components along the basement membrane (see Table 11.1). It may be difficult otherwise to differentiate pemphigoid from other mucosal blistering diseases. Paraffin sections show separation of the epithelium from the underlying connective tissue, which is infiltrated by inflammatory cells, often with many eosinophils. Localization of immunoglobulins (IgG) along the line of the epithelial basement membrane can be shown in fewer than 50% but complement components may be demonstrable in about 80%. If there is any suspicion of ocular involvement, referral to an ophthalmologist is essential. The danger of ocular involvement is regarded as an indication for giving systemic corticosteroids. Other lesions can often be adequately controlled by potent topical corticosteroids. Dapsone or systemic corticosteroids may be needed for more severe cases.

Fig. 11.11 Pemphigoid affecting conjunctiva.

Dental aspects

LA is safe and CS can be given if required. Orofacial manifestations are as described above.

BULLOUS PEMPHIGOID

Bullous pemphigoid is essentially a skin disease that rarely affects the mouth but histologically or immunologically does not appear to differ from mucous membrane pemphigoid. There are associations with diabetes or psoriasis.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an uncommon chronic skin disease related to coeliac disease.

Clinical features

Dermatitis herpetiformis usually affects males past middle age, and causes an itchy papulovesicular eruption, usually on the extensor surfaces of the upper limbs and trunk. It leaves pigmented areas on healing. The coeliac disease is milder than in isolated coeliac disease. There may be associations with thyroid disease, gastric achlorhydria, pernicious anaemia and lymphoma.

General management

Diagnosis of dermatitis herpetiformis is by demonstrating deposits of IgA in the papillae at the epithelial basement membrane zone (BMZ), with papillary tip microabscesses and a subepithelial split. The biopsy should be from uninvolved skin. Anti-endomysial and anti-transglutaminase antibodies may be detectable. Serum immune complexes are often detectable but decline if the patient is put on a gluten-free diet, which may be of considerable benefit (Ch. 7). Patients are usually treated with dapsone, sulfapyridine or sulfamethoxypyridazine.

Dental aspects

Indometacin may exacerbate the condition and should be avoided. Oral lesions are usually innocuous but may be erythematous, vesicular, purpuric or sometimes erosive. They may be confused with pemphigoid. Coeliac-type enamel defects may rarely occur.

Drug reactions may be seen. Dapsone rarely causes a lichenoid eruption; sulfapyridine or other sulphonamides may cause erythema multiforme.

LINEAR IGA DISEASE

General aspects

Linear IgA disease (LAD) is a rare variant of dermatitis herpetiformis, in which the IgA deposits are linear at the BMZ but coeliac disease is absent. LAD may occasionally be induced by vancomycin.

Clinical features

Similar oral manifestations to dermatitis herpetiformis may be seen and LAD is most likely to be confused with pemphigoid. A variant seen in childhood is termed chronic bullous dermatosis of childhood. There may be an association with lymphoma.

General management

The diagnosis and treatment are as for dermatitis herpetiformis but a gluten-free diet is not required.

Dental aspects

Oral lesions are clinically indistinguishable from those in dermatitis herpetiformis.

ERYTHEMA MULTIFORME

General aspects

Erythema multiforme primarily affects young males and is characterized by recurrent mucosal and/or cutaneous lesions, including virtually any type of rash. The aetiology is uncertain but it may be an immune complex disorder in which the antigens can be various microorganisms or drugs (Table 11.3). Herpes simplex may be involved in most cases limited to the mouth.

Severe cases with multiple mucosal involvement and fever are termed toxic epidermal necrolysis (TEN), or Stevens–Johnson syndrome. TEN is the term often used when there is very extensive skin detachment and involvement of mucosae, and the condition is drug-induced. It has up to 40% mortality. Stevens–Johnson syndrome is a less severe form than TEN, also affecting several sites.

Clinical features

Skin, and ocular, genital or oral mucous membranes, may be involved together or in isolation. The typical skin lesion is the target or iris lesion (Figs. 11.12 and 11.13), in which there are concentric erythematous rings affecting particularly the hands and feet. Vesicles or bullae may also be seen. Typical oral features are grossly swollen, crusted and blood-stained lips, and widespread superficial oral ulceration with ill-defined margins (Fig. 11.14).

General management

When typical mucosal lesions are associated with dermal lesions, the diagnosis can usually be made largely on clinical grounds. Diagnosis can be difficult when the disease is limited to mucosae. Other suggestive features are recent use of drugs (particularly sulphonamides) or

recent infections, particularly by herpes simplex or *Mycoplasma pneumoniae*. Biopsy can be useful to exclude other more serious diseases, such as early-onset pemphigus. An ophthalmological opinion should be obtained if the conjunctivae are involved. Oral lesions can be symptomatically managed with topical corticosteroids, chlorhexidine or lidocaine gel to ease the pain. Healing usually takes 10–14 days.

Severe erythema multiforme and TEN may necessitate hospital admission, as feeding may be difficult; systemic corticosteroids are frequently given but may not provide anything more than symptomatic relief. Aciclovir is indicated for prophylaxis of recurrent erythema multiforme, since herpes simplex virus (HSV) is often involved.

Fig. 11.12 Erythematous rings in erythema multiforme.

- Pemphigus
- Erythema multiforme
- Pyostomatitis vegetans

Dental aspects

LA is safe. CS can be given if required. Orofacial manifestations are as described above.

DESQUAMATIVE GINGIVITIS

Desquamative gingivitis is the term given to the clinical description of chronically red and occasionally sore gingivae. It is caused mainly by pemphigoid or lichen planus, and sometimes by other mucocutaneous disorders (Box 11.2).

BEHÇET DISEASE**General aspects**

Behçet disease is a clinical triad of oral and genital ulceration, and uveitis, tending particularly to strike people with 'Silk Road' blood-lines, especially those from Turkey and Japan. Behçet disease mainly affects young adult males, and there is an association with HLA-B5 and HLA-B51(B5101). Features such as arthralgia and leukocytoclastic vasculitis suggest an immune complex-mediated basis. The immunological changes seen mimic those in patients with recurrent aphthous stomatitis (RAS), with various T-lymphocyte abnormalities (especially T-suppressor cell dysfunction), changes in serum complement, and increased polymorphonuclear leukocyte motility. There is also evidence that mononuclear cells may initiate antibody-dependent cellular cytotoxicity to oral epithelial cells, and evidence of disturbance of natural killer cell activity.

Clinical features

Behçet disease is a multisystem disease with a wide variety of manifestations. Oral ulceration is the most constant feature and is indistinguishable from the common types of aphthous-like stomatitis. Ocular and genital lesions are common, as are rashes, arthritis, thrombophlebitis, cardiovascular disease and central nervous system (CNS) involvement (Box 11.3).

MAGIC syndrome (*mouth and genital ulcers and interstitial chondritis*) is a recognized variant of Behçet disease.

General management

A clinical diagnosis of Behçet disease is usually made on the presence of any two of the oral, genital and ocular features, but similar oral ulceration may also develop in other diseases that have multisystem involvement and these must be excluded when making the diagnosis. Behçet disease must enter into the differential diagnosis of recurrent

Box 11.3 Behçet disease: clinical features and possible complications**Orals**

aphthae but the diagnosis may be difficult to confirm for the reasons given earlier. Oral and genital ulceration may also result from folate deficiency, when other features characteristic of Behçet syndrome are lacking. Recurrent oral, ocular and genital lesions may also be seen in erythema multiforme and sometimes in ulcerative colitis and other conditions. The primary features of Behçet disease are as follows:

- Recurrent oral ulceration (painful aphthous-like ulcers, testing negative for herpes) in almost 100% of patients *plus*
- Any two of the following four:
 - Recurrent genital ulcerations
 - Eye inflammation (uveitis or retinal vasculitis)
 - Skin lesions (erythema nodosum, pseudofolliculitis, papulopustular lesions or acneiform nodules)
 - A positive pathergy test (a skin-prick test using a sterile needle and sterile saline solution).

However, UK or US patients rarely test positive, even during disease activity. Behçet disease international criteria were revised in 2013.

Other manifestations that may be useful in diagnosis but are not considered part of the international Behçet criteria, include:

- subcutaneous thrombophlebitis, deep vein thrombosis
- epididymitis, arterial occlusion and/or aneurysm
- CNS involvement (including difficulties in movement or speech, or memory loss)
- severe headaches with stiff neck, joint pain or non-destructive arthritis

- gastrointestinal tract involvement (bloating, cramping, diarrhoea, bloody stools)
- renal involvement
- pulmonary vascular inflammation and pleuritis.

Reliable diagnostic tests for Behçet disease are not available but there are many immunological findings including: circulating autoantibodies (e.g. against intermediate filaments, cardiolipin and neutrophil cytoplasm); circulating immune complexes and abnormal levels of complement; immunoglobulins and complement deposition within and around blood vessel walls; and a depressed T-helper (CD4): T-suppressor (CD8) ratio. Behçet disease is thus diagnosed mainly on clinical grounds alone, though findings of HLA-B5101 and pathergy are supportive, as are antibodies to cardiolipin and neutrophil cytoplasm. Activity of the disease may be assessed by serum levels of acute-phase proteins or antibodies to intermediate filaments, both raised in active Behçet disease.

Medical and ophthalmological opinions should be obtained since ocular involvement often culminates in impaired sight.

Available treatments include mainly colchicine, systemic corticosteroids, azathioprine, interferon alpha, mycophenolate mofetil and thalidomide. However, the multiplicity of other medications, including levamisole, cyclophosphamide, dapsone and ciclosporin or chlorambucil, confirms their overall low level of success. Anti-tumour necrosis factor (TNF) biological therapies and rituximab have been used with some success.

Dental aspects

Oral lesions can be managed symptomatically like common aphthae. Topical tetracycline mouthwash is the topical drug of choice for controlling the ulcers. Topical corticosteroids and LA may help. Colchicine may be of value and thalidomide may be the most effective treatment for otherwise intractable oral ulceration.

SWEET SYNDROME

Sweet syndrome, or acute neutrophilic dermatosis, is rare but consists of persistent high fever, raised erythrocyte sedimentation rate and neutrophilia, and a rash. Some cases are associated with malignancy (especially acute myeloid leukaemia), and some have followed infections – especially upper respiratory tract infections.

The rash consists of dull red skin nodules or plaques on the neck and forearms especially; these may become pustular. Sweet syndrome may also include oral ulceration, conjunctivitis, episcleritis and arthralgia. Treatment is with systemic corticosteroids.

GENETIC MUCOCUTANEOUS DISORDERS

ECTODERMAL DYSPLASIA

The ectodermal dysplasias (EDs) are a family of hereditary diseases that involve defects in two or more tissues derived from ectoderm – skin, hair, teeth, nails and sweat glands. Oral manifestations of the EDs are associated with the teeth. Alterations in tooth development can include hypodontia, anodontia and conically shaped teeth.

General aspects

ED is a relatively common genodermatosis characterized by hypoplasia or agenesis of many skin appendages. There are many variants. The

skin is fragile and nails may be defective. The teeth and salivary glands may also be defective or fail to form. Sweat glands may also fail to form and heat control is then disrupted (hypohidrotic ectodermal dysplasia).

Clinical features

There may be frontal bossing and a depressed nasal bridge. The hair is fine, blond and scanty (hypotrichosis), especially in the tonsural region, and the eyelashes and eyebrows may be absent. If the teeth are absent, there may be a prematurely senile (nutcracker) profile with protuberant lips.

Dental aspects

ED rarely causes management problems, apart from those related to its oral manifestations. LA is safe, as is CS. General anaesthesia (GA), as with other dental patients, must be given in hospital. Especial care is indicated in intubation in hypohidrotic forms. Teeth are often few in number (hypodontia or oligodontia), and those present may be of simple conical form. The enamel is thin. Either the deciduous or the permanent dentition, or in extreme cases both, may fail to form (anodontia), causing hypoplasia of the jaws. Salivary glands may also fail to form, which causes xerostomia. Preventive dental care is therefore particularly important.

EPIDERMOLYSIS BULLOSA

General aspects

Epidermolysis bullosa is an uncommon bullous disease affecting mainly skin and mucosae. There are several forms that show different patterns of inheritance and vary greatly in severity. The severe form appears soon after birth; milder forms may not become evident until adolescence or later (Table 11.4).

An acquired form, with antibodies against collagen VII, is also recognized.

Clinical features

Vesicles and bullae form in response to mild or insignificant trauma and may lead to disabling scarring.

General management

Corticosteroids may help prevent blister formation and some success has been claimed for vitamin E and phenytoin.

Dental aspects

Early dietary advice and preventive dental care is overwhelmingly important, since even 'normal' toothbrushing can cause ulceration. Adequate oral hygiene is difficult to achieve, and dental diseases such as caries and periodontal disease are common. Oral scarring and severe microstomia may restrict access. Blistering, erosions and aggravation of scarring following dental treatment (however carefully carried out) may possibly be reduced by applying KY jelly or silicone oil to the mucosa. A short preoperative course of corticosteroids an hour before treatment, and again on the following day, then tapering the dose off over the next 3 days may possibly help.

Intramuscular injections can cause sloughing and adhesive tapes easily traumatize the epidermis and thus should be avoided. Antimicrobials to cover surgery may possibly be helpful.

Table 11.4 The main types of epidermolysis bullosa

Type	Onset	Main site of lesions ^a	Oral mucosal lesions	Dental defects	Nail defects	Scarring	Inheritance
<i>I. Non-scarring types</i>							
Simplex ^b	Neonatal onwards	Hands, feet and elbows	Rarely	No	No	No	AD
Letalis ^c	Birth	Widespread	Yes ^d	Yes	Severe	No	AR
<i>II. Scarring types</i>							
Dermolytic dominant (dystrophic) ^e	Childhood	Extremities	Uncommon	No	Yes	Yes. Soft scars	AD
Dermolytic recessive (polydysplastic) ^f	Birth or infancy	Widespread	Yes. Severe, mutilating	No	Destruction	Mutilating ^g	AR

AD = autosomal dominant; AR = autosomal recessive.

^aUsually also any site of trauma.

^bMay improve by puberty; commonest type.

^cUsually fatal in neonatal period or childhood; also known as Hurler disease.

^dVermilion border of lips spared: lesions are perioral and perinasal. May be corneal lesions.

^eA cemental defect has been reported, but destruction and loss of teeth from caries and periodontal care is a typical result of inability to brush the teeth.

^fRare and fatal.

^gTypically leads to destruction of hands and feet. Oesophageal stricture may lead to aspiration into airway.

GA should be avoided where possible. Bullae may form on the face or in the airway if intubation is attempted. If intubation must be used, the face should be protected with petroleum jelly gauze and the route should be oral rather than nasal. Iron deficiency anaemia is common and may need correction before GA (Ch. 8). Intravenous ketamine has proved a useful anaesthetic in these patients. Atropinics are often needed to control excessive salivation.

Rarely, squamous cell carcinoma can complicate the oral lesions. Rare cases are associated with poikiloderma congenitale and may present with early-onset periodontitis or desquamative gingivitis.

MULTIPLE BASAL CELL NAEVI SYNDROME (GORLIN–GOLTZ SYNDROME)

General aspects

The multiple basal cell naevi syndrome consists of multiple basal cell carcinomas of early onset, keratocystic odontogenic tumours, anomalies of the vertebrae and ribs, and many other abnormalities. It is an autosomal dominant trait with poor penetrance.

Clinical features

Skin lesions appear in childhood or adolescence. Multiple naevoid basal cell carcinomas over the nose, eyelids, cheeks and elsewhere are often an early sign (Fig. 11.15).

There is frontal and temporoparietal bossing, a broad nasal root, prominent supraorbital ridges and a degree of mandibular prognathism. Multiple jaw cysts develop. Short fourth metacarpals are common. There may also be pitting of the palms or soles.

Many other problems may be associated, including learning impairment or cerebral tumours. Pseudohypoparathyroidism has been described in some patients and there is also a slightly greater incidence of diabetes mellitus. Cardiac lesions may be present and cerebral tumours can be fatal.

General management

Radiography may reveal bifid ribs, vertebral defects with kyphoscoliosis and calcification of the falx cerebri.

Fig. 11.15 Basal carcinomas in multiple basal cell naevi (Gorlin–Goltz) syndrome.

Dental aspects

LA is safe. CS can be given. GA must be given in hospital for treatment of the jaw cysts.

GARDNER SYNDROME (FAMILIAL ADENOMATOUS POLYPOSIS COLI)

General aspects

Gardner syndrome is the association of multiple osteomas, skin fibromas and epidermoid cysts, and pigmented ocular fundus lesions with colonic polyposis.

It is an autosomal dominant trait of variable penetrance.

Clinical features

Multiple osteomas characteristically involve the jaws, facial skeleton or frontal bone, and appear in adolescence. Fibromas, desmoid tumours, epidermoid cysts or lipomas affect any site. Multiple colonic polyps invariably undergo malignant change. Thyroid, adrenal and biliary carcinomas may also develop.

Fig. 11.16 Neurofibromatosis.

General management

Colonic resection is usually required. Desmoid tumours often arise in the abdominal wall scar.

Dental aspects

LA is safe. CS can be given if required. Multiple osteomas, particularly on the alveolar margins, should suggest the presence of Gardner syndrome. Compound odontomas and dental anomalies may be associated.

COWDEN SYNDROME

This is an autosomal dominant condition of multiple hamartomas, with a predisposition to carcinomas of the breast, thyroid or colon. Skin and mucosal papules precede the onset of malignant disease. Other lesions include keratoses on the palms and soles, and sometimes learning impairment.

Oral mucosal papillomatosis may suggest the diagnosis. When associated with cerebellar hypertrophy, the syndrome is known as Cowden–L’Hermitte syndrome.

PHAKOMATOSES

The phakomatoses (neurodermatoses) are hereditary hamartomatous autosomal dominant disorders affecting the skin and nervous system. They include neurofibromatosis, tuberous sclerosis and Sturge–Weber syndrome. Sporadic cases are not uncommon. The fourth member of this group, cerebroretinal angiomas, is not discussed here.

Neurofibromatosis type I (von Recklinghausen disease)

General aspects

Neurofibromatosis type I is a simple autosomal dominant condition in which there are multiple neurofibromas or, less often, neurilemmomas.

Clinical features

Neurofibromas sometimes form in vast numbers (Fig. 11.16). These may be disfiguring but are often asymptomatic unless pressure effects develop: for example, on the spinal nerve roots with compression of the spinal cord. Patches of skin hyperpigmentation (café-au-lait spots)

are common. Sarcomatous change may develop in about 10% of severely affected patients. There is also a greater frequency of cerebral gliomas.

Complications may include learning impairment and epilepsy in a minority. Multiple neuroendocrine adenoma syndrome may be associated (Ch. 6).

Dental aspects

LA can be given safely. CS can be given if required. GA must, as always, be given in hospital.

Oral mucosal neurofibromas are uncommon and more typically associated with endocrine disorders (multiple endocrine adenoma [MEA] type III; Ch. 6).

Neurofibromatosis type II is characterized by bilateral acoustic neuromas, which can cause deafness and any of the symptoms of cerebellopontine angle lesions, but the skin lesions of type I are lacking.

Tuberous sclerosis (Bourneville disease; epiloia)

General aspects

Tuberous sclerosis is characterized by adenoma sebaceum and leaf-shaped depigmented naevi of the skin, epilepsy and sometimes learning disability.

It is a simple autosomal dominant trait linked to chromosome 9 or 16.

Clinical features

The skin adenoma sebaceum are angiofibromas typically distributed in a butterfly pattern across the cheeks, nasolabial folds, bridge of the nose, forehead and chin. Epilepsy, learning impairment and cardiac or renal involvement, or endocrinopathies, particularly diabetes mellitus, may be features.

Dental aspects

Dental management may be complicated by cardiac or renal involvement, or diabetes mellitus, in addition to epilepsy and sometimes learning impairment. LA with or without CS can be given, unless there is severe cardiac or renal involvement. GA must, as always, be given in hospital.

The facial ‘adenomas’ may be conspicuous and suggest the diagnosis. Oral lesions include hyperplastic gingivitis and pit-shaped dental defects in both dentitions.

Sturge–Weber syndrome

General aspects

Sturge–Weber syndrome (encephalotrigeminal angiomas) is characterized by an angiomatous defect (hamartoma), which is usually on the upper part of the face and also within the skull.

Clinical features

The angioma is often large, usually sited in the upper part of the face, and may appear to occupy the area of a division of the trigeminal

nerve, extending into the mouth. The occipital lobe of the brain is usually involved, but the parietal and frontal lobes may be affected if the lower face is involved by the angioma.

Clinically, there are often convulsions, hemiplegia and learning impairment.

Dental aspects

Dental surgery in the area affected by the haemangioma may be complicated by profuse haemorrhage and should therefore only be attempted in hospital. When the vascular naevus involves the face, it usually extends to the underlying oral mucosa and gingivae, which are red and sometimes hyperplastic, and also to the alveolar bone.

LA is safe. CS can usually be given if required.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum is a rare autosomal recessive disorder of connective tissue characterized by yellow papular or reticular skin lesions, visual impairment and cardiovascular abnormalities. The skin is hyperextensible and there may be blue sclerae and loose-jointedness. Abnormalities in the eyes include streaks beneath the retina (angioid streaks) and often haemorrhages and scarring.

Cardiovascular involvement includes calcification of elastic tissue in vessel walls, leading to poor blood flow, which in turn causes ischaemic heart disease and intermittent claudication. Hypertension is common. Some patients have a normal lifespan but others succumb to haemorrhage, cardiac disease or cerebrovascular accidents. Some individuals develop hypothyroidism; others bleed from the upper gastrointestinal tract, uterus, or renal or respiratory tracts.

Dental management may be complicated particularly by cardiovascular disease.

Lesions may be seen around the face and mouth, and there may be nodules in the lips or rarely in the mouth.

ORAL MUCOSAL DISORDERS

Mouth ulcers are generally caused by local factors but some are recurrent aphthae; others are due to malignant disease (Ch. 22), drugs or systemic disease (diseases of blood, infections, gastrointestinal disease or skin diseases; Chs 7, 8 and 21).

RECURRENT APHTHAЕ (RECURRENT APHTHOUS STOMATITIS)

General aspects

Recurrent aphthae (recurrent aphthous stomatitis; RAS) typically appear as round or ovoid ulcers, with onset usually in childhood or adolescence, and recurrences at intervals. RAS is common and may affect up to 25% of the population. The cause is usually unclear and most patients are otherwise healthy, but there are occasional associations with a familial basis, no tobacco use, menstrual cycle, haematinic deficiency (iron, folate or vitamin B₁₂), trauma, stress and particular foods.

Aphthous-like ulcers may be seen in relation to a number of conditions (Box 11.4).

Box 11.4 Aphthous-like ulcers: related conditions

- Autoinflammatory syndromes such as periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis (PFAPA)
- Behçet syndrome, when there is usually genital ulceration, uveitis and other lesions
- Coeliac or Crohn disease, or other intestinal diseases, notably ulcerative colitis
- Drugs (e.g. cytotoxics, mammalian target of rapamycin [mTOR] inhibitors, NSAIDs, nicorandil) or defective immunity (e.g. HIV infection: major aphthae may be the presenting feature) or cyclic neutropenia: typically (but rarely) causes recurrent infections, fever, malaise and enlarged cervical lymph nodes. Oral ulceration may appear at 21-day intervals, coincident with the falls in circulating neutrophils, and may be the main manifestation of the disease. In others, severe periodontal disease may develop

Table 11.5 Clinical variants of aphthae

Minor aphthae	Major aphthae	Herpetiform aphthae
Common	Uncommon	Uncommon
Usually round or ovoid discrete ulcers	Usually round or ovoid discrete ulcers	Ulcers initially 1–3 mm across but later coalesce to form ragged ulcers
Not on attached gingiva or hard palate and rarely on dorsum of tongue	Ulcers may be 1 to several cm in diameter	Ulcers form in crops of 10–100 with widespread erythema
Most are 2–4 mm in diameter	Persist for months before healing with scarring	
Heal within 10 days without scarring		

Clinical features

The onset is usually in childhood or adolescence. Ulcers are typically round or ovoid, and recur at intervals. Three different clinical patterns are recognized (Table 11.5).

General management

In addition to a careful history, patients with aphthous-like ulcers should be screened haematologically, particularly if the history suggests a systemic disorder or if the ulcers develop or worsen in middle age or later. A full screen includes haemoglobin and blood indices, serum ferritin (or iron and iron-binding capacity), vitamin B₁₂ levels, corrected whole blood or red cell folate levels, and transglutaminase and anti-endomysial antibodies (to exclude coeliac disease). There are no useful laboratory diagnostic tests for RAS. Systemic conditions, such as Behçet disease and HIV infection, should be excluded if the history is suggestive.

There is no specific or reliably effective treatment; topical corticosteroids are often used. For severe or intractable RAS, systemic corticosteroids or other immunosuppressants may be given, but overall thalidomide appears to be most effective. In patients with HIV infection, aphthous-like ulcers may respond to antiretroviral therapy (ART), granulocyte–macrophage colony-stimulating factor or thalidomide. Anti-TNF biological therapies may be successful in severe aphthae.

PERIODIC FEVER, APHTHOUS STOMATITIS, PHARYNGITIS AND CERVICAL ADENITIS (PFAPA)

See Chapter 19.

CHRONIC ULCERATIVE STOMATITIS

General aspects

Chronic ulcerative stomatitis (CUS) is a rare disease with an appearance similar to erosive lichen planus, which mainly affects the oral mucosa. CUS is associated with unusual antinuclear antibodies reacting exclusively with squamous epithelia (squamous epithelium-specific antinuclear antibodies; SES-ANA). Sera from CUS patients bind a keratinocyte protein, KET, which is closely related to the *p53* tumour suppressor gene. The *KET* gene is expressed exclusively in epithelia and thymus, and thus may play a role in keratinocyte cell-cycle control. This might explain the specificity of SES-ANA for keratinocytes. However, the antibodies persist after clearance of mucosal lesions, are fixed *in vivo* and also in uninvolved skin and other mucosa, and may appear in patients without CUS. Thus their pathogenic potential remains to be established.

Clinical features

CUS mainly affects older females. The clinical appearances are similar to erosive lichen planus (see earlier) and it seems likely that many cases of CUS have been misdiagnosed clinically as lichen planus.

General management

Antimalarials are highly effective initially. Relapses usually respond only to combined therapy with chloroquine and small doses of corticosteroids.

INFLAMMATORY DENTAL DISEASE: RELATIONSHIP WITH SYSTEMIC DISEASE

Increasing evidence supports, but does not prove, an association between periodontal infection and various systemic diseases, especially with atherosclerotic cardiovascular disease or its sequelae, and possibly other conditions. The possible mechanisms behind these associations ultimately include increased systemic inflammation due to periodontal diseases and/or dissemination of bacteria and direct damage on endothelium and other target organs. There is some evidence supporting links with pre-eclampsia, pre-term and low-birthweight babies, endometriosis, ischaemic heart disease, cerebrovascular disease, aspiration pneumonia, diabetes mellitus, metabolic syndrome, chronic kidney disease, osteoporosis, Alzheimer disease, pancreatic cancer, kidney cancer, haematological cancers and even oral cancer. It is possible that endodontic infections have similar associations, as chronic inflammatory lesions following carious lesions could both trigger a systemic inflammatory state as well as induce short-lived bacteraemias (for this vast topic, see Chapple and Hamburger, 2006).

APPENDIX 11.1 CONGENITAL ORAL AND INTESTINAL DISORDERS

Syndrome	Cutaneous and other extraintestinal features	Gastrointestinal lesions
Cowden syndrome	Skin nodules Breast malignancy	Polyps
Gardner syndrome (familial adenomatous polyposis coli)	Osteomas of jaws (especially mandible), epidermal cysts, sebaceous cysts, lipomas, fibroma, dental anomalies	Colon polyps, adenocarcinomas, biliary neoplasia
Multiple endocrine adenoma (MEA) III	Ch. 6	Mucosal neuromas
Peutz-Jeghers syndrome	Pigmented macules of mouth, lips and digits Risk of neoplasia	Small intestine polyps and carcinoma rarely
Tylosis	Hyperkeratosis of palms and soles	Oral leukoplakia Oesophageal carcinoma

KEY POINTS

- Chronic kidney disease is common and often undiagnosed
- Dialysis and transplants are common treatments

The kidneys (nephrons) have many functions, especially fluid and electrolyte balance, waste removal, acid–base balance, vitamin D metabolism and stimulation of erythrocyte production. The kidney makes urine by filtering small molecules and ions from the blood and then reclaiming useful materials such as glucose (Fig. 12.1). The nephron consists of a Bowman's capsule, glomerulus (a capillary network within Bowman's capsule), proximal convoluted tubule, loop of Henle, and distal convoluted and collecting tubules (Table 12.1).

The kidneys constantly pass urine through the ureters to the bladder; it is stored in the bladder to be passed from time to time via the urethra (Fig. 12.2). Nearly a quarter of the blood volume perfuses the kidneys each minute. The glomerular filtration rate (GFR) can be calculated from creatinine clearance, inulin clearance, or clearance of isotopes, such as ^{125}I -iothalamate, ^{51}Cr -EDTA (ethylenediamine tetra-acetic acid) or $^{99\text{m}}\text{Tc}$ -DPTA (diethylenetriamine penta-acetic acid), or plasma creatinine levels; it is increasingly expressed as an estimate calculated by using the Modification of Diet in Renal Disease (MDRD) study equation, which takes into account patient age, gender and serum creatinine level. In health, the GFR is around 120 mL/min per 1.73 m^2 for women and 130 mL/min per 1.73 m^2 for men. In population terms, this declines by 1–2 mL/min per year over the age of 20 years. The kidneys also act in the excretion of drugs and hormones, and as endocrine organs for the synthesis of hydroxycholecalciferol (active vitamin D), erythropoietin, renin and prostaglandins, and as target organs for parathyroid hormone and aldosterone.

Renal failure can come on suddenly (acute renal failure; ARF), as after surgery or severe injuries, or when renal blood vessels become obstructed, but more usually develops slowly (chronic renal failure, CRF; chronic kidney disease, CKD). Renal failure results in fluid retention, acidosis, accumulation of metabolites and drugs, damage to platelets (leading to a bleeding tendency), hypertension, anaemia and endocrine effects.

ACUTE RENAL FAILURE

Acute renal failure can be caused by pre-renal, renal or post-renal factors:

- *Pre-renal factors* (55%) include: hypotension (haemorrhage or severe burns), renal thrombosis, sepsis, dehydration, heat stroke or drugs, e.g. non-steroidal anti-inflammatory drugs (NSAIDs), fluoroquinolones, androgen-deprivation therapy and angiotensin-converting enzyme inhibitors (ACEIs). Clarithromycin given to patients on antihypertensive calcium-channel blockers may cause acute kidney injury, hypotension, and even death.
- *Renal factors* (15%) include: interstitial nephritis; toxic acute tubular necrosis; complicated surgery or trauma (myoglobin

blocks tubular function); drugs – contrast dyes used in arteriography, antibiotics (especially streptomycin, gentamicin or amphotericin), aspirin and other NSAIDs, paracetamol (acetaminophen) overdose; toxins (betel, heavy metals, solvents); multiple organ failure, in which the heart, lungs, liver, brain and kidneys totally or partially shut down (most often the result of major trauma or sepsis); the haemolytic–uraemic syndrome, which is caused in children by *Escherichia coli* O157:H7 (which expresses verotoxin – also called Shiga toxin) and in adults by HIV, antiphospholipid syndrome, post-partum renal failure, malignant hypertension, scleroderma or cancer chemotherapy.

- *Post-renal factors* include: obstructed urine flow.

ARF is a medical emergency, which may lead to confusion, seizures and coma. Management is often by dialysis.

CHRONIC KIDNEY DISEASE (CKD; CHRONIC RENAL DISEASE)

General aspects

Chronic kidney disease is defined as kidney damage, or a reduction in the GFR, for 3 or more months. All individuals with a GFR of less than 90 mL/min per 1.73 m^2 for 3 months are classified as having CKD, if there is also proteinuria or haematuria. They are at increased risk of loss of kidney function and development of cardiovascular disease (Table 12.2).

Historically, CKD has been classified according to the part of the renal anatomy involved, as follows:

- *Vascular*, which includes disease of large vessels (e.g. bilateral renal artery stenosis) or small vessels (e.g. ischaemic nephropathy, haemolytic–uraemic syndrome, vasculitis)
- *Glomerular*, a diverse group subclassified into disease that is primary (e.g. focal segmental glomerulosclerosis, immunoglobulin A [IgA] nephritis) or secondary (e.g. diabetic nephropathy, lupus nephritis)
- *Tubulointerstitial*, which includes polycystic kidney disease, drug- and toxin-induced chronic tubulointerstitial nephritis and reflux nephropathy
- *Obstructive*, as with renal or bladder stones and prostate diseases.

CKD is said to be present when damaged kidneys perform their functions less well, causing waste substances such as urea to accumulate and leading to other issues. CKD is not a specific disease. The most common causes (75% of all adult cases) are diabetes, hypertension and glomerulonephritis. Renal diseases (e.g. chronic glomerulonephritis, polycystic renal disease, renal artery stenosis), systemic diseases (lupus erythematosus, myeloma, amyloid), poisoning (e.g. lead or betel) and drugs (e.g. long-term use of aspirin or other NSAIDs, or large amounts of paracetamol [acetaminophen]) are other causes.

CKD is more common among women than men. In men, it is 50% more likely than in women to progress to renal failure. It is seen in 35% of people aged 20 years or older with diabetes, and 20% of people aged 20 years or older with hypertension. Since diabetes and hypertension are both common in people of South Asian and of African heritage, such individuals have a high prevalence of CKD.

Fig. 12.1 Diagram of renal tubular structure. ADH = antidiuretic hormone; Cl⁻, chloride; H₂O = water; H⁺, hydrogen; K⁺, potassium; Na⁺ = sodium; NaCl = sodium chloride; NaHCO₃ = bicarbonate.

Table 12.1 The kidney: constituents and functions

Proximal convoluted tubule	Loop of Henle	Distal convoluted tubule	Collecting tubule
Actively reabsorbs glucose, amino acids, uric acid and inorganic salts Active transport out of Na ⁺ controlled by angiotensin II Active transport of phosphate (PO ₄ ³⁻) suppressed by parathyroid hormone Water follows by osmosis	Water continues to leave by osmosis	More Na ⁺ is reclaimed by active transport, and still more water follows by osmosis	Final adjustment of body Na ⁺ and water content Surplus or waste ions and molecules flow out as urine

Fig. 12.2 Genitourinary anatomy.

Other risk factors include cardiovascular disease, obesity, hypercholesterolaemia and a family history of CKD. Inadequately controlled diabetes and hypertension increase the risk of progression of CKD to kidney failure. Repeated kidney injury (e.g. infections, drugs or toxins injurious to the kidney) can also contribute to progression to kidney failure, especially in older people. CKD is usually irreversible and progressive and can lead to end-stage renal disease (ESRD; renal failure), through five stages defined by the National Kidney Foundation (see [Table 12.2](#)). CKD can be compensated by structural and functional hypertrophy of surviving nephrons, to a point at which around 50% of renal function remains, when chronic renal insufficiency ensues. This inevitably progresses to ESRD.

Clinical features

People with early CKD often have no symptoms; at this point, only a blood test to estimate kidney function and a urine test to assess kidney damage will help the diagnosis. Only when kidney function has fallen to less than 25% of normal do nocturia and anorexia appear, and

Table 12.2 Stages of chronic kidney disease

Stages ^a	Renal health	GFR mL/min/1.73 m ²	Features
–	Normal	130	–
1	Diminished renal reserve (early CKD)	>90	Abnormalities in blood or urine tests or imaging studies but few overt symptoms
2	Mild CKD (azotaemia)	60–89	Abnormalities in blood or urine tests or imaging studies
3	Moderately severe	30–59	Abnormalities in blood or urine tests or imaging studies
4	Severe CKD	15–29	Uraemic symptoms
5	End-stage renal failure (ESRF), also called end-stage renal disease (ESRD), chronic kidney failure (CKF) or chronic kidney disease (CKD)	<15	Life-threatening and requires some form of renal replacement therapy

^aStages are based on estimated glomerular filtration rate (eGFR): National Kidney Foundation. *Am J Kidney Dis* 2002; 39(2 Suppl 1):S1.

Table 12.3 Laboratory features of chronic kidney disease

Urea	Creatinine	Potassium	Phosphate	Calcium	Haemoglobin
Raised	Raised	Normal or Raised	Raised	Low	Low

serum levels of nitrogenous compounds (urea) become raised (azotaemia or uraemia). Later, problems such as cardiovascular disease (heart attacks, heart failure, heart rhythm disturbances and strokes), anaemia and bone disease cause clinical features.

Leading causes of ESRD are diabetes and hypertension. Less common causes include glomerulonephritis, hereditary kidney disease, and malignancies such as myeloma.

Premature death from both cardiovascular disease and from all causes is higher in adults with CKD compared to adults without CKD.

CKD can be associated with fluid overload, sodium and potassium imbalances, bone and mineral disorders, and anaemia. Advanced CKD causes significant impairment of all renal functions, affects virtually all body systems, and causes changes in urea and electrolytes and other blood constituents (Table 12.3; Fig. 12.3). CKD can manifest in a range of clinical features (Table 12.4). Purpura and a bleeding tendency may appear from abnormal platelet production (a consequence of diminished thrombopoietin production); diminished platelet factor 3 (thromboxane), which impairs conversion of prothrombin to thrombin; raised prostacyclin (prostaglandin I), leading to vasodilatation and poor platelet aggregation; and defective von Willebrand factor. Hypertension is common. Anaemia is frequently found and is caused by toxic suppression of the bone marrow, lack of renal production of erythropoietin and/or iron deficiency, from blood loss in the gut. A tendency to infection arises because of defective phagocyte function, which results from reduced interleukin-2 (IL-2) and increases in pro-inflammatory cytokines (IL-1, IL-6, tumour necrosis factor [TNF]).

Renal osteodystrophy is common; phosphate retention leads to depression of plasma calcium levels and subsequently raised parathyroid activity (secondary hyperparathyroidism). There is also deficiency of renal production of 1,25-dihydroxycholecalciferol (vitamin D₃) and calcium absorption is thereby impaired. Parathyroid hyperplasia may eventually become adenomatous and irreversible (tertiary hyperparathyroidism).

General management

CKD is diagnosed by clinical history and presentation, and by rising plasma urea (in the USA, blood urea nitrogen; BUN) and creatinine levels and a falling GFR, which is increasingly expressed as an estimate (eGFR; calculated by using the Modification of Diet in Renal Disease [MDRD] equation, which takes into account patient age, gender and serum creatinine level). There is also a correction that can be applied for those of Afro-Caribbean background.

**Fig. 12.3** Chronic kidney disease.

The decline in eGFR can be plotted over time, allowing accurate prognosis (such as timing of requirement for dialysis, creation of arterio-venous fistulae, etc.). It also allows for demonstration of effects of therapy, the most important of which is control of blood pressure – by using ACEIs and angiotensin II blockers (ARBs). Underlying causes of CKD should be treated where possible and any stress, infection or urinary tract obstruction should be dealt with, as this may precipitate symptoms. The treatment goal is to slow down or halt the progression of CKD to stage 5, measured by a falling eGFR and rising plasma urea and rising creatinine levels, and aimed at reducing cardiovascular risk, which is the main cause of mortality. A normal diet (low-protein diets are now rarely

Table 12.4 Clinical features of chronic kidney disease

Blood and immune	Cardiovascular	Gastrointestinal	Neuromuscular	Metabolic and endocrine	Skin
Bleeding	Hypertension	Anorexia	Weakness and lassitude	Nocturia and polyuria	Pruritus
Anaemia	Congestive cardiac failure	Nausea and vomiting	Drowsiness leading to coma	Thirst	Bruising
Lymphopenia	Pericarditis	Hiccoughs	Headaches, confusion	Glycosuria	Hyperpigmentation
Liability to infections	Cardiomyopathy	Peptic ulcer and gastrointestinal bleeding	Disturbances of vision	Raised urea, creatinine, lipids and uric acid	Infections
	Atheroma, peripheral vascular disease		Sensory disturbances	Electrolyte disturbances	
			Tremor	Secondary hyperparathyroidism	
				Renal osteodystrophy	
				Impotence, amenorrhoea, infertility	

advocated); potassium restriction; and salt or water control are used. As cardiovascular risk is high in patients with low GFR, management includes statins, aspirin, smoking cessation and other measures (Ch. 5).

Symptoms and complications, such as hiccough, vomiting, fits and calcium loss, are treated. Iron stores are replenished using iron and epoietin (recombinant erythropoietin) or darbepoietin, which has a longer half-life. Calcium carbonate, vitamin D₃ or its synthetic analogue, a low-phosphate diet or intravenous clodronate help inhibit bone resorption. Cinacalcet, which reduces parathyroid hormone, may be used. Parathyroidectomy may be necessary in cases of tertiary hyperparathyroidism (Ch. 6). A bisphosphonate may be needed for the management of renal osteodystrophy.

Drug therapy requires certain cautions. Dosages of drugs cleared renally, such as penicillins, cephalosporins and erythromycin, should be reduced based on renal function (Table 12.5). The least nephrotoxic agents should be used (NSAIDs or tetracyclines should be avoided), and alternative medications should be prescribed if necessary to avoid potential drug interactions. Clinicians should be aware of drugs with active metabolites that can exaggerate pharmacological effects in patients with CKD. Patients with CKD should also be asked about over-the-counter and herbal medicine use.

CKD can be treated through medication and lifestyle changes to slow disease progression, and to prevent or delay the onset of kidney failure. However, the only treatment options for kidney failure/ESRD are dialysis or a renal transplant. When the patient reaches stage 5 CKD (end-stage renal failure; ESRF), renal replacement therapy is required – dialysis or transplantation.

Dialysis

There are two primary types of dialysis – peritoneal dialysis and haemodialysis.

Peritoneal dialysis (PD) works on the principle that the peritoneal membrane can act as a natural semi-permeable membrane. Dialysis fluid is instilled via a catheter (often a Tenckhoff catheter) placed near the umbilicus, into the abdominal cavity (Fig. 12.4) or tunnelled under the skin from near the sternum (called a pre-sternal catheter). PD has advantages since it is relatively easy to learn, fluid balance is usually easier than on haemodialysis, it is usually done at home and it is relatively easy to travel with (e.g. dialysis solution bags can be transported); though less efficient than haemodialysis, it is as beneficial overall, since it is performed more frequently. Continuous ambulatory peritoneal dialysis (CAPD) has around 4–5 manual changes daily, while with continuous cyclic peritoneal dialysis (CCPD) a machine does the exchanges at night. Intermittent peritoneal dialysis (IPD) uses

the same type of machine as CCPD; if done overnight, it is called nocturnal intermittent peritoneal dialysis (NIPD). Control of infection is of paramount importance. PD carries the risk of peritonitis (as well as fluid leaks into the tissues and hernias). Infections of the PD catheter's exit site or 'tunnel', however, are less serious.

Haemodialysis (HD) is used to remove metabolites (e.g. urea, potassium) and excess water, by exposing the patient's blood across a semi-permeable membrane to a hypotonic solution to allow the diffusion and osmosis of solutes and fluid from the body. The dialysis solution has levels of minerals like potassium and calcium that are similar to their natural concentration in healthy blood. For another solute, bicarbonate, the dialysis solution level is set slightly higher than that in normal blood, to encourage diffusion of bicarbonate into the body and thus to neutralize the metabolic acidosis often present. HD is often carried out at home or as an outpatient. Optimal effects are from 5–7 dialysis sessions of 6–8 hours each per week, but most patients have two or three 3–6-hourly sessions per week. An arteriovenous fistula is usually created surgically above the wrist to facilitate the introduction of infusion lines (Fig. 12.5); alternatively, a Gortex or polytetrafluoroethylene (PTFE) graft is placed, or an indwelling tunnelled cuffed catheter used. The patient is heparinized during dialysis to keep both the infusion lines and the dialysis machine tubing patent and the patient's blood is passed through an extracorporeal circulation (Fig. 12.6).

Dialysis can totally rehabilitate up to 20% of patients but cannot prevent all complications, and is itself associated with some adverse effects (collectively referred to as dialysis 'hangover' or 'washout'). These features are caused by removing fluid too rapidly or to excess, and may include:

- Hypotension
- Cramps
- Febrile reactions
- Arrhythmias
- Haemolysis
- Hypoxaemia.

Other and longer-term adverse effects include worsened ischaemic heart disease, cardiac valve calcification (especially affecting the aortic valve), dialysis-related amyloidosis and neuropathies. Cardiovascular disease and infection are the leading causes of death. In addition, haemodialysis may mechanically damage platelets – creating an additional bleeding tendency.

HD grafts and catheters may be at risk of infection, and bacterial endocarditis, osteomyelitis, blood-borne virus infections (mainly hepatitis or HIV) and tuberculosis were common in the past. Patients who

Table 12.5 Drug modification in patients with chronic kidney disease^a

	Usually safe (no dosage change usually required)	Fairly safe (dosage change only in severe CKD)	Less safe (dosage reduction indicated ^b even in mild CKD)	Avoid (best avoided in any patient with CKD)
Anaesthetics	Lidocaine	Prilocaine, articaine	–	–

Antimicrobials	Azithromycin Cloxacillin Doxycycline Flucloxacillin Fucidin Minocycline Rifampicin	Ampicillin Amoxicillin Benzylpenicillin Clindamycin Co-trimoxazole Erythromycin Ketoconazole Lincomycin Metronidazole Phenoxymethyl penicillin	Aciclovir ^c Cephalosporins ^d Ciprofloxacin Fluconazole Levofloxacin Ofloxacin Vancomycin	Aminoglycosides Carbenicillin Cefadroxil Cefalexin Cefixime Cefalotin Gentamicin Imipenem/cilastatin Itraconazole Sulphonamides Tetracyclines ^e Valaciclovir
Anticonvulsants			Carbamazepine Gabapentin Lamotrigine	
Sedatives	Diazepam Midazolam			

^aMany other drugs unlikely to be used in oral health care may be contraindicated; check the formulary. Gadolinium-containing contrast agents are contraindicated as they may cause nephrogenic system fibrosis. Clarithromycin should not be prescribed for patients already taking antihypertensive calcium-channel blockers.
^bSevere CKD – glomerular filtration rate (GFR) < 10 mL/min; moderately severe CKD – GFR < 25 mL/min; mild CKD – GFR < 50 mL/min.
^cSystemic aciclovir.
^dExcept cephaloridine and cefalotin, which are contraindicated.
^eExcept doxycycline and minocycline.

Fig. 12.4 Peritoneal dialysis.

undergo haemodialysis still have a higher risk of infection, due to the following:

- Frequent use of catheters or insertion of needles
- Compromised immunity
- Frequent hospital stays and surgery.

Fig. 12.5 Arteriovenous anastomosis (shunt) for haemodialysis.

In order to take some basic steps to prevent infections in HD patients, staff should:

- clean hands before and after every patient contact
- wear gloves and other personal protective equipment (PPE) for all patient care
- promote vascular access safety
- promote fistula use
- improve catheter care
- remove catheters
- separate clean areas from contaminated areas
- use medication vials safely
- clean and disinfect the dialysis station between patients
- perform safe handling of dialysers.

Fig. 12.6 Haemodialysis.

Haemofiltration

In haemofiltration, the blood is pumped through a 'haemofilter', as in dialysis; rather than a dialysate being used, however, a pressure gradient is applied. Water thus moves across the very permeable membrane rapidly, facilitating removal of metabolites, especially those with large molecular weights that are cleared less well by haemodialysis. The salts and water lost from the blood during haemofiltration are replaced with a 'substitution fluid' infused into the extracorporeal circuit during the treatment.

Haemodiafiltration combines haemodialysis and haemofiltration in one process.

Renal transplantation

See below.

Dental aspects of chronic kidney disease

In CKD there is a correlation between tooth loss and the proportion of patients with low protein and calorie intake. Oral disease is common, especially periodontitis, and preventive measures may be lacking. Oral hygiene measures are important. The haematologist should first be consulted about the bleeding tendency; dental treatment is usually best carried out on the day after dialysis, when there has been maximal benefit from the dialysis and the effect of the heparin has abated. Careful haemostasis should be ensured if surgical procedures are necessary (Ch. 8). Should bleeding be prolonged, desmopressin (DDAVP) may provide haemostasis for up to 4 hours. If this fails, cryoprecipitate may be effective; it has a peak effect at 4–12 hours and lasts up to 36 hours. Conjugated oestrogens may aid haemostasis; the effect takes 2–5 days to develop but persists for 30 days.

Infections are poorly controlled by the patient with CKD, especially if immunosuppressed, and may spread locally as well as giving rise to septicaemia. They also accelerate tissue catabolism, causing clinical deterioration, and there is some evidence that periodontitis can perpetuate inflammation in CKD. Tuberculosis is also more frequent, but is usually extrapulmonary and therefore does not constitute a risk to dental staff. Infections can be difficult to recognize, as signs of inflammation are masked. Haemodialysis predisposes to blood-borne viral infections, such as hepatitis viruses. Odontogenic infections should be treated vigorously (see Table 12.5). Erythromycin, particularly when prescribed to patients with CKD, has been associated with reversible hearing loss. Flucloxacillin and fucidin can be given in standard dosage. Patients with CKD receiving doxycycline, azithromycin, sparflaxacin, trovafloxacin, and grepafloxacin require no alteration of dosage. Tetracyclines can worsen nitrogen

retention and acidosis, and are best avoided, though doxycycline or minocycline may be given. Benzylpenicillin has significant potassium content and may be neurotoxic; penicillins (other than phenoxymethyl penicillin and flucloxacillin) and metronidazole should be given in lower doses, since high serum levels can be toxic to the central nervous system.

Vascular access infections are usually caused by skin organisms such as *Staphylococcus aureus* and only rarely by oral microorganisms; thus patients with most arteriovenous fistulas are not considered at risk from infection during dental treatment and not considered to require antimicrobial prophylaxis. Patients with indwelling intraperitoneal catheters are also not considered to need antimicrobial prophylaxis. Before having dental extractions, scaling or periodontal surgery, patients with CKD may be considered for antimicrobial prophylaxis, especially those with renal transplants (Ch. 35), those with polycystic kidneys (who may also have mitral valve prolapse), those on PD, or those on HD with prosthetic bridge grafts of PTFE or tunnelled cuffed catheters. One regimen is to give 400 mg teicoplanin intravenously during dialysis, which gives cover for at least a day.

Drugs excreted mainly by the kidney may have undesirably enhanced or prolonged activity if doses are not lowered, depending on the degree of renal failure, the dialysis schedule or the presence of a transplant. Except in an emergency, such drugs should be prescribed only after consultation with the renal physician. Drugs that are directly nephrotoxic must be avoided (see Table 12.5). Aspirin (often a 75 mg dose will already be being given as prophylaxis against cardiovascular disease) and other NSAIDs should be avoided, since they aggravate gastrointestinal irritation and bleeding associated with CKD. Their excretion may also be delayed and they may be nephrotoxic, especially in the older patient or where there is renal damage or cardiac failure. Some patients have peptic ulceration – a further contraindication to aspirin. Even cyclo-oxygenase (COX)-2 inhibitors may be nephrotoxic and are best avoided. Use of NSAIDs is linked to a risk for ARF, nephrotic syndrome with interstitial nephritis, and CKD. Sodium excretion is reduced and can lead to peripheral oedema, elevated blood pressure and exacerbation of heart failure. Antihypertensive effects of beta-blockers, ACEIs or ARBs can be decreased. Short-term NSAID use is well tolerated if the patient is well hydrated and has good renal function and no heart failure, diabetes or hypertension. Serum creatinine should be checked every 2–4 weeks in early treatment.

Antihistamines or drugs with antimuscarinic side-effects may cause dry mouth or urinary retention. In patients undergoing haemodialysis, there may be: difficulties in chewing, swallowing, tasting and speaking; increased risk of oral disease, including lesions of the mucosa, gingiva and tongue; bacterial and fungal infections, such as candidiasis, dental caries and periodontal disease; interdialytic weight gain resulting from increased fluid intake; and a reduction in quality of life. Unfortunately, there is no effective treatment for hyposalivation in patients on chronic haemodialysis. Uraemic stomatitis is now a rare complication of CKD (Fig. 12.7).

Systemic fluorides should not be given because of doubt about fluoride excretion by damaged kidneys, but they can usually be used safely as a topical treatment for caries prophylaxis. Antacids containing magnesium salts should not be given, as there may be magnesium retention. Antacids containing calcium or aluminium bases may impair absorption of penicillin V and sulphonamides. Colestyramine, sometimes used in CKD, may also interfere with the absorption of penicillins.

Consideration must also be given to the effect on dental care of underlying diseases, such as hypertension (Ch. 5), diabetes (Ch. 6), systemic lupus erythematosus (Ch. 16), polyarteritis nodosa (Ch. 5), myelomatosis (Ch. 8) and amyloidosis (Ch. 8), or complications such as peptic ulceration (Ch. 7). Major surgical procedures may be complicated by hyperkalaemia as a result of tissue damage, acidaemia and blood transfusion, which predisposes to arrhythmias and may cause

Fig. 12.7 Uraemic stomatitis in chronic kidney disease.

cardiac arrest. Dialysis is deferred postoperatively if possible, since heparinization is required.

Local anaesthesia (LA) is safe unless there is a severe bleeding tendency. For conscious sedation (CS), relative analgesia is preferred, since the veins of the forearms and the saphenous veins are lifelines for patients on regular haemodialysis. If it is necessary to give intravenous sedation or to take blood, other veins, such as those at or above the elbow, should be used because of the risk of consequent fistula infection or thrombophlebitis. Never put a cannula into the arteriovenous fistula arm. Midazolam is preferable to diazepam because of the lower risk of thrombophlebitis.

General anaesthesia (GA) is contraindicated if the haemoglobin is below 10 g/dL. Patients are also highly sensitive to the myocardial depressant effects of anaesthetic agents, and may develop hypotension at moderate levels of anaesthesia. Myocardial depression and cardiac arrhythmias are especially likely in those with poorly controlled metabolic acidosis and hyperkalaemia. Enflurane is metabolized to potentially nephrotoxic organic fluoride ions and therefore should be avoided if other nephrotoxic agents are used concurrently. Isoflurane and sevoflurane are probably safer. Induction with thiopental followed by very light GA with nitrous oxide is generally the technique of choice.

Although data are conflicting, most studies show that dental health of CKD patients is comparable with that of controls but there is more periodontal disease. Secondary hyperparathyroidism does not have an appreciable effect on periodontal indices and radiographic bone height. Osseous lesions include loss of the lamina dura, osteoporosis and osteolytic areas (renal osteodystrophy). Secondary hyperparathyroidism may lead to giant cell lesions. There may be abnormal bone repair after extractions, with socket sclerosis. Patients with renal disease should therefore be screened carefully for bone disease before implant placement. Dry mouth, halitosis and a metallic taste, and insidious oral bleeding and purpura can also be conspicuous. The salivary glands may swell, salivary flow is reduced, and there are protein and electrolyte changes, and calculus accumulation. In children with CKD, jaw growth is usually retarded and tooth eruption may be delayed. There may be malocclusion and enamel hypoplasia with brownish discolouration, but tetracycline staining of the teeth should no longer be seen. A lower caries rate and less periodontal disease have been reported in children with CKD. A variety of mucosal lesions may be seen. The oral mucosa may be pale because of anaemia and there may be oral ulceration.

THE NEPHROTIC SYNDROME

General aspects

The nephrotic syndrome is a non-specific condition in which glomerular damage (usually because of minimal change disease, diabetic

nephropathy or systemic lupus erythematosus) leads to massive proteinuria with hypoalbuminaemia and oedema.

Clinical features

Oedema affects especially the face, genitals and lower limbs, and there are transudates in serous cavities (especially the peritoneal cavity – ascites). Loss of immunoglobulins (especially IgG) in the urine predisposes to infections with encapsulated bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Loss of antithrombin III, with raised factor VIII, fibrinogen and other clotting factors, leads to hypercoagulability – predisposing to thromboses. Loss of cholecalciferol-binding protein leads to vitamin D deficiency, secondary hyperparathyroidism and bone disease. In response to albumin loss, the liver synthesizes more of its proteins and levels of large proteins (such as alpha₂-macroglobulin and lipoproteins) increase. Patients also develop hypercholesterolaemia and become susceptible to atheroma and ischaemic heart disease.

General management

Treatment aims to reduce proteinuria, control infections and prevent thromboembolism, and to remove or treat the basic cause of nephrosis. Many of the considerations in the management of the patient with CKD are also applicable to the nephrotic patient. Corticosteroids, a low-salt but high-protein diet, warfarin and prophylactic antimicrobials may be given.

Dental aspects

Long-term corticosteroid therapy is the main problem (Ch. 6). Prophylactic antimicrobials may be indicated for procedures likely to cause a bacteraemia. Cardiovascular and haematological disorders and anticoagulation may complicate care (Ch. 8).

RENAL STONES (NEPHROLITHIASIS)

Renal stones (calculi) are not uncommon and may cause symptoms of renal colic or secondary renal damage; 90% can be seen on radiography. Systemic disease is rarely identified as underlying renal stones, but they may complicate gout, hyperparathyroidism, hyperoxaluria, cystinosis or renal tubular acidosis. A recent outbreak in China was related to melamine contamination of milk. There is no known predisposition to salivary calculi or dental calculus formation in patients who develop renal stones. An enamel-renal syndrome of amelogenesis imperfecta and nephrocalcinosis, and the amelogenesis imperfecta-gingival fibromatosis syndrome have both been associated with mutations in FAM20A. Renal calculi are treated by lithotripsy or surgical removal.

RENAL CANCER

Most kidney cancers (90%) are adenocarcinomas – renal cell cancers. Transitional cell cancer is rare. It is rare for people under 40 to have renal cancer, but the rare Wilms tumour (nephroblastoma) affects very young children. Renal cancer affects more men than women. Risk factors are shown in [Box 12.1](#).

Clinical features

Renal cancer may be symptomless but blood in the urine is the most common feature. There can be pain or a lump in the area of the kidney, or persistent fevers, night sweats, tiredness and weight loss.

Box 12.1 Risk factors for renal cancer

- Cigarette smoking
- Dialysis
- Heredity: von Hippel–Lindau disease
- Hypertension
- Obesity
- Occupation (working in the steel and coal industries with blast furnaces or coke ovens, or exposure to cadmium, lead or asbestos)

General management

Diagnosis is confirmed by cystoscopy, ultrasound, computed tomography/magnetic resonance imaging, intravenous urography and biopsy. The main treatment is surgery, usually nephrectomy. Other treatments may include biological treatments (interferon-alpha or the IL-2 analogue aldesleukin) or targeted treatments (the multikinase inhibitors sorafenib or sunitinib, or bevacizumab or temsirolimus). Occasionally, radiotherapy or chemotherapy is used, or hormones.

Dental aspects

Renal cancer occasionally metastasizes to the jaws or mouth.

RENAL TRANSPLANTATION

Transplantation is now recommended for patients with ESRD who are medically suitable, since a successful transplant offers enhanced quality and duration of life, and is more effective (medically and economically) than chronic dialysis. Transplantation is the renal replacement modality of choice for child patients and for patients with diabetic nephropathy.

Outcomes are improved by 'pre-emptive' live donor transplantation – using a kidney from an unaffected relative and performing the transplant before the patient needs to have dialysis. Transplants can be from cadaveric or living donors. Graft survival is as high as 90% at 1 year and about 70% survival at 5 years, while overall mortality is less than 5%. The transplanted kidney is usually sited in the right iliac fossa of the abdomen.

All kidney transplant recipients require lifelong immunosuppression to prevent a T-cell alloimmune rejection response. Immunosuppressive regimens vary among transplantation centers but most often include a calcineurin inhibitor (CNI) and an adjuvant agent, with or without corticosteroids. The most common maintenance immunosuppressive agents include:

- CNIs (cyclosporin and tacrolimus)
- co-stimulation blockers (belatacept)
- mammalian target of rapamycin (mTOR) inhibitors (sirolimus and everolimus)
- antiproliferatives (azathioprine and mycophenolic acid derivatives)
- corticosteroids.

Alemtuzumab, basiliximab or daclizumab is increasingly used, with a CNI. Systemic complications of transplantation include transplant rejection, increased risk of atheroma and ischaemic heart disease, cyclosporin-induced nephropathy and immunosuppression-induced infection or malignancy (Ch. 35).

Dental aspects of renal transplantation

See also above and Chapter 35.

Any oral sign of infection must be examined immediately and treated aggressively in an immunosuppressed transplant recipient. There should be careful observation to detect any malignant complications. Drug-induced gingival overgrowth (DIGO) is commonly caused by ciclosporin or nifedipine. Oral ulceration may be caused by sirolimus and everolimus. Dental pulp narrowing has been noted – apparently a corticosteroid effect.

Consideration should also be given to haematological abnormalities, such as anaemia and platelet–haemostatic dysfunction; viral hepatitis B and C; and cardiovascular disorders such as hypertension, atherosclerotic heart disease with myocardial infarction, congestive heart failure, and left ventricular hypertrophy. Bone and joint disease is common because of low calcium levels, high phosphorus concentrations and elevated serum parathyroid hormone.

LA is safe unless there is a severe bleeding tendency. For CS, relative analgesia is preferred. If it is necessary to give intravenous sedation, midazolam is preferable to diazepam because of the lower risk of thrombophlebitis.

KEY POINTS

- Neurological disorders often lead to significant disability
- Headaches are common and usually inconsequential but can signify life-threatening disease
- Stroke is a common cause of collapse, disability and death

The central nervous system (CNS) consists of the brain and spinal cord. The brain is the chief regulator of neuroendocrine, autonomic and immune systems, as well as behaviour. The brain contains the cerebral motor and sensory cortices essential for life, and other areas have specialized functions (Tables 10.1, 13.1 and 13.2; Figs 10.1, 13.1 and 13.2). Brain damage can lead to motor and/or sensory defects, variable disability, or even to loss of consciousness and/or death.

Table 13.1 Functions of main parts of the brain

Part of brain	Known functions
Cerebral lobe	
Frontal	Higher mental functions, such as motivation, planning, social behaviour and speech production
Occipital	Visual processing and visual cortex
Parietal	Integration of sensory information from various parts of the body, knowledge of numbers and their relations, manipulation of objects, processing of information relating to the sense of touch, visuospatial processing
Temporal	Auditory perception, such as hearing and language, interpretation of visual stimuli, aiding recognition of long-term memory
Lower brain	
Basal ganglia	Voluntary motor control, procedural learning relating to routine behaviours or 'habits' such as eye movements, cognitive emotional functions
Cerebellum	Motor control, coordination, precision, accurate timing, attention, language, fear and pleasure responses
Brainstem	Basic functions, including regulation of heart rate, breathing, sleeping, eating and central nervous system – pivotal in maintaining consciousness. Main motor and sensory innervation to face, mouth and neck via cranial nerves. Nerve connections of motor and sensory systems from the brain to the rest of the body pass through the brainstem

Table 13.2 Location of the main functions in the cerebral cortex

Frontal lobe	Pre-central gyrus	Post-central gyrus	Superior temporal lobe	Occipital lobe
Olfactory	Motor	Sensory (somatosensory)	Hearing	Vision
Language (on dominant side) and speech (Broca's area)			Word comprehension (Wernicke's area)	

The CNS controls the peripheral nervous system (PNS), which consists of the somatic (SNS) and (ANS) autonomic nervous systems, and extends to the limbs and organs (Fig. 13.3). The SNS is under conscious control and is responsible for receiving external stimuli and for coordinating movement. The ANS consists of the sympathetic, parasympathetic and enteric nervous systems. The sympathetic system responds to danger or stress by release of adrenaline (epinephrine) – increasing anxiety, cardiac rate and output, and other physiological changes. The parasympathetic system is responsible for slowing the

Fig. 13.1 Nervous system.

Fig. 13.2 Brain.

Fig. 13.3 Cervical and thoracic dermatomes.

heart, dilating blood vessels, and stimulating digestive and genitourinary systems. The enteric nervous system controls digestion in the gastrointestinal tract.

The core components of the nervous system are neurons. Action potentials travel down the neuronal axon to open calcium (Ca^{2+}) channels in the plasma membrane, triggering the exocytosis of vesicles containing neurotransmitters, which affect a receiving cell. The main neurotransmitters are acetylcholine (ACh) and noradrenaline (norepinephrine), but there are many others (see [Tables 13.1](#) and [10.3](#)).

ACh at excitatory synapses depolarizes the post-synaptic membrane, causing an excitatory post-synaptic potential and an action potential in the post-synaptic cell. ACh is released at the terminals of all motor neurons activating skeletal muscle, all pre-ganglionic neurons of the ANS and post-ganglionic neurons of the parasympathetic system. ACh also mediates transmission at brain synapses involved in acquisition of short-term memory.

Amino acids such as glutamic acid are involved in CNS transmission at excitatory synapses and are essential for long-term potentiation, a form of memory. Gamma-aminobutyric acid (GABA) at inhibitory synapses hyperpolarizes the post-synaptic membrane, causing an inhibitory post-synaptic potential.

NEUROLOGICAL DISEASE

Patients whose symptoms have a neurological basis are relatively common. Dental professionals may well be involved in the care of these people, especially of those with the most important brain disorders, such as cerebral palsy, epilepsy, cerebrovascular accidents (CVAs; strokes) and facial palsy. The most common neurological complaints are shown in [Box 13.1](#). The role of stress is discussed in Chapter 10.

Orofacial pain is common and may have a neurological cause. Patients with head or maxillofacial injuries may have brain damage with impaired ocular movements or pupil reactions and loss of the sense of smell (anosmia). Dental professionals should therefore be able to examine and recognize gross neurological abnormalities, and especially problems involving the cranial nerves – particularly the trigeminal, facial, glossopharyngeal, vagal and hypoglossal nerves.

Box 13.1 The 12 most common neurological complaints

- Cerebrovascular accidents
- Compressive neuropathies (e.g. carpal tunnel syndrome)
- Diabetic neuropathy
- Epilepsy
- Headaches
- Meningitis
- Multiple sclerosis
- Parkinsonism
- Tremors
- Trigeminal neuralgia
- Tumours
- Zoster

NEUROLOGICAL EVALUATION

The nervous system may need to be evaluated, as in [Table 13.3](#). Mental status can be assessed using a standard screening test, such as the Mini-Mental State Examination (MMSE) or Folstein test (simple questions and problems in a number of areas: the time and place of the test, repeating lists of words, arithmetic, language use and comprehension, and basic motor skills). Testing can also be achieved as shown in [Table 13.4](#).

If cognitive functions seem unaffected, there is no related complaint, and the patient appears, behaves and supplies a history normally, formal cognitive evaluation is not required.

HEADACHES AND OROFACIAL PAIN

Pain is broadly divided into nociceptive pain and neuropathic pain.

Nociceptive pain is caused by actual or potential damage to tissues (e.g. trauma, cut, burn). Nerve endings become activated or damaged by the injury, with pain that tends to be sharp or aching and is often

Table 13.3 *Neurological evaluation*

Aspects	Details	Assessment
Speech	Dysarthria may be detected	
Mental state or higher mental function	See Table 13.4	
Level of consciousness	See Ch. 24	Glasgow Coma Scale is widely used
Cognition	See Table 13.4	
Sensory system	Sensory nerves carry information from the body to the brain about such things as touch, pain, heat, cold, vibration, position of body parts, and shape of objects	Test using a pin and a blunt object to see if the patient can distinguish. Test ability to feel light touch, heat and vibration. Test position sense – move finger or toe up or down and ask the person to describe its position without looking. Dermatomes are shown in Figure 13.3
Motor system	Muscle weakness or paralysis may indicate damage to the muscle, motor nerve or synapse, brain or spinal cord A reflex is an automatic response to a stimulus. Those most commonly tested are the knee jerk, and elbow, ankle and plantar reflexes. The knee jerk tests the pathway consisting of the sensory nerve to the spinal cord, the spinal cord connections, and the motor nerves back to the muscle	Assess muscle size change (increased size or wasting/atrophy); involuntary movements or twitching; strength; and tone changes – increase (spasticity, rigidity) or decrease (flaccidity) The plantar reflex, tested by firmly stroking the outer border of the sole of foot with an object that causes minor discomfort, normally causes toes to curl downward; if the big toe goes upward and other toes spread out, this suggests a brain or spinal cord lesion (except in infants <6 months) The extent of brain injury in a comatose person is tested by noting whether pupils constrict when light is shined on them (pupillary light reflex). Facial sensation and movement are determined by whether eyes blink when the cornea is touched (corneal reflex)
Cerebrum and cerebellum	Gait, coordination and balance testing require integration of signals from sensory and motor nerves by brain and spinal cord	Gait is tested by asking the patient to walk in a straight line, placing one foot in front of the other; walk on heels and then on toes; and then hop on each foot Coordination is tested by asking the patient to use the forefinger to reach out and touch an object, and then their own nose, and then to repeat actions rapidly and then with the eyes closed Balance is assessed by the Romberg test: the patient stands still, with feet together and eyes closed. In health, balance should be retained
Autonomic nervous system (ANS)	–	Test by determining whether blood pressure changes when the person lies, sits or stands (orthostatic hypotension), or if there is a reduction or absence of sweating
Cranial nerves	See Table 13.12	

Table 13.4 *Testing mental status*

Test	Test indicates
Give today's date	Orientation in time, place and person
State the place where you are	
Name specific people	
Name the last three Prime Ministers	Knowledge
Describe an event that happened yesterday	Recent memory
Describe events from schooldays	Remote memory
Interpret a proverb (e.g. 'There's many a slip between cup and lip')	Abstract thinking
Do simple arithmetic	Ability to calculate numbers
Repeat a short list of objects	Attention
Recall the short list of objects after 5 minutes	Immediate recall
Describe feelings and opinions about your illness	Insight
Explain how you feel today	Mood
Comb your hair	Ability to perform action
Name simple objects and body parts	Ability to use language
Identify, without seeing them, small objects held in the hand, and discriminate between being touched in two places	Ability of brain to process and interpret complex information from the hand
Follow simple command involving different body parts on different sides (such as 'put your right thumb in your left ear and stick out your tongue')	Language comprehension
Draw a clock, cube or house	Ability to understand spatial relationships

eased by traditional analgesics such as paracetamol (acetaminophen), non-steroidal anti-inflammatory drugs (NSAIDs) and opioids.

Neuropathic pain (neuralgia) is a pain arising from nerve signal problems and is often persistent, with features such as burning, stabbing, aching or electric shock-like qualities. Neuropathic pain may be experienced in:

- alcoholism
- burning mouth syndrome
- cancer
- chemotherapy pain
- diabetic neuropathy
- human immunodeficiency virus (HIV) infection
- idiopathic (atypical) facial pain
- multiple sclerosis
- phantom pain (follows surgery)
- post-herpetic neuralgia (follows zoster)
- trigeminal neuralgia.

Related to these pains there may also be phenomena including:

- *Allodynia* – Pain starts, or worsens, with a touch or stimulus that would not normally cause pain.
- *Hyperalgesia* – Severe pain is experienced from a stimulus or touch that would normally cause slight discomfort only.
- *Paraesthesia* – Unpleasant or painful feelings are experienced, even when there is no stimulus.

Neuropathic pain is less likely than nociceptive pain to be eased by traditional analgesics but is often improved by:

- antidepressants
- antiepileptics
- capsaicin
- physical treatments (physiotherapy, acupuncture, nerve blocks and transcutaneous electrical nerve stimulation [TENS])
- psychological treatments (stress management, counselling, cognitive behavioural therapy and pain management programmes).

Pain receptors can be stimulated by stress, muscular tension, dilated blood vessels and other triggers. Headache and orofacial pain are the most common neurological complaints; they are often chronic and are mainly caused by local disease, vascular disease, referred pain, neurological disorders or psychogenic disorders (Table 13.5 and Box 13.2). Headaches can also occasionally herald serious brain disorders, such as tumour, infection or bleeding (Box 13.3). Features suggesting serious or life-threatening headaches are shown in Box 13.4.

Some headaches have quite specific and less serious precipitating factors (Table 13.6); foods such as alcohol, caffeine, chocolate, cheeses and nuts can cause headaches in some people and may trigger migraine. About 50% of patients seen in headache clinics are thought to suffer from muscle contraction (tension) headaches, which appear to involve the tightening or tensing of facial and neck muscles because of stress (see Ch. 10 and below). Virtually *all* types of headache are influenced, at least to some extent, by stress, emotional factors and individual personalities.

Table 13.5 Causes of headache and orofacial pain

Cause	Diseases
Local	Dental or oral disease
	Infections or tumours of paranasal sinuses and nasopharynx
	Ocular or aural lesions
	Neck lesions
Vascular	Migraine
	Migrainous neuralgia
	Idiopathic stabbing headache
	Chronic paroxysmal hemicranias
	Temporal arteritis
Neurological	Trigeminal neuralgia
	Glossopharyngeal neuralgia
	Herpetic neuralgia
	Raeder neuralgia
	Intracranial disease: pontine infarction, cerebellopontine angle tumours, middle cranial fossa lesions, cavernous sinus thrombosis, Bell palsy
Psychogenic	Tension headaches
	Oral dysaesthesia
	Idiopathic (atypical) facial pain
	Temporomandibular pain–dysfunction syndrome
Other	Trauma
	Raised intracranial pressure
	Diseases of the skull
	Meningeal irritation
	Drugs (e.g. vinca alkaloids, nitrites, dapsone, some analgesics)
	Referred pain (e.g. heart or chest)
	Medical diseases (e.g. severe hypertension)

Box 13.2 International Headache Society (IHS) classification of headache

1. Migraine
 - 1.1. Migraine without aura
 - 1.2. Migraine with aura
 - 1.3. Ophthalmoplegic migraine
 - 1.4. Retinal migraine
 - 1.5. Childhood periodic syndromes that may be precursors to or associated with migraine
 - 1.6. Complications of migraine
 - 1.7. Migrainous disorder not fulfilling above criteria
2. Tension-type headache
 - 2.1. Episodic tension-type headache
 - 2.2. Chronic tension-type headache
 - 2.3. Tension-type headache not fulfilling above criteria
3. Cluster headache and chronic paroxysmal hemicrania
 - 3.1. Cluster headache
 - 3.2. Chronic paroxysmal hemicrania
 - 3.3. Cluster headache-like disorder not fulfilling above criteria
4. Miscellaneous headaches not associated with structural lesion
 - 4.1. Idiopathic stabbing headache
 - 4.2. External compression headache
 - 4.3. Cold stimulus headache
 - 4.4. Benign cough headache
 - 4.5. Benign exertional headache
 - 4.6. Headache associated with sexual activity
5. Headache associated with head trauma
 - 5.1. Acute post-traumatic headache
 - 5.2. Chronic post-traumatic headache
6. Headache associated with vascular disorders
 - 6.1. Acute ischaemic cerebrovascular disorder
 - 6.2. Intracranial haematoma
 - 6.3. Subarachnoid haemorrhage
 - 6.4. Unruptured vascular malformation
 - 6.5. Arteritis
 - 6.6. Carotid or vertebral artery pain
 - 6.7. Venous thrombosis
 - 6.8. Arterial hypertension
 - 6.9. Headache associated with other vascular disorder
7. Headache associated with non-vascular intracranial disorder
 - 7.1. High cerebrospinal fluid (CSF) pressure
 - 7.2. Low CSF pressure
 - 7.3. Intracranial infection
 - 7.4. Intracranial sarcoidosis and other non-infectious inflammatory diseases
 - 7.5. Headache related to intrathecal injections
 - 7.6. Intracranial neoplasm
 - 7.7. Headache associated with other intracranial disorder
8. Headache associated with substances or their withdrawal
 - 8.1. Headache induced by acute substance use or exposure
 - 8.2. Headache induced by chronic substance use or exposure
 - 8.3. Headache from substance withdrawal (acute use)
 - 8.4. Headache from substance withdrawal (chronic use)
 - 8.5. Headache associated with substances but with uncertain mechanism
9. Headache associated with non-cephalic infection
 - 9.1. Viral infection
 - 9.2. Bacterial infection
 - 9.3. Headache related to other infection
10. Headache associated with metabolic disorder
 - 10.1. Hypoxia
 - 10.2. Hypercapnia

- 10.3. Mixed hypoxia and hypercapnia
- 10.4. Hypoglycaemia
- 10.5. Dialysis
- 10.6. Headache related to other metabolic abnormality
- 11. Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
 - 11.1. Cranial bone
 - 11.2. Neck
 - 11.3. Eyes
 - 11.4. Ears
 - 11.5. Nose and sinuses
 - 11.6. Teeth, jaws and related structures
 - 11.7. Temporomandibular joint disease
- 12. Cranial neuralgias, nerve trunk pain and deafferentation pain
 - 12.1. Persistent (in contrast to tic-like) pain of cranial nerve origin
 - 12.2. Trigeminal neuralgia
 - 12.3. Glossopharyngeal neuralgia
 - 12.4. Nervus intermedius neuralgia
 - 12.5. Superior laryngeal neuralgia
 - 12.6. Occipital neuralgia
 - 12.7. Central causes of head and facial pain other than tic douloureux
 - 12.8. Facial pain not fulfilling criteria in groups 11 or 12
- 13. Headache not classifiable

Box 13.3 Serious causes of headache

- Acute glaucoma
- Acute hypertension
- Acute lesions affecting the carotid vessels
- Brain tumours
- Giant cell arteritis
- Meningitis
- Subarachnoid haemorrhage
- Subdural or epidural haemorrhage

Box 13.4 Indicators of seriousness in headache

- Abrupt, severe 'thunderclap' or bilateral headache
- Confusion, loss of consciousness, convulsions, fever, stiff neck, rash, mental confusion, seizures, diplopia, weakness, numbness, pain in the eye or ear, or dysarthria
- Disruption of normal life
- Follows a recent sore throat or respiratory infection
- New headache pain after age 55
- Persistence in a person who was previously headache-free
- Preceded by head trauma
- Recurrence in children
- Severity of headache
- Worsening after coughing, exertion, straining or a sudden movement

Table 13.6 Some less serious causes of headache

Conditions	Causes
Chinese restaurant syndrome	Monosodium glutamate
Hangover headache	Acetaldehyde
Hot dog headache	Nitrites/nitrates
Post-coital headache	Intercourse
Vitamin A-induced headache	Vitamin A

LOCAL CAUSES OF OROFACIAL PAIN

The mouth

Oral causes of facial pain (e.g. pulpitis, apical periodontitis, periodontal abscesses, pericoronitis and various intraosseous lesions) are common and are discussed in other texts.

The sinuses and nasopharynx

Sinusitis causes localized pain. In acute maxillary or frontal sinusitis, local pain and tenderness (but not swelling), with radio-opacity of the affected sinuses, usually follow a cold (Ch. 14).

Tumours of sinuses or nasopharynx can also cause facial pain. These are rare, usually carcinomas, and involve trigeminal nerve branches; they may cause pain simulating pain-dysfunction syndrome. They can remain undetected until late in their course.

Eagle syndrome, due to calcification of the stylohyoid ligament, may be a rare cause of pain on chewing, swallowing or turning the head. The elongated styloid process may be visualized radiographically, and palpation of it in the wall of the pharynx causes intense pain. The stylohyoid process can be shortened surgically, but regrowth and relapse are common.

The eyes

Glaucoma (raised intraocular pressure) may cause pain in and around the orbit. Disorders of refraction can cause frontal headaches. Retrobulbar neuritis (e.g. in multiple sclerosis) can cause pain in and around the orbit.

The ears

Pharyngeal or middle ear disease may cause headaches. Oral disease can rarely cause pain referred to the ear; the classic picture is that of the older man with tongue cancer whose complaint is earache.

The neck

Cervical vertebral disease occasionally causes headache or pain referred to the face and may aggravate tension headaches. Nerve block with local anaesthesia (LA) may temporarily relieve this pain. Carotidynia is unilateral pain arising from the cervical carotid artery that radiates to the ipsilateral face and ear, and sometimes to the head; it is associated with carotid artery tenderness and overlying soft tissue swelling, and is responsive to corticosteroids.

VASCULAR CAUSES OF FACIAL PAIN

Vasomotor states are responsible for certain headaches; either widening or narrowing of extracranial and intracranial arteries may produce pain. Both vasodilatation and neurogenic inflammation are under the influence of serotonin (5-hydroxytryptamine; 5HT); the 5HT_{1B} receptor controls vasodilatation, whereas 5HT_{1D} regulates neurogenic inflammation.

Serotonin agonists, such as ergotamine and triptans, can prevent neurogenic inflammation.

Migraine

Further information on migraine may be found at: <http://www.disabled-world.com/health/neurology/migraine/> (accessed 30 September 2013).

General aspects

Migraine is a recurrent headache combined with autonomic disturbances, affecting over 14% of women and 7% of men. The prodrome is usually accompanied by diminished cerebral blood flow, possibly the result of a neuronal trigger mechanism in the trigeminovascular nucleus, but the headache itself is usually associated with increased cerebral and extracranial blood flow, possibly caused by serotonin adsorbed to blood vessel walls, since platelet serotonin rises before a migraine headache. This may cause the trigeminal nerve to release neuropeptides; the combination of serotonin and bradykinin may cause blood vessels to become dilated and inflamed.

Clinical features

Migraine triggers can include:

- weather, season, altitude, or time zone changes
- drugs (e.g. cimetidine, fenfluramine, nifedipine and theophylline)
- low blood sugar
- mealtime changes, skipped meals or fasting
- intense physical exertion, including sexual activity
- tobacco
- lack of sleep
- bright lights, loud noises or strong odours
- menstrual cycle hormone changes
- stress, anxiety, or relaxation after stress
- alcohol (often red wine)
- caffeine (excess or withdrawal)
- nitrates, such as in hot dogs and lunch meats
- monosodium glutamate (MSG), a flavour enhancer in fast foods, broths, seasonings and spices
- tyramine, such as in aged cheeses, soy products, broad (fava) beans, hard sausages, smoked fish and Chianti wine. The highest levels of tyramine are in aged cheeses, spoiled meats, aged and cured meats, Marmite®, sauerkraut, fermented soybean products, broad bean pods and draft (tap) beer, but there is little or no tyramine in non-alcoholic beverages, breads, fats, cottage cheese, ricotta, cream cheese, soft farmer's cheese, mozzarella cheese, processed cheese slices, sour cream, yogurt, milk, eggs, tomatoes, fresh meat, poultry, fish, shellfish and soy milk (Table 13.7; see also <http://www.headaches.org/pdf/Diet.pdf>, accessed 30 September 2013).
- aspartame
- botulinum toxin A (Botox) injections.

Large quantities of nuts (peanuts, coconuts and brazil nuts) may trigger hypertensive reactions and headaches, but not via tyramine.

The fact that migraine attacks are more frequent at weekends, for example, should not be interpreted as excluding stress, as there is no doubt that some find the company and demands of their families more stressful than their work. Going away on holiday (Freud's *Reisefieber* – 'travel fever') is also highly stressful for many.

Several types of migraine are recognized (Table 13.8); migraine without aura is the most frequent – presenting with unilateral headache – but migraine with aura is the most readily recognizable.

Classical migraine presents with an aura (warning symptoms), which may last about 15 minutes and consists of visual, sensory, motor or speech disturbances. Visual phenomena are typically of zigzag flickering light (fortification spectra) or other transient visual defects. Sensory phenomena include paraesthesia or anaesthesia – usually of the contralateral upper limb, or face and mouth. Motor symptoms are mainly weakness – again, of the contralateral upper limb. Obvious vascular phenomena may be

Table 13.7 Tyramine in foods

Tyramine-containing	Low in tyramine	Not usually tyramine-containing
All draft (tap) beer and ale, Chianti, port, sherry, vermouth, red wine, white wine	Domestic bottled beers	Non-alcoholic beverages
Most aged cheeses	Cream cheese and cottage cheese	Normal cheese of the type typically used on bread and pizza
Banana skin, figs, grapes, oranges, pineapples, plums, prunes, raisins, overripe avocados	Avocados – provided not overripe	Chocolate
Broad (fava) beans, aubergine (eggplant)		Tomatoes
Processed foods; Marmite®, Vegemite®, sauerkraut and shrimp paste		Processed cheese
Processed meats, cured or pickled meats, and meat by-products and broths. Game birds and wild animals if hung; old liver and meat		Fresh liver, meat, poultry, fish and shellfish
All soy products: soya beans, soy sauce, tofu, miso and teriyaki sauce		Soy milk

Table 13.8 Migraine variants

Type/subtype	Clinical features
Migraine	
Status	Intense pain that usually lasts longer than 72 h
Abdominal	Abdominal pain without a gastrointestinal cause (lasts up to 72 h), nausea, vomiting, and flushing or paleness. Children who have abdominal migraine often develop typical migraine as they age
Headache-free	Aura without headache
Migraine without aura	Tiredness or mood changes the day before the headache, which may be on one or both sides of head. Nausea, vomiting and also sensitivity to light
Classic	Unilateral headache preceded by an aura (a neurological phenomenon) experienced 10–30 min before the headache. Most auras are visual (bright shimmering lights around objects or at the edges of the field of vision or zigzag lines, castles, wavy images, or hallucinations). Other patients have temporary vision loss. Non-visual auras include motor weakness, speech or language abnormalities, dizziness, vertigo, and tingling or numbness of face, tongue or extremities
Hemiplegic	Often familial; hemiparesis may outlast headache by several days; may rarely cause facial palsy
Ophthalmoplegic	Affects children (boys) mainly. As headache progresses, eyelid droops and eye movements become paralysed. Ptosis may persist for days or weeks
Vertebrobasilar	Affects adolescent girls mainly. Aura associated with ataxia, vertigo, diplopia; headache usually occipital; there may be loss of consciousness at the onset
Complicated	Any form of migraine complicated by residual neurological defect after attack
Migrainous neuralgia	
Classic	Pain typically around the eye, often with visible effects of vasodilatation
Facial migraine	Affects lower face (lower-half migraine or carotidynia). Episodes may occur several times weekly and last a few minutes to hours. Deep, dull, aching and sometimes piercing pain in the jaw or neck. There is usually tenderness and swelling over the carotid artery

associated and range from facial flushing and oedema on the affected side to temporary hemiplegia. Unilateral headache (hemicrania), which is usually severe, often becomes throbbing and generalized, may be associated with facial pallor, and can last for hours or days. Photophobia and sometimes phonophobia, nausea and sometimes vomiting may be seen. The number, frequency, intensity and duration of migraine attacks vary widely, but they tend to diminish in frequency and intensity with increasing age.

General management

The diagnosis of migraine is clinical. Spontaneous remissions are not uncommon and migraine tends to improve during pregnancy. Management is usually with drugs and avoidance of precipitating factors but there is also a significant placebo factor.

In acute attacks, patients usually prefer to lie in a quiet, dark room. Analgesics such as aspirin, paracetamol (acetaminophen) or ibuprofen can be effective. Intranasal lidocaine can give early relief within 5 minutes in over half of those suffering from migraine, but the pain returns after about an hour in half of the responders. Triptans (serotonin (5HT₁) receptor agonists), such as sumatriptan, are effective in up to 80% if given within 1 hour; possible adverse effects include nausea, dizziness, muscle weakness and, rarely, stroke or myocardial infarction. Sumatriptan may cause coronary spasm and angina, or permanent neurological damage if given in hemiplegic migraine or with ergotamine. Triptans are contraindicated for patients taking monoamine oxidase inhibitors (MAOIs).

If triptans are ineffective, ergotamine given orally may abort an attack but, in many cases, absorption by mouth is too slow to be effective and a better alternative is to use it by inhalation from a Medihaler. Even so, ergotamine must not be used within 6 hours of sumatriptan. The maximum permissible dose of ergotamine is 4 mg in 24 hours; this must not be exceeded and treatment must not be repeated at intervals of less than 4 days. Ergotamine can cause peripheral vasospasm and gangrene, abdominal pain, nausea and vomiting. It can also be given with caffeine, or as a suppository, which overcomes the problem of poor absorption if the patient is vomiting.

Oral antiemetics, such as metoclopramide, domperidone or buclizine, should be given early to overcome the autonomic dysfunction preventing gastric emptying. In severe cases of vomiting, an antiemetic such as metoclopramide or prochlorperazine by suppository may also be required.

If attacks of migraine are more frequent than two a month, the treatment of choice is prophylaxis with propranolol or another beta-blocker, but sometimes a serotonin antagonist (pizotifen or cyproheptadine) or amitriptyline is used. Pizotifen can cause drowsiness and should be used with caution in renal disease, pregnancy, glaucoma or urinary retention. Low-dose aspirin may reduce attacks by 20%, probably by blocking prostaglandin production in response to stimulation of a 5HT (serotonin) receptor. Calcium-channel blockers, such as verapamil or nifedipine, may be useful alternatives. Methysergide may help but has dangerous toxic effects (retroperitoneal fibrosis, and fibrosis of heart valves and pleura) and is therefore given only for refractory cases under specialist supervision. The Transcranial Magnetic Stimulator (TMS) is FDA approved for use in migraine in people who have no epilepsy and have no metals in the head, neck, or upper body that are attracted by a magnet, or an active implanted medical device such as a pacemaker or deep brain stimulator.

Dental aspects

Dental procedures, such as tooth extraction, amalgam removal or the use of occlusal splints, are of no proven value in the management of true migraine.

Trigeminal autonomic cephalgias

The trigeminal autonomic cephalgias (TACs) include migrainous neuralgia and short-lasting unilateral neuralgia with conjunctival injection and tearing (SUNCT).

Migrainous neuralgia (periodic migrainous neuralgia, cluster headaches, Horton neuralgia, superficial petrosal neuralgia, histamine cephalgia, Sluder headaches)

General aspects

Migrainous neuralgia is less common than migraine. It is a pain in the head and face, defined by the International Headache Society (IHS) as:

unilateral excruciatingly severe attacks of pain principally in the ocular, frontal and temporal areas, recurring in separate bouts with daily or almost daily attacks for weeks or months, usually with ipsilateral lacrimation, conjunctival injection, photophobia and nasal stuffiness and/or rhinorrhoea.

Males are mainly affected and attacks often begin in middle age.

Occasionally, pain mimicking migrainous neuralgia is caused by organic disease, such as ocular disorders or lesions of the trigeminal nerve, brainstem or middle cranial fossa near the midline, including the cavernous sinus, circle of Willis or pituitary. Presentation is then often atypical.

Clinical features

Attacks of migrainous neuralgia are sometimes precipitated by the factors shown in [Box 13.5](#). Typical features are the onset of severe pain at night (classically at around 2.00 a.m.), and clustering of attacks at the same time, for several weeks. Migrainous neuralgia causes unilateral pain usually localized around the maxillary premolars, eye, forehead, cheek and temple ([Table 13.9](#)). Pain may occasionally be occipital, cervical or scapular. Episodes, which commence and often terminate suddenly, last less than 1 hour (often 30–45 minutes), and may recur from 1 to 8 times daily. Autonomic features include flushing and/or sweating on the affected side of the face and features such as lacrimation, conjunctival injection and nasal congestion, sometimes with Horner syndrome.

General management

Migrainous neuralgia should be differentiated from migraine and other headaches (see [Table 13.9](#)). Diagnosis is clinical but, as similar symptoms may be related to tumours around the cavernous sinus and craniospinal junction, a scan (computed tomography/magnetic

Box 13.5 Precipitants of migrainous neuralgia

- Alcohol
- Cocaine
- Exercise
- High altitude
- Histamine
- Hot baths
- Hypoxaemia
- Nitroglycerin

Table 13.9 *Differentiation of headaches and orofacial pain of different cause*

Factor	Temporomandibular joint (TMJ) pain–dysfunction	Psychogenic	Idiopathic trigeminal neuralgia	Migraine	Migrainous neuralgia
Age (years)	20–30	35–60	50+	Any	30+
Sex	F > M	F > M	F > M	F > M	M > F
Site	Temple, ear, jaws, teeth Usually unilateral	Diffuse, deep, sometimes across midline	Mandible or maxilla Unilateral	Any	Retro-orbital Unilateral
Associated features	Click in TMJ, trismus	Life events, back pain, etc. Stress, fatigue	± Trigger area	± Photophobia Nausea Vomiting	Nasal stuffiness, lacrimation
Character	Dull, continuous	Dull, boring, continuous	Lancinating	Throbbing	Throbbing
Duration of episode	Weeks to years	Weeks to years	Brief (seconds)	Hours (or usually days)	Minutes to hours, Early mornings, may be daily for a few days

resonance imaging [CT/MRI] is indicated. Precipitants should be avoided and oxygen inhalations help (pain relief from these is sometimes regarded as diagnostic). Other therapies include ipsilaterally applied intranasal lidocaine; triptans (usually sumatriptan), when there is neither hypertension nor coronary artery disease – zolmitriptan, rizatriptan, eletriptan or naratriptan are also available; ergotamine; butorphanol tartrate nasal spray; capsaicin; and pizotifen. Preventive medications include ergotamine, propranolol, amitriptyline, cyproheptadine, diltiazem, lithium carbonate, prednisolone (prednisone) and verapamil. Neurosurgery may be required for those with intractable cluster headaches.

Dental aspects

Migrainous neuralgia must be distinguished from dental pain by the characteristic history and confirmation of the absence of a dental cause.

Short-lasting unilateral neuralgia with conjunctival injection and tearing (SUNCT)

This syndrome is a form of TAC seen mainly in males above 50 years, who have short-lasting unilateral attacks of intermittent, moderate to severe, burning, piercing or throbbing daytime pain, usually unilaterally, around the eye or temple; these last 5 seconds to 5 minutes per episode and are accompanied by autonomic disturbances, such as conjunctival injection, lacrimation, nasal stuffiness, rhinorrhoea and subclinical forehead sweating. Systolic blood pressure may rise during the attacks. Movement of the neck may trigger these headaches. SUNCT is therefore similar to migrainous neuralgia but may occur in the daytime. SUNCT is generally non-responsive to analgesics. Trigeminal injections of glycerol may provide temporary relief in some severe cases. Corticosteroids and antiepileptics (e.g. gabapentin, lamotrigine or carbamazepine) may help relieve some symptoms.

Idiopathic stabbing headache (ice-pick pains)

Idiopathic stabbing headache is pain confined to the head and exclusively or predominantly felt unilaterally in the distribution of the first division of the trigeminal nerve (orbit, temple and parietal area), mostly in the orbital region. It often recurs in the same place, but may move to other places on the same side of the head or, less commonly, to the opposite side. Pain forms a single stab or a series of stabs; each stab lasts for seconds only and episodes recur at irregular intervals of hours to days.

Diagnosis depends upon the exclusion of structural changes at the site of pain and in the distribution of the affected cranial nerve. Indometacin may relieve idiopathic stabbing headache.

Chronic paroxysmal hemicrania

Chronic paroxysmal hemicrania is similar to migrainous neuralgia, but only sometimes comes at night and is rarely triggered by alcohol. In 20% it follows head injury or whiplash injury, and invariably responds well to indometacin.

Cranial arteritis (temporal or giant cell arteritis)

General aspects

Cranial arteritis is an immunologically mediated vasculitis closely related to polymyalgia rheumatica, causing inflammation of the walls of medium-sized arteries with prominent giant cells, and obliteration of the vessel lumen. Women are predominantly affected, usually after the age of 55.

Clinical features

The most common complaint is severe unilateral, mainly temporal, throbbing headache. Associated features may be malaise, proximal muscle stiffness, weight loss and fever. The superficial temporal artery is typically prominent, tortuous and tender.

The most severe complication of cranial arteritis is ischaemia of the optic nerve, causing blindness in up to 30%. Hemiplegia or myocardial infarction is also possible. Pain on mastication (misnamed jaw claudication) is seen in about 20% of cases and occasionally there is limited mouth opening.

General management

Cranial arteritis should be suspected in an older patient who suddenly experiences headache associated with a warm, tender scalp vessel. There is no diagnostic serological test but erythrocyte sedimentation rate (ESR) is usually greatly raised. Serum levels of interleukin (IL)-6 and alkaline phosphatase may also be raised. Temporal artery biopsy is the one confirmatory diagnostic measure and even this may be negative, as lesions are patchily distributed.

As soon as the diagnosis is made it is obligatory to give systemic corticosteroids (60 mg prednisolone [prednisone] daily, reducing as the

ESR returns to normal) because of the risk of eye involvement. The clinical response is rapid.

Dental aspects

Ischaemic pain in the muscles of mastication can cause severe discomfort when eating and has been reported in 20% of patients. A rare manifestation is ischaemic necrosis and gangrene of the tongue or lip.

NEUROLOGICAL CAUSES OF FACIAL PAIN

Sensory innervation of the face and scalp is carried by the trigeminal nerve. Lesions of the trigeminal at any stage from its nuclei along its course from the pons can cause facial pain or sensory loss, sometimes with serious implications. Pain may be amenable to treatment with pregabalin, gabapentin or carbamazepine.

Idiopathic trigeminal neuralgia

General aspects

Trigeminal neuralgia (TN) has been described by the IHS as 'a painful, unilateral affliction of the face, characterized by brief electric-shock, lightning-like (lancinating) pains limited to the distribution of one or more divisions of the trigeminal nerve'. TN usually afflicts patients over the age of 50. The incidence is less than 0.2% in those under 40 years but rises to 25% in those over 70.

About 15% of cases have structural causes; about 5% are produced by posterior fossa tumours (meningiomas, acoustic neurinomas or carcinomas) that are not suspected before operation and a slightly smaller percentage have multiple sclerosis.

The cause of *idiopathic* TN is unclear but may be demyelination triggered by a tortuous arteriosclerotic blood vessel in the posterior cranial fossa that presses on the trigeminal (the disease predominantly affects older people, many of whom have hypertension or arteriosclerosis).

Clinical features

The pain of TN has the following characteristics:

- It is confined to the trigeminal area of one side, usually the maxillary or mandibular division, or occasionally both. Infraorbital or lower lip/lower jaw pain is common, and supraorbital pain uncommon.
- It is severe and sharply stabbing (lancinating), of only a few seconds' duration, but paroxysms may follow in quick succession. Typically, the pain is remarkably severe and a patient seen crying with pain during an attack is not easily forgotten.
- Triggers are mild stimuli, which, applied to trigger zones within the trigeminal area, typically provoke an attack, and include:
 - shaving
 - stroking or touching the face
 - eating
 - drinking a hot or cold liquid
 - brushing teeth
 - talking
 - putting on cosmetics
 - encountering a cold breeze
 - walking into an air-conditioned room.

Idiopathic TN is likely when there is an intact corneal reflex, no abnormal neurological signs, no objective sensory loss in the area and no other defined neurological deficit.

Secondary TN is more likely if the patient's pain started when younger than 40 years, if there is predominant forehead and/or orbit pain (i.e. first division of the trigeminal nerve), if the pain is bilateral, if there are abnormal trigeminal reflexes, or if there are physical signs such as facial sensory or motor impairment. The latter can result from posterior cerebral fossa lesions, particularly tumours or aneurysms (the combination of neuralgia with hemifacial spasm also suggests a posterior cranial fossa lesion), multiple sclerosis, brainstem ischaemia or infarction in cerebrovascular disease, neurosyphilis or other lesions.

Atypical TN is a syndrome that overlaps TN and trigeminal neuropathy, and affects up to 5% after facial surgery or significant trauma, and up to 1% after the removal of impacted teeth. It includes unusual symptoms, such as more continuous rather than lightning attacks of pain, or triggering by warmth rather than cold, and may result from lesions or injuries of the trigeminal nerve root distal to the root entry zone but with even greater compression than found in the idiopathic form of TN. Attacks consist of constant pain that episodically intensifies and produces both lancinating triggered pain and a baseline, constant, dull and throbbing discomfort.

General management

The diagnosis is clinical. Organic disease must be excluded by neurological examination to confirm normal corneal reflexes, sensory appreciation, and masseter muscle bulk and strength. Loss of the corneal reflex excludes the diagnosis of idiopathic TN, unless a previous trigeminal nerve section procedure has been performed. The other main differential diagnoses are glossopharyngeal neuralgia (the two can coexist), idiopathic facial pain, Raeder paratrigeminal syndrome and Frey syndrome.

Investigations, required especially if there are any neurological features, may include skull radiographs, MRI or CT brain scans, and occasionally cerebrospinal fluid (CSF) examination or neurophysiological tests (e.g. trigeminal evoked potentials and corneal reflex latency). Many now advocate MRI as routine.

A few patients with mild symptoms recover spontaneously but most require treatment. This is initially with anticonvulsants, particularly carbamazepine, which change GABA levels in the central pain-inhibiting systems. Spontaneous remissions of a month or two are relatively common and may make the assessment of treatment difficult. Carbamazepine is indicated first, if only because its use may constitute a therapeutic challenge to the correct diagnosis. If, for example, a patient presumed to have TN does not respond to carbamazepine in 24–48 hours, then the physician may wish to reconsider the initial diagnosis. Carbamazepine is not an analgesic and, if given when an attack starts, will not relieve the pain. If used prophylactically, it may control up to 90% of cases over the first few months, but this falls to about 25% by 1 year.

Carbamazepine absorption is slow, and its antineuralgic activity depends on its metabolites; it must therefore be given continuously for long periods until symptoms are controlled or adverse effects become excessive. Though about 80% obtain pain relief within 24 hours, about 20 days are required before the full effect is noted. Carbamazepine can cause severe ataxia but the many other possible toxic effects are uncommon. Ataxia and drowsiness are dose-related, may interfere with driving and can be dose-limiting.

Some Asians metabolize carbamazepine poorly and can thus suffer from overdose or other adverse events, so they should be screened for the human leukocyte antigen (HLA). The HLA-B*1502 allele has been shown to be strongly correlated with carbamazepine-induced Stevens–Johnson syndrome and toxic epidermal necrolysis (SJS–TEN).

in Han Chinese and other Asian populations but not in European populations. The presence of HLA-A*3101 allele is associated with carbamazepine-induced hypersensitivity among people of northern European ancestry. Carbamazepine is contraindicated in pregnancy and porphyria, and should be used with caution in persons with hepatic, renal, cardiac (especially atrioventricular conduction defects) or bone marrow disease. Monitoring of blood carbamazepine levels and, for adverse reactions, regular assessment of blood pressure, blood urea and electrolytes, liver function, platelet and white cell counts is helpful. Carbamazepine may predispose to liver damage from paracetamol (acetaminophen) and may interfere with the effectiveness of the contraceptive pill, though most patients are beyond the age of concern in that respect. Drugs such as erythromycin, cimetidine and isoniazid can raise serum carbamazepine levels.

Should carbamazepine in maximum dosage fail to control neuralgia, oxcarbazepine, gabapentin, baclofen and lamotrigine are second choices. Additional therapeutic agents that may be added or may replace carbamazepine include phenytoin, tizanidine, topical capsaicin, and valproate.

Surgery may be indicated if medical therapy fails (25–50% of patients eventually fail to respond to drugs) or adverse effects are intolerable. Surgery (surgical division, cryosurgery, injections of alcohol or phenol) to the trigeminal nerve branches involved is usually carried out under open operation under LA. Cryosurgery can bring pain relief without permanent anaesthesia. However, the benefit of all peripheral nerve procedures may only be temporary, with relapse common within 2 years. If these treatments fail, intracranial neurosurgery is available. All destructive surgical procedures result in a sensory deficit in up to 20% of patients; relapse is common beyond 2 years and the more peripheral the procedure, the greater the risk of recurrence. Although all the surgical procedures are inherently supported by low-level evidence, the results in thousands of patients indicate that surgical treatments for TN are efficacious and acceptably safe. Percutaneous Gasserian lesions can be safely performed in older people but often cause facial numbness. Microvascular decompression provides the longest-lasting pain relief but involves some risk of major neurological complications. Gamma-knife surgery is the least invasive and safest procedure but pain relief may take 1 month to develop.

Percutaneous radiofrequency trigeminal (retrogasserian) rhizotomy (PRTR) is the most widely used technique and is minimally invasive, involving the insertion of a needle, but has morbidity and some mortality. Trigeminal-innervated muscle weakness is a significant early side-effect and anaesthesia also results, causing danger of damage to the cornea.

Percutaneous trigeminal ganglion compression (rhizotomy) is minimally invasive and uses a Fogarty balloon. This may be effective. Over 50% of patients have mild to moderate postoperative numbness but this does not affect the cornea; 16% have ipsilateral masseter/pterygoid weakness. The overall recurrence rate is 26% but 60% of patients are pain-free 8 years after surgery.

Microvascular decompression (MVD) is an invasive procedure performed via a suboccipital craniotomy. This may be effective but occasionally results in damage to the VII or VIII cranial nerves and also carries a small risk of mortality.

Gamma knife radiosurgery (GKR) is non-invasive. It involves delivering high doses of radiation to the trigeminal nerve root without any need for injection or skin incision. It can be successful in eliminating pain in up to 80% but pain recurs in more than half the cases.

Neurosurgical techniques can occasionally be followed by continuous facial pain (anaesthesia dolorosa) that responds very poorly to treatment.

Dental aspects

Patients may be reluctant to brush their teeth or attend for dental treatment.

Glossopharyngeal (vagoglossopharyngeal) neuralgia

Glossopharyngeal neuralgia is rare and usually idiopathic, possibly caused by an abnormal intracranial blood vessel, as in trigeminal neuralgia. The pain is similar to that of TN (rarely, the two coexist), but affects the throat, especially the tonsillar region, and is typically triggered by swallowing or coughing. Pain may also be felt in the ipsilateral ear (vago-Collet–Sicard syndrome) and this may simulate neuralgia of the nervus intermedius (Hunt neuralgia). There are no sensory or motor defects but, in 10%, there is associated bradycardia and fall in blood pressure, sometimes with syncope, especially when the neuralgia is secondary to a throat tumour. During longer attacks, asystole may occur and long, severe attacks may be marked by protracted cardiac arrest, absence of pulse, pallor, mental confusion, syncope or convulsions.

The mechanism usually proposed has been spillover of impulses from the glossopharyngeal nerve via the tractus solitarius to the dorsal motor nucleus of the vagus nerve, resulting in reflex bradycardia, heart block or asystole.

Unlike TN, glossopharyngeal neuralgia rarely appears to be associated with intracranial tumours and even more rarely with multiple sclerosis. Tumours in the posterior cranial fossa or jugular foramen (jugular foramen syndrome) can rarely cause similar pain, together with lesions of the vagus (X) and accessory (XI) nerves (Appendix 13.1). Hoarseness, dysphagia, palatal deviation to the intact side, anaesthesia of the posterior pharyngeal wall, and weakness of the sternomastoid and upper trapezius are then seen.

A 10% cocaine or other anaesthetic throat spray will cause temporary pain relief and is diagnostic. Therapy is as for TN, but carbamazepine is usually less effective and gabapentin is probably better. If drugs fail to give adequate relief, neurosurgery is indicated but is more difficult than for TN and has a higher morbidity and mortality.

Raeder paratrigeminal neuralgia

Raeder paratrigeminal neuralgia is severe, persistent pain in and around the eye, with associated Horner syndrome; it is often caused by a lesion at the skull base that requires neurological attention.

Herpetic and post-herpetic facial neuralgia

Herpes zoster (shingles) is often preceded, usually accompanied and sometimes followed by neuralgia in up to 70% of cases. It mainly affects older people, but antivirals may help prevent it (Ch. 21).

Post-herpetic neuralgia is defined as pain persisting a month after the eruption of zoster, causing continuous burning pain, worse with movement and thermal change, and sometimes sensory changes in the affected area. Treatment is difficult, and pain may be so intolerable that suicide can become a risk. However, spontaneous improvement may sometimes follow after about 18 months.

NSAIDs are generally ineffective but topical lidocaine or capsaicin cream may help. Tricyclic antidepressants, particularly desipramine or amitriptyline, may relieve the pain better than valproate or carbamazepine. TENS or neurosurgery may sometimes help.

Pontine infarction

Pontine ischaemia may be due to bilateral ventral pontine infarction. Lateral medullary infarction may cause a similar but unilateral effect. Burning orofacial pain may be an early symptom.

Bilateral ventral pontine infarction causes the syndrome of quadriplegia and lower cranial nerve palsies but preservation of movement of the upper eyelids and vertical gaze (termed the 'locked-in syndrome' because the patient, though able to understand what is being said and what is happening, is imprisoned by an inability to speak or move anything apart from the eyes; see later). The prognosis is poor.

Cerebellopontine angle tumours

Lesions in the posterior cranial fossa (e.g. cerebellopontine angle tumours) can cause facial pain associated with an absent corneal reflex (V nerve), deafness, tinnitus and vertigo (from involvement of the VIII nerve), facial palsy (VII nerve involvement), ataxia, intention tremor and nystagmus (cerebellar involvement), and spasticity of the leg (pyramidal tract involvement). Acoustic neuromas and meningiomas are usually operable.

Middle cranial fossa lesions

Middle cranial fossa lesions can involve the V and VI nerves, and also cause lateral rectus palsy. Carotid aneurysms, especially those in the cavernous sinus, or cavernous sinus thrombosis may also cause facial pain and associated cranial nerve lesions (III, IV and VI nerves; see Fig. 6.3).

Cavernous sinus thrombosis

Cavernous sinus thrombosis is a life-threatening complication that may rarely result from infection spreading back through the emissary veins from the maxillary or nasal region, or upper teeth, or from infected thrombi in the anterior facial vein or less commonly the pterygoid plexus. Infection can reach the cavernous sinus via either the ophthalmic veins or the foramen ovale.

Clinically, cavernous sinus thrombosis causes gross eyelid oedema, ipsilateral pulsatile exophthalmos, cyanosis due to venous obstruction, rigors and high swinging pyrexia. The superior orbital fissure syndrome (proptosis, fixed dilated pupil and limitation of eye movements) rapidly develops.

There is a mortality of up to 50%, and a further 50% of those that survive are likely to lose the sight of one or both eyes. Vigorous and early use of anticoagulants, antibiotics, drainage and elimination of infection are essential.

Bell palsy

Bell (facial) palsy is preceded or accompanied by pain in the region of the ear, spreading down the jaw in about half the cases. However, the appearance of the typical facial paralysis leaves little doubt as to the diagnosis (see below).

Facial pain caused by extracranial lesions

Branches of the trigeminal nerve may be affected by inflammatory, traumatic or neoplastic lesions causing pain or sensory loss in their distribution.

PSYCHOGENIC CAUSES OF HEADACHE OR OROFACIAL PAIN

See Chapter 10. This type of pain may need treatment with antidepressant agents, particularly selective serotonin reuptake inhibitors (SSRIs) and serotonin–noradrenaline (norepinephrine) reuptake inhibitors (SNRIs).

Tension headaches

Tension headaches are common, especially in young adults, and particularly in emotionally tense, aggressive, frustrated and anxious individuals. They may be caused by sustained contraction of the head and neck muscles and vasoconstriction of nutrient arterioles. Patients are frequently adamant that they suffer from migraine and sometimes the two conditions do coexist. The possibility of associated depression should also be considered.

Clinical features

The pain must be experienced on more than 15 days monthly to be classified as tension headache. It affects the frontal, occipital or temporal muscles, and is felt as a constant ache or band-like pressure, of mild or moderate intensity, bilateral in location, and lasting from 30 minutes to 7 days. The pain onset often is associated with emotional conflict but does not worsen with routine physical activity. Nausea is absent, but photophobia or phonophobia may be present. Pain can often be elicited by palpation of the trapezius or pericranial muscles; it is often worse in the evening and at night but does not waken the patient.

General management

Hypertension and hyperthyroidism should be excluded, as must drug-associated headaches (e.g. analgesics, antihistamines, anticonvulsants, ergotamine, steroids and antibiotics). The pain may be treated by rest, simple analgesics, or combination drugs with biofeedback, and particularly with counselling. Reassurance may be effective and may be bolstered by a short course of diazepam, which is both an anxiolytic and a muscle relaxant. Failing this, amitriptyline is usually effective. Even acupuncture may offer relief.

Oral dysaesthesias

A complaint of a burning tongue or mouth is the common type of oral dysaesthesia. Dry mouth, disturbed taste sensations and delusions of halitosis are other dysaesthesias. These are often manifestations of monosymptomatic hypochondriasis, somatization pain disorder or a depressive neurosis. There is sometimes cancer phobia, or anxiety about the possibility, for example, of venereal disease or human immunodeficiency virus (HIV) infection.

Burning mouth syndrome (glossopyrosis; glossodynia)

General aspects

Burning mouth 'syndrome' (BMS) is a common chronic complaint seen especially in middle-aged or elderly females. Organic causes of burning mouth include:

- glossitis
- erythema migrans (geographic tongue)

- candidosis
- lichen planus
- dry mouth
- drugs (such as angiotensin-converting enzyme inhibitors [ACEIs] or proton pump inhibitors [PPIs])
- habits and denture difficulties
- diabetes.

Burning mouth syndrome is the term usually used when symptoms persist in the absence of identifiable organic aetiological factors. Many of these cases appear related to psychogenic factors such as cancer phobia, depression or anxiety. Sometimes, factors such as restricted tongue space from poor denture construction, or parafunction, such as tongue-thrusting, may be at play. Denture allergy is rarely responsible. Systemic disorders, such as a haematological deficiency state or hypothyroidism, are found in some (Table 13.10).

Clinical features

A burning sensation starts after waking and grows in intensity during the day. It may sometimes be relieved by chewing or drinking. By contrast, pain caused by organic lesions is typically made worse by eating.

BMS most frequently affects the tongue but may also involve the palate or, less commonly, the lips or lower alveolus. There are often multiple oral and/or other psychogenic related complaints, such as dry mouth, a bad taste in the mouth, headaches, chronic back pain, irritable bowel syndrome or dysmenorrhoea.

Patients are often high users of health-care services; there have often already been multiple consultations and attempts at treatment. There are no clinically detectable signs of mucosal disease and no tenderness or swelling of the tongue or affected areas; there is a total lack of objective signs and all investigations are negative. Patients use analgesics only uncommonly.

Three types have been described on the basis of the pattern of symptoms of burning sensation (Table 13.11).

General management

Laboratory screening may be indicated to rule out anaemia and vitamin or iron deficiency (blood tests), diabetes (blood and urine analyses), hyposalivation (salivary flow rates) and candidosis (smear). Pontine infarction should be excluded (see above).

Table 13.10 Organic causes of burning mouth

Examples	Comments/examples
Local causes	
Candidosis	Sometimes associated with hyposalivation
Denture problems	–
Erythema migrans (geographical tongue)	–
Lichen planus	–
Systemic causes	
Deficiency	B vitamins, especially B ₁₂ Folate Iron
Diabetes	–
Drugs	–
Dry mouth	–
Psychogenic	Anxiety states Cancer phobia Depression Hypochondriasis

Few patients with BMS have spontaneous remission and thus treatment is indicated, including attention to any local factors such as dentures, psychogenic assessment and occasionally psychiatric care, but many refuse this. Psychological screening using, for example, the hospital anxiety and depression (HAD) scale may be helpful. Treatment may include topical agents such as capsaicin or clonazepam, alpha lipoic acid, or antidepressants such as amitriptyline, dosulepin, doxepin, fluoxetine or trazodone.

Idiopathic facial pain (atypical or psychogenic facial pain)

General aspects

The IHS defines this as ‘facial pain not fulfilling other criteria’ or:

persistent facial pain that does not have the characteristics of the cranial neuralgias and is not associated with physical signs or demonstrable organic causes. It is present daily and persists for most or all of the day. It is confined at onset to a limited area on one side of the face and may spread to the upper and lower jaws or other areas of the face or neck. It is deep and poorly localized. The pain is not associated with sensory loss or other physical signs. Laboratory investigations including radiographs of face and jaws do not demonstrate relevant abnormalities.

A few patients with similar symptomatology eventually prove to have organic disorders, such as an adenocystic carcinoma that has invaded perineurally, but in others it may be a somatization pain disorder (Ch. 10).

Clinical features

Pain is continuous, often of a dull boring or burning type; it generally has an ill-defined location but involves the maxilla particularly. The pain may waken the patient in the early morning and has no obvious precipitating factors, although it may be attributed to dental disease or treatment; it is rarely relieved completely by analgesics. There are often multiple oral and/or other psychogenic related complaints. There have often been multiple consultations and treatment attempts.

General management

Idiopathic facial pain is a clinical diagnosis reached by careful examination of the mouth, perioral structures and cranial nerves. Imaging with CT or MRI to exclude organic disease is important.

Cognitive therapy is indicated but, since many of these patients have already rejected the idea of mental illness, it may be difficult to persuade them of the need for this type of help. Sometimes it is helpful to make it clear that depression both is common and is an illness like

Table 13.11 Types of burning mouth syndrome

Type	Symptom pattern	Frequency	Other features
1	No symptoms on waking but increasing during the day	–	Unremitting
2	Symptoms on waking and through the day	Most common	Unremitting
3	No regular pattern of symptoms	Least common	May remit

any other; as with other disorders, it can also cause physical symptoms. Sometimes the pain may appear as a hysterical conversion neurosis and many patients have obsessional personality traits.

Antidepressants that can be useful include amitriptyline, dosulepin, nortriptyline and fluoxetine.

Idiopathic odontalgia is a variant characterized by the complaint of severe throbbing pain in one or several teeth, which are hypersensitive to any stimulus. Extractions typically lead to transference of the symptoms to adjacent teeth.

Temporomandibular pain–dysfunction syndrome (facial pain–dysfunction, myofascial pain–dysfunction, TMJ pain–dysfunction or facial arthralgia)

General aspects

Temporomandibular joint (TMJ) pain–dysfunction is a common problem, predominantly affecting young women. The TMJ shows no pathology, in contrast to internal derangement of the TMJ, which may also lead to pain. The cause is unclear but there have been many hypotheses, ranging from trauma to malocclusion and even psychogenic factors.

Some occupations or hobbies, such as scuba diving, may predispose to abnormal habits and TMJ pain–dysfunction.

There may be a greater frequency of migraine, rhinitis, peptic ulcer and irritable bowel syndrome associated, leading some to believe that depression may be contributory. A psychiatric basis for the syndrome is, however, controversial, but it may be seen particularly in ambitious, obsessional personalities, in anxiety states or in agitated depression.

Clinical features

There is typically dull pain, usually in front of the TMJ; the pain tends to radiate over the masseter and temporalis muscles and sometimes occipitally or cervically. Tenderness in the masticatory muscles, including the pterygoids, is characteristic.

There may be an audible click or palpable crepitus in the joint, the mandible often deviates towards the affected side on opening and there may be restricted mouth opening, or ‘locking’. There is sometimes faceting on the teeth, ridging of the tongue margins and buccal mucosa at the occlusal line, and sometimes signs of lip-chewing if patients frequently grind or clench their teeth or develop various (parafunctional) habits, such as pencil chewing.

General management

Radiography shows no significant abnormality but, nevertheless, organic disease must be excluded. In any case, symptoms eventually resolve spontaneously. Degenerative joint disease is not usually a consequence. Treatment consists of reassurance. A bite-raising appliance to provide a free, sliding occlusion may help. Mild anxiolytics, such as diazepam, which is also a muscle relaxant, may help but should only be given for a limited period and may need to be supplemented with analgesics or peri-articular injection of benzocaine. If there is real evidence of depression, tricyclic antidepressants may be more useful.

Dental aspects

Limited mouth-opening may interfere with dental treatment. Attrition may require special restorative care. Dental treatment may be blamed for the onset of symptoms.

OTHER CAUSES OF HEADACHE AND OROFACIAL PAIN

See Table 13.5. Orofacial pain may be referred from the chest, particularly in ischaemic heart disease but occasionally in lung cancer. Headache can be a feature of many systemic diseases, such as any fever, hypertension, chronic obstructive airways disease or some endocrinopathies, and head injuries.

Head injuries

Headaches after head injuries, though common, do not normally persist. If they do, neurological advice must be sought to exclude intracranial haemorrhage. In the absence of neurological complications, persistent post-traumatic headaches may be due to compensation neurosis (Ch. 10).

Raised intracranial pressure

Raised intracranial pressure is one of the most serious but also the least common cause of headache. It is a dangerous condition, usually related to space-occupying lesions such as intracranial haemorrhage, abscess or tumours; it is occasionally drug-induced (e.g. by tetracyclines) and may be caused by malignant hypertension. The headache is severe and often worse on waking, but improves during the day. Nausea and vomiting are common and the headache is aggravated by straining, coughing, sneezing or lying down. Neurological attention is essential.

Skull disease

Headache is occasionally the presenting feature of diseases of the skull, such as bony metastases or Paget disease (Ch. 16).

Meningeal irritation

Meningeal irritation, seen in meningitis or subarachnoid haemorrhage, provokes severe headache with nausea, vomiting, neck pain or stiffness (inability to kiss the knees) or pain on raising the straightened legs (Kernig sign). Urgent neurological attention is needed.

New daily persistent headache

Epstein–Barr virus appears to be associated with these headaches in young adults; they recur daily but resolve spontaneously within a year.

Drugs

Facial pain may occasionally be induced by drugs (e.g. nitrites, vinca alkaloids, phenothiazines or even analgesics). Daily or near-daily analgesic use can perpetuate the headache process. Analgesia rebound headache (medication overuse headache, or MOH) mimics tension-type or migraine-like headaches and is usually associated with products containing caffeine or butalbital (a barbiturate often combined with other medications, such as paracetamol [acetaminophen], codeine or aspirin). To avoid MOH, simple analgesics should not be used for more than 15 days per month, while those such as ergots, triptans, opioids and barbiturates should not be taken on more than 10 days per month. Usually, when analgesics are discontinued, MOH may worsen for several days and the sufferer may have nausea or vomiting, but then begins to improve spontaneously.

GENERAL MANAGEMENT OF HEADACHE AND OROFACIAL PAIN

Features of pain that need to be ascertained are previous episodes, duration, onset, site, nature, duration, moderating factors, referral and severity. Patients with headache should be evaluated initially by history supplemented by physical examination, including examination of the cranium, sinuses, ears and eyes, and mental and neurological status. Some differentiating features are shown in Table 13.9.

Investigations may need to include a full blood picture, basic blood chemistry and possibly endocrinological examination, as well as urinalysis,

imaging (CT or MRI) and sometimes lumbar puncture, electroencephalography (EEG), electrocardiography (ECG) or arteriography.

CRANIAL NERVE LESIONS

Cranial nerves can be damaged by trauma, infections, tumours, drugs or chronic diseases (e.g. diabetes, connective tissue diseases, leukaemia, sarcoidosis, midline granulomas, Behçet disease or demyelinating diseases; Table 13.12).

Table 13.12 Cranial nerves: main features, causes of lesions and testing

Number	Name	Main functions	How to test the nerve	Main lesion features	Main causes
I	Olfactory	Olfaction	With an odorous substances	Anosmia or hyposmia	Trauma Infection Neoplasm
II	Optic	Vision	Vision chart. Ask patient to stare at your face from about 30cm away and (with both eyes open and with each eye shut in turn) report if any part of your face is missing	Visual defect or blindness	Trauma Infection Neoplasm Cerebrovascular accident (CVA) Multiple sclerosis
III	Oculomotor	Most eye muscles	'Follow the moving finger' in a 'rugby post' configuration	Ptosis Dilated pupil Diplopia Eye points 'down and out'	Diabetes Trauma
IV	Trochlear	Superior oblique eye muscle	Look down at the tip of the nose	Diplopia Unable to look down when looking medially	Trauma
V	Trigeminal	Facial sensation, muscles of mastication	Touch the face, clench the teeth	Anaesthesia or hypo-aesthesia	Trauma Infection Neoplasm Multiple sclerosis Connective tissue disease
VI	Abducens	Lateral rectus eye muscle	Look to each side	Diplopia Unable to look laterally to the affected side	Trauma Neoplasm CVA Raised intracranial pressure
VII	Facial	Facial expression, taste	Smile, raise the eyebrows Test taste for sugar and salt	Facial palsy	Trauma Infection Neoplasm CVA Multiple sclerosis Connective tissue disease
VIII	Auditory/ vestibular	Hearing and balance	Tuning fork	Impaired hearing or balance	Trauma Infection Neoplasm CVA Bone disease
IX	Glossopharyngeal	Pharynx sensation	Test gag reflex	Impaired gag reflex	Trauma Neoplasm
X	Vagus	Pharynx and larynx muscles, parasympathetic	Check for hoarseness, open wide and say 'Ah'	Voice changes Impaired gag reflex	Trauma Neoplasm CVA
XI	Accessory	Sternomastoid and trapezius	Test turning the head or shrugging shoulders	Weakness	CVA Trauma Infection (poliomyelitis)
XII	Hypoglossal	Tongue muscles	Protrude tongue	Tongue deviation to affected side, and sometimes wasting	Trauma Neoplasm

History and full neurological and physical examinations are essential aspects of assessment, including that of people with cranial nerve lesions. Investigations that may be useful include: blood tests (full blood count, electrolytes, liver, kidney or endocrine function tests); CSF examination – lumbar puncture; electrophysiological studies (EEG); and imaging (plain radiography, CT, MRI and positron emission tomography [PET]) – allows cerebral functional studies and opened the way for advances, such as single-photon emission computed tomography (SPECT).

OLFACTORY NERVE (CRANIAL NERVE I)

The olfactory nerve permits the smelling of odours. Unilateral anosmia is often unnoticed but bilateral anosmia causes loss of ability to smell odours; in practice, the patient may complain of loss of taste rather than of smell. Anosmia is common in upper respiratory infections and after head injuries, as the nerves may be torn as they pass through the cribriform plate; this is experienced especially in Le Fort III fractures of the middle third of the facial skeleton. Olfactory neuroblastoma is a rare tumour linked tentatively to dental staff. An olfactory lesion is confirmed by inability to smell substances, such as orange, soap, coffee, cloves or peppermint oil. Each nostril is tested separately. Ammoniacal solutions must not be used, as they stimulate the trigeminal rather than the olfactory nerve.

OPTIC NERVE (CRANIAL NERVE II)

The optic nerve is central to vision (Fig. 13.4) and can be damaged by trauma, glaucoma, raised intracranial pressure, neoplasms, radiation, toxins or drugs, resulting in impaired vision. Visual ability is tested by asking the person to read an eye chart. Peripheral vision is tested by asking the person to detect objects or movement from the corners of the eyes.

Fig. 13.4 Optic nerve lesions, site of lesion and resultant visual defects.

The ability to detect light is tested in a darkened room by shining a bright light (as from a torch) into each pupil.

OCULOMOTOR NERVE (CRANIAL NERVE III)

Extraocular (orbital) muscles are complex but responsible for moving the globe. The medial rectus (supplied by the third nerve) moves the eye medially (adducts). The adducted eye is depressed by the superior oblique muscle (fourth nerve) and elevated by the inferior oblique (third nerve). The lateral rectus (sixth nerve) abducts the eye. The abducted eye is depressed by the inferior rectus (third nerve) and elevated by the superior rectus (third nerve).

The oculomotor nerve thus supplies most of the orbital muscles (not the lateral rectus and superior oblique), as well as the ciliary muscle, the constrictor of the pupil, and the muscle that raises the upper eyelid. Disruption of the third nerve can be caused by extracranial causes (trauma, arteriosclerosis, diabetes, orbital apex disease, cavernous sinus disease, aneurysm of the posterior communicating artery) or supratentorial (raised intracranial pressure with uncus herniation). Disruption of the third nerve causes the following:

- Paralysis of internal, upward and downward movement of the eye. Lateral movement is retained
- Double vision (diplopia) and a divergent squint with the affected eye pointing downwards and laterally – ‘down and out’ in all directions except when looking towards the affected side
- Ptosis (drooping upper eyelid)
- A dilated pupil, which fails to constrict on accommodation or when light is shone either on to the affected eye (negative direct light reaction) or into the unaffected eye (negative consensual light reaction), i.e. a fixed pupil.

The upper eyelid is checked for drooping (ptosis). The pupils’ response to light is checked by shining a bright light (as from a torch) into each pupil in a darkened room. The ability to move each eye up, down and inward is tested by asking the person to follow a target moved by the examiner.

TROCHLEAR NERVE (CRANIAL NERVE IV)

The trochlear nerve supplies only the superior oblique muscle, which moves the eye downwards and medially towards the nose. Damage may be caused by vascular disease, diabetes, cavernous sinus syndrome, trauma or orbital apex syndrome. A trochlear lesion is characterized by:

- the head tilted away from the affected side
- diplopia, maximal on looking downwards and inwards, and causing difficulty descending stairs or reading
- normal pupils.

The ability to move each eye down and inward is tested by asking the person to follow a target moved by the examiner. There is often damage to the third and fourth nerves as well.

TRIGEMINAL NERVE (CRANIAL NERVE V)

The trigeminal (= three twins) nerve supplies sensation over the face (apart from the angle of the jaw), scalp (back to a line drawn across the vertex, between the ears) and most of the mucosae of the oral cavity, conjunctivae, nose, tympanic membrane and paranasal sinuses (Fig. 13.5). Taste fibres from the anterior two-thirds of tongue are carried in the trigeminal nerve. The motor division of the trigeminal nerve supplies the muscles of mastication. Secretomotor fibres to submandibular and sublingual salivary glands and lacrimal glands are

Fig. 13.5 Distribution of sensory divisions of the trigeminal nerve.

Table 13.13 Causes of sensory loss in the trigeminal area

Source	Type	Main causes
Intracranial		
Congenital	Syringobulbia	–
Acquired	Inflammatory	Multiple sclerosis
		Neurosyphilis
		Sarcoidosis
		Tuberculosis
		Connective tissue disease
		HIV/AIDS
	Neoplastic	Cerebral tumours
	Vascular	Cerebrovascular disease
	Drugs	Stilbamidine
	Occupational	Trilene (dry cleaning)
	Idiopathic	Benign trigeminal neuropathy
		Paget disease
Extracranial		
Acquired	Trauma	To infraorbital, inferior dental, lingual or mental nerves or middle cranial fossa fracture
	Inflammatory	Osteomyelitis
	Neoplastic	Carcinoma of antrum or nasopharynx
		Oral carcinoma
		Metastatic tumours
		Leukaemic deposits

also carried in trigeminal branches. Damage to the trigeminal can be extracranial (trauma [e.g. surgical, fractures], bone disease, drugs, multiple sclerosis, diabetes or tumours) or intracranial (trauma [e.g. surgical, fractures], inflammatory [infections, sarcoidosis, connective tissue disorders], tumours, cerebrovascular disease, syringobulbia, diabetes, bone disease, drugs or multiple sclerosis).

Trigeminal sensory loss (Table 13.13)

Normal facial sensation, mediated by the trigeminal, is important to protect the skin, mucosae and especially the cornea from damage. Loss of facial sensory awareness, which can be caused by lesions of a sensory branch of the trigeminal nerve or the central connections,

may be completely lost (*anaesthesia*) or partially lost (*hypoaesthesia*). *Paraesthesia* does not mean loss of sensation; rather it means abnormal sensation, often ‘pins and needles’ or similar discomfort.

Extracranial causes of facial sensory loss are most common and include damage to the trigeminal from trauma, which is the usual cause – especially by inferior alveolar local analgesic injections, fractures or surgery (particularly lower third molar removal, osteotomies or jaw resections), mainly after orthognathic or cancer surgery. Rarely, endodontics or implants may be responsible. Ipsilateral lower labial hypoaesthesia or anaesthesia usually results. The lingual nerve may be damaged, especially during removal of lower third molars, and particularly when the lingual split technique is used. Ipsilateral lingual hypoaesthesia or anaesthesia usually results. Occasionally, the mental foramen is close beneath a lower denture and there is anaesthesia of the lower lip on the affected side, as a result of pressure from the denture. Damage to branches of the maxillary division may be caused by the following:

- Trauma – usually middle-third facial fractures
- Bone disease – osteomyelitis in the mandible may affect the inferior alveolar nerve to cause labial anaesthesia. Paget disease is a rare cause of sensory loss
- Malignant disease – oral carcinomas may invade the jaws to cause anaesthesia. Jaw metastases or malignant disease in the bone marrow may damage the nerve supply. Tumours such as carcinoma of the maxillary antrum may cause ipsilateral upper labial hypoaesthesia or anaesthesia. Nasopharyngeal carcinomas may invade the pharyngeal wall to infiltrate the mandibular division of the trigeminal nerve, causing pain, sensory loss and, by occluding the Eustachian tube, deafness (Trotter syndrome). Tumours around the skull base may also involve the trigeminal nerve. Numbness that spreads is a possible indicator of malignancy
- Neuropathies – multiple sclerosis, diabetes, sarcoidosis, toxin
- Drug-induced – e.g. mefloquine; infections – e.g. HIV, herpes simplex virus (HSV), syphilis, Lyme disease, leprosy; amyloidosis; or sickle cell disease.

Intracranial lesions affecting the trigeminal or connections are uncommon but serious, and include inflammatory disorders (multiple sclerosis, sarcoidosis, connective tissue disorders), infections (e.g. HIV, HSV, syphilis, leprosy), neoplasms (tumours around the Gasserian ganglion or posterior cranial fossa may involve the trigeminal nerve; numbness that spreads is a possible indicator of malignancy), syringobulbia or drugs.

Since other cranial nerves are anatomically close, there may be neurological deficits associated with intracranial causes of facial sensory loss. In posterior cranial fossa lesions, for example, there may be cerebellar features such as ataxia. In middle cranial fossa lesions, there may be associated neurological deficits affecting cranial nerve VI and thus mediolateral eye movements.

Benign trigeminal neuropathy is a transient sensory loss in one or more divisions of the trigeminal nerve that seldom occurs until the second decade or affects the corneal reflex. The aetiology is unknown, though some patients prove to have connective tissue disorder. *Psychogenic causes of facial sensory loss* include hysteria, and particularly hyperventilation syndrome. Facial sensation is mediated through the trigeminal nerve but the skin over the angle of the mandible is supplied by cervical nerves.

Trigeminal neuropathy or post-traumatic trigeminal neuropathy may develop after irreparable damage to the trigeminal nerve, most commonly after destructive procedures, such as rhizotomies used for treatment of trigeminal neuralgia, but also after craniofacial trauma

(road traffic accidents), or dental or sinus trauma (e.g. Caldwell–Luc procedures).

Other causes of neuropathic pain can be metabolic (diabetes), inflammatory, infective (post-herpetic neuralgias), neoplastic and, rarely, after local analgesic injections.

Hypoaesthesia or anaesthesia may become associated with abnormal sensations or pain, related to excessive firing of pain-mediating nerve cells (phantom or deafferentation pain), which can start immediately or days to years later. Neuropathic pain may be burning, stabbing, stinging or like an electric shock. Trigeminal neuropathic pain often presents as a constant, unilateral, often mild facial pain with prominent sensory loss; it is spontaneous and unremitting. In the most extreme form (anaesthesia dolorosa), there is continuous severe pain in areas of complete numbness.

Analgesics are rarely effective. The first-line treatment is with a tricyclic antidepressant, such as amitriptyline; gabapentin is the best alternative. Topical capsaicin, which appears to deplete substance P, may also be effective. Trigeminal nerve stimulation procedures may offer relief. More invasive procedures, such as brain surface (pre-motor cortex) stimulation or tractotomy, may be needed.

The blink reflex is tested by touching the cornea of the eye with a wisp of cotton wool. Facial sensation is assessed using a pin and a wisp of cotton wool. Strength and movement of muscles that control the jaw are tested by asking the person to clench the teeth and open the jaw against resistance.

Damage to a sensory branch of the trigeminal causes hypoaesthesia in its area of distribution, initially resulting in a diminishing skin response to pinprick and, later, complete anaesthesia. Lesions involving the ophthalmic division cause corneal anaesthesia: gently touching the cornea with a wisp of cotton wool (which the patient must not see), twisted to a point (corneal reflex), normally causes a blink, but not if the cornea is anaesthetic or the facial nerve is damaged.

It is important, with patients complaining of facial anaesthesia, to test all areas but particularly the corneal reflex, and the reaction to pinprick over the angle of the mandible. If, however, the patient complains of complete facial or hemifacial anaesthesia but the corneal reflex is retained or there is anaesthesia over the angle of the mandible, the symptoms are probably functional rather than organic.

Damage to taste can be tested with sweet, salt, sour or bitter substances carefully applied to the dorsum of the tongue.

Trigeminal motor neuropathy

Trigeminal motor neuropathy may occasionally be seen in isolation – possibly related to a viral infection. Trigeminal motor neuropathy is more frequently associated with trigeminal sensory neuropathy or due to lesions affecting the motor division of the trigeminal nerve when there are usually other cranial nerve deficits, sometimes caused by an intracranial tumour. Weakness may develop, sometimes with masseter and temporalis wasting. Damage to the motor part of the trigeminal can be difficult to establish; it is usually asymptomatic if unilateral but the jaw may deviate towards the affected side on opening. It is easier to detect motor weakness by asking the patient to open the jaw against resistance, rather than by trying to test the strength of closure.

ABDUCENS NERVE (CRANIAL NERVE VI)

The abducens nerve supplies only the lateral rectus muscle. Damage to this nerve may be caused by vascular disease, cavernous sinus syndrome, trauma, orbital apex syndrome or raised intracranial pressure. Lesions can be surprisingly disabling, presenting with (Fig. 13.6):

Fig. 13.6 Lesions of the abducens nerve. With the patient looking directly ahead, the affected left eye deviates medially as its lateral rectus muscle is functionless.

Fig. 13.7 Motor branches of the facial nerve to muscles of facial expression.

- paralysis of abduction of the eye
- deviation of the affected eye towards the nose, and convergent squint – the diplopia is maximal on looking laterally towards the affected side
- normal pupils.

The ability to move each eye outward beyond the midline is tested by asking the person to look to the side.

FACIAL NERVE (CRANIAL NERVE VII)

The facial nerve is the motor supply to the muscles of facial expression (Fig. 13.7), but it also carries taste sensation from the anterior two-thirds of the tongue (via the chorda tympani), secretomotor fibres to the submandibular and sublingual salivary glands and lacrimal glands, and branches to the stapedius muscle.

Causes of damage to the facial nerve include, especially, stroke, trauma and infection; these and other causes are shown in Table 13.14.

The motor neurons supplying the lower face receive upper motor neurons (UMNs) from the contralateral motor cortex, whereas the neurons to the upper face receive bilateral UMN innervation. Thus a UMN lesion (e.g. stroke) causes unilateral facial palsy with some sparing of the frontalis and orbicularis oculi muscles (because of the bilateral cortical representation) and, although voluntary facial movements are impaired, the face may still move with emotional responses (e.g. laughing). Paresis of the ipsilateral arm (monoparesis) or of the arm and leg (hemiparesis), or dysphasia, may also be associated because of more extensive cerebrocortical damage.

Table 13.14 Localization of site of lesion in, and causes of, unilateral facial palsy

Muscles paralysed	Lacrimation	Hyperacusis	Sense of taste	Other features	Probable site of lesion	Type of lesion
Lower face	N	–	N	Emotional movement retained ± monoparesis or hemiparesis ± aphasia	Upper motor neuron (UMN)	Stroke Brain tumour Trauma HIV infection
All facial muscles	↓	+	↓	± VIth nerve damage	Lower motor neuron (LMN)	Multiple sclerosis
				± VIIIth nerve damage	Facial nucleus	Fractured base of skull Posterior cranial fossa tumours Sarcoidosis
	N	±	N or ↓	–	Between nucleus and geniculate ganglion	Otitis media Cholesteatoma
Isolated facial muscles		–	N	–	Between geniculate ganglion and stylomastoid canal	Bell palsy Trauma
					In stylomastoid canal or extracranially	Local analgesia (e.g. misplaced inferior dental block) Parotid malignant neoplasm Guillain–Barré syndrome Herpes simplex virus Lyme disease HIV infection Granulomatous disorders
						Trauma Local analgesia

N = normal.

In contrast, lower motor neuron (LMN) facial palsy (e.g. Bell palsy) is characterized by unilateral paralysis of all muscles of facial expression – for both voluntary and emotional responses.

In facial palsy, the forehead is unfurrowed; the patient is unable to close the eye on that side and attempted closure causes the eye to roll upwards (Bell sign). Lacrimation is diminished in a seventh nerve lesion but, because of the weakness, tears tend to overflow on to the cheek (epiphora), the nasolabial fold is obliterated, and the corner of the mouth droops and saliva may dribble from it and cause angular stomatitis. On the affected side, food collects in the vestibule and plaque accumulates on teeth. Other defects, such as loss of taste or hyperacusis, may be associated.

Facial weakness is demonstrated by asking patients to smile, close their eyes against resistance, raise the eyebrows, whistle or raise the lips to show their teeth. The Schirmer test, carried out by gently placing a strip of filter paper on the lower conjunctival sac and comparing the wetting of the paper with that on the other side, may show reduced lacrimation. Taste is tested by applying sugar, salt, sour lemon juice or vinegar, and bitter substances (aspirin, quinine or aloes) on the tongue and asking the patient to identify each one.

Bell palsy

Bell palsy is facial paralysis for which no local or systemic cause can be identified, though it is now recognized to be a lower motor neuron palsy and mainly due to infection with herpes simplex virus. There appears to be inflammation of the facial nerve in the stylomastoid canal, sometimes with demyelination.

Similar features may occasionally be seen after other herpes virus infections (e.g. varicella zoster virus [VZV], cytomegalovirus [CMV] and Epstein–Barr virus [EBV]), influenza viruses, retroviruses (e.g. HIV and human lymphotropic virus-1 [HTLV-1]), and other infections

Fig. 13.8 Bell palsy. The right side of the face is completely paralysed (A), as demonstrated when the patient tries to smile (B).

such as Lyme disease (*Borrelia burgdorferi*). There are occasional associations with hypertension, lymphoma, Melkersson–Rosenthal syndrome, Crohn disease, orofacial granulomatosis, sarcoidosis, connective tissue disorders, acoustic neuroma, Guillain–Barré syndrome, multiple sclerosis and a variety of other disorders (see Table 13.14). Bell palsy is more common in pregnancy, diabetes, influenza, a cold or another respiratory illness.

Clinical features

There is acute unilateral facial paralysis (with no other paralyses) over a few hours, maximal within 48 hours (Fig. 13.8). Pain in the region of the ear or in the jaw may precede the paralysis by a day or two. Occasionally, hyperacusis (oversensitivity to sound due to loss of

function of the nerve to stapedius) or loss of taste (chorda tympani) on the anterior tongue, or changes in salivation/lacrimation are associated (see Table 13.14). Patients may complain of facial numbness but sensation is intact on testing.

General management

LMN palsy must be distinguished from UMN palsy (Table 13.15) and the degree of palsy assessed (Table 13.16).

Electromyography (EMG) can confirm nerve damage and its severity. If paralysis is progressive, imaging of the internal acoustic canal, cerebellopontine angle and mastoid may be needed to exclude an organic lesion. Most patients with Bell palsy, however, are otherwise healthy, present no management difficulties and totally recover spontaneously within weeks. Nevertheless, active treatment is indicated and includes anti-inflammatory medication (a short course of prednisolone [prednisone] may result in 80–90% complete recovery, compared with about 50–60% in the absence of such treatment); antiviral medication (aciclovir or famciclovir); and facial massage (may help prevent permanent contractures of the paralysed muscles during the acute phase; the cornea should be protected with an eye pad). Patients offered antivirals should be counselled that a benefit from antivirals has not been fully established; if there is a benefit, it is likely to be only modest.

Where paralysis is complete, only 50% recover completely within 1 week but another 25% recover over 2 weeks or so. Few who have not

recovered by 2 weeks will do so. Favourable prognostic signs are incomplete paralysis in the first week and persistence of the stapedial reflex, measured by electroneurography. Bad prognostic signs are hyperacusis, severe taste impairment and/or diminished lacrimation or salivation, especially in older, diabetic or hypertensive patients. Although many patients recover spontaneously, the after-effects in the remaining 10–20% can be severe and distressing, when surgical decompression of the nerve in the stylomastoid canal may be attempted. If paralysis persists and function remains incomplete, the palpebral fissure may narrow, the nasolabial fold deepens and facial spasm may develop. Rare complications, apparently caused by anomalous regeneration of the facial nerve, include irregular or anomalous lacrimation (crocodile tears) when the facial muscles are used – for example, during eating, retraction of the commissure when the eye is closed, or hemifacial spasm.

Dental aspects

In chronic palsy, construction of a splint to support the angle of the mouth may improve aesthetics to some degree, as may a facial graft or other manœuvres such as facial–hypoglossal nerve anastomosis, but results are not always entirely satisfactory.

Ramsay–Hunt syndrome

Severe facial paralysis with vesicles in the ipsilateral pharynx and external auditory canal (Ramsay–Hunt syndrome) may be due to varicella zoster virus (VZV) of the facial nerve geniculate ganglion.

Bilateral facial paralysis

Bilateral facial paralysis is rare but may result from acute idiopathic polyneuritis (Guillain–Barré syndrome, Ch. 37), sarcoidosis (Heerfordt syndrome, Ch. 37), arachnoiditis or posterior cranial fossa tumours.

Other causes of facial weakness

An apparent facial palsy may be caused by myasthenia gravis, some myopathies or Romberg syndrome.

Table 13.15 Differentiation of upper motor neuron (UMN) from lower motor neuron (LMN) lesions of the facial nerve

Action	UMN lesion	LMN lesion
Emotional movements of the face	Retained	Lost
Blink reflex	Retained	Lost
Ability to wrinkle forehead	Retained	Lost
Drooling from commissure	Uncommon	Common
Lacrimation, taste and hearing	Unaffected	May be affected
Tongue protrusion	Normal	Deviates to unaffected side

Table 13.16 Facial palsy severity score

House and Brackmann grades	Facial function	Features	Dysfunction and outcomes
I	Normal	–	–
II	Incomplete paralysis	Slight weakness. The patients may have a slight synkinesis Normal symmetry and tone at rest Forehead motion is moderate to good, complete eye closure is achieved with minimal effort but slight mouth asymmetry	Mild dysfunction Good outcomes
III	Incomplete paralysis	An obvious but not disfiguring difference between the sides. A noticeable but not severe synkinesis, contracture or hemifacial spasm Normal symmetry and tone at rest Forehead movement is slight to moderate, complete eye closure is achieved with effort, and a slightly weak mouth movement is noted	Moderate dysfunction
IV	Incomplete paralysis	An obvious weakness and/or disfiguring asymmetry Symmetry and tone normal at rest No forehead motion. Eye closure is incomplete and an asymmetric mouth is noted	Moderate dysfunction
V	Incomplete facial paralysis	Only a barely perceptible motion Asymmetry at rest No forehead motion Eye closure is incomplete and mouth movement is only slight	Severe dysfunction
VI	Complete facial paralysis	Gross asymmetry Total palsy: no movement	Severe dysfunction

VESTIBULOCOCHLEAR (OR AUDITORY) NERVE (CRANIAL NERVE VIII)

This nerve has two components, the vestibular (concerned with appreciation of the movements and position of the head) and the cochlear (hearing).

Damage to the auditory nerve can be caused by loud noise (explosions, music or occupations where loud sounds are produced), ageing, infections of inner ear and brain, drugs (e.g. aminoglycosides), trauma, stroke or multiple sclerosis. Damage to the vestibular component may be caused by infections (vestibular neuritis and labyrinthitis).

Lesions of the auditory nerve may cause loss of hearing, vertigo or ringing in the ears (tinnitus). An otological opinion should be obtained, as special tests are needed for diagnosis. Hearing is tested with a tuning fork or with headphones that play tones of different frequencies (pitches) and loudness (audiometry). Balance is tested by asking the person to walk a straight line.

GLOSSOPHARYNGEAL NERVE (CRANIAL NERVE IX)

The glossopharyngeal nerve supplies the posterior third of the tongue and the pharynx; it carries taste sensation from the posterior third of the tongue, motor supply to the stylopharyngeus and secretomotor fibres to the parotid. The glossopharyngeal can be damaged by infections, trauma, tumours or surgery in the cerebellopontine angle, pharynx or parapharyngeal space, and lesions are usually associated with lesions of vagus, accessory and hypoglossal nerves (bulbar palsy). They typically cause impaired pharyngeal sensation, so that the gag reflex may be weakened. Bulbar palsy is the term given to weakness or paralysis of muscles supplied by the medulla (tongue, pharynx, larynx, sternomastoid and upper trapezius; cranial nerves IX–XII inclusive). Acute bulbar palsy can be caused by poliomyelitis or diphtheria, chronic progressive bulbar palsy by tumours or aneurysms of the posterior cranial fossa or nasopharynx, or strokes. Various other syndromes, some of which are rare, are tabulated in Appendix 13.1. Because the ninth and tenth cranial nerves control similar functions, they are tested together. The person is asked to swallow, and to say 'aah' (to check movement of the palate and uvula); the back of the throat may be touched with a tongue blade, which evokes the gag reflex in healthy people. The person is asked to speak to determine whether the voice sounds nasal.

VAGUS NERVE (CRANIAL NERVE X)

The vagus has a wide parasympathetic distribution to the thoracic and upper abdominal viscera and the motor supply to some soft palate, pharyngeal and laryngeal muscles. The vagus can be damaged particularly by trauma, including neck surgery, and in particular carotid artery or thyroid surgery. Lesions of one vagus are rare in isolation but can cause impaired gag reflex, hoarse voice and bovine cough; if the patient is asked to say 'aah', the soft palate moves towards the unaffected side.

ACCESSORY NERVE (CRANIAL NERVE XI)

The accessory nerve provides the motor supply to sternomastoid and trapezius muscles. It can be damaged iatrogenically, surgically in neck resections or occasionally in lymph node biopsy or excision. Accessory nerve lesions are often associated with damage to the ninth and tenth nerves and cause ipsilateral sternomastoid weakness (on turning the head away from the affected side) and weakness of the trapezius on

Fig. 13.9 Lesion of hypoglossal nerve with wasting of the left side of the tongue (lower motor neuron lesion).

shrugging the shoulders. There may be an asymmetric neckline, a drooping shoulder, weakness of forward elevation of the shoulder, and a winged scapula – exaggerated on arm abduction.

Testing this nerve is also useful in differentiating patients with genuine palsies from those with functional complaints since, in an accessory nerve lesion, there is weakness on turning the head away from the affected side but those shamming paralysis often simulate weakness when turning the head towards the 'affected' side.

HYPOGLOSSAL NERVE (CRANIAL NERVE XII)

The hypoglossal nerve is the motor supply to the tongue muscles and may be damaged in its intracranial or extracranial course. A tumour or bone disease at the skull base, stroke, infection of the brainstem, an injury to the neck – such as during endarterectomy, or amyotrophic lateral sclerosis can damage the nerve. Intracranial lesions typically cause bulbar palsy (see later). Disease in the condylar canals, such as Paget disease or bone tumours, and peripheral lesions, such as glomus jugulare, carotid body or other tumours, trauma or radiation damage, can cause an isolated hypoglossal nerve deficit. In a UMN lesion the tongue is spastic but not wasted; in an LMN lesion there is wasting and fibrillation of the affected side (Fig. 13.9).

Hypoglossal lesions cause dysarthria (difficulty in speaking), particularly for lingual sounds, and deviation of the tongue towards the affected side on protrusion.

DISORDERS OF TASTE

The complex process of tasting begins when molecules stimulate special sensory (gustatory or taste) cells in the nose, mouth or throat. Another chemosensory mechanism, the common chemical sense, contributes to appreciation of food flavour, especially to sensations like the sting of ammonia, the coolness of menthol and the irritation of chilli peppers.

Humans can commonly identify at least five different taste sensations: sweet, sour, bitter, salty and umami (the taste elicited by glutamate, found in chicken broth, meat extracts and some cheeses). Flavours are recognized largely through the sense of smell. Taste buds are present on the tongue mainly, but also on the soft palate, uvula, epiglottis, pharynx, larynx and oesophagus. Taste perception can be tested with salt (sodium chloride), sweet (saccharin), acidic (citrus) and bitter (quinine) or by electrogustometry. Disorders of taste (dysgeusia) are fairly common and have a wide range of causes (Table 13.17), similar to those causing halitosis.

Table 13.17 Causes of taste loss or change

Cause	Examples
Ageing	–
Local causes	Hyposalivation Irradiation of the oral cavity or salivary glands
Drugs	Acetazolamide Albuterol Amiloride Angiotensin-converting enzyme inhibitors (ACEIs) Anticholinergics Antidepressants Antihistamines Antihypertensives Aspirin Azelastine Captopril Carbimazole Chlorhexidine Clarithromycin Clofibrate Cytotoxic agents Dorzolamide Eszopiclone Etoposide Gold Griseofulvin Imipramine L-dopa Lithium Metformin Metronidazole Penicillamine Phenindione Protease inhibitors Salbutamol (albuterol) Terbinafine Topiramate Zopiclone
Neurological disorders	Alzheimer disease Bell palsy Carotid dissection Encephalitis Facial palsy Head trauma Multiple sclerosis Nerve damage (chorda tympani, facial, glossopharyngeal, lingual) Parkinson disease Posterior cranial fossa disorders Riley–Day syndrome Temporal lobe epilepsy
Nutritional defects	Cancer Vitamin B deficiency Zinc deficiency
Endocrinopathies	Addison disease Cushing syndrome Diabetes Hypopituitarism Hypothyroidism
Metabolic disorders	Chronic renal failure Hepatic disease
Viral infections	Various

Perceived loss of taste usually reflects a smell loss, which is often confused with a taste loss. The sense of taste can also be temporarily disturbed by the use of chemicals such as chlorhexidine.

Rarely, there is complete lack of perception to taste sweet, sour, bitter, salty and umami (ageusia). More commonly, testing may demonstrate a weakened ability to taste (hypogeusia). In other disorders of the chemical senses, the system may misread and/or distort an odour, a taste or a flavour. The most common taste complaint is that of phantom taste perceptions. Alternatively, a person may detect a foul taste from a substance that is normally pleasant-tasting.

Loss of taste can be due to medical disorders, or anaesthesia of the nerves involved, particularly surgery with lingual nerve damage (e.g. resections or third molar extraction); damage to the chorda tympani (from middle ear surgery, herpes zoster oticus, otitis media, mastoiditis or cholesteatoma); upper respiratory infections; head injury; radiation therapy; diabetes; hypertension; malnutrition; chemicals such as insecticides; some drugs (gymnemic acid abolishes the perception of sweet tastes while amiloride abolishes salt perception); or degenerative neurological diseases (Parkinson disease, Alzheimer disease and Korsakoff psychosis).

CEREBROVASCULAR ACCIDENTS, STROKES AND TRANSIENT ISCHAEMIC ATTACKS

General aspects

Blood enters the brain from the two carotid and two vertebral arteries, which branch to supply each specific area of brain. If blood flow from these arteries is interrupted for more than a few seconds, brain cells can die, causing infarction and damage, and resulting in loss of function – a stroke or cerebrovascular accident (CVA) – the syndrome of rapidly developing clinical signs and symptoms of focal and, at times, global disturbance of cerebral function lasting more than 24 hours (or death within that time).

Strokes are a common cause of death (the third leading cause of death, accounting for 1 out of every 15 deaths in the developed world) and disability, especially in older people. The high mortality relates not only to the acute brain damage but also to complications (thrombosis and infection, especially respiratory). A stroke may be preceded by a transient ischaemic attack (TIA), which, by definition, is characterized by a focal neurological deficit that lasts less than 60 minutes and resolves completely within 24 hours. Patients who have had a TIA are at high risk of a stroke and require prompt evaluation. A reversible ischaemic neurological deficit (RIND) is similar but persists for more than 24 hours; again, it is a predictor of a stroke.

The most common cause of CVA is carotid or intracerebral artery atheroma, in which plaque rupture results in arterial occlusion or thrombosis. An embolism from the left side of the heart (a potential complication of atrial fibrillation) may also obstruct cerebral blood flow, and intracerebral or subarachnoid haemorrhages account for the other 20% of strokes. TIAs are typically embolic and cause focal cerebral and neurological deficits. Risk factors for CVA include increasing age, hypertension, atrial fibrillation, ischaemic or valvular heart disease, preceding CVA, diabetes, hypercholesterolaemia, smoking, alcohol, obesity, hyperviscosity syndromes, and prothrombotic and haemorrhagic states. Emboli may also reach the cerebral vessels from fibrillating atria. Rarely, CVAs are secondary to carotid stenosis or dissection; cocaine use; fibromuscular dysplasia; or syphilis. Prevention involves controlling risk factors and taking more exercise.

Clinical features

The clinical manifestations vary according to the duration, severity and pattern of cerebral ischaemia. Typical features include sudden visual deterioration (monocular or homonymous), speech disturbance (expressive or receptive dysphasia) and hemiplegia (loss of voluntary movement of the opposite side of the body to the cerebral lesion). Most patients who sustain an ischaemic or haemorrhagic stroke remain conscious but, if the ischaemia, oedema or haemorrhage is extensive, raised intracranial pressure may impair consciousness – progressing to coma and/or death. Approximately 45% of people with a stroke die within a month; 50% of those who survive 6 months may survive another 7 years. Of survivors, 40% have mild disability, 40% require special care, 10% recover completely and 10% require long-term hospitalization. Prognosis is better in young patients and if there is incomplete paralysis of a limb, no loss of consciousness at onset or later, and no confusion.

Transient ischaemic attacks are typically embolic and may cause focal cerebral deficits such as facial numbness, hemiplegia or dysarthria; about 30% progress to stroke. *Reversible ischaemic neurological deficit* is similar to TIA but persists for more than 24 hours.

Stroke-in-evolution is when such a cerebral deficit persists and worsens. Common symptoms include changes in vision, speech and comprehension, weakness, vertigo, loss of sensation in part of the body, or changes in conscious level.

Typical features of *full stroke* (Table 13.18) include: sudden unconsciousness, often going on to coma or death; hemiplegia (loss of voluntary movement of the opposite side of the body to the brain lesion); changes in speech (slurred, thick, difficult speech or inability to speak – aphasia), often with loss of the ability to write (both the result of a left-sided brain lesion); and visual loss or deterioration, especially in one eye. Other symptoms depend on the area of brain affected, the extent of damage and the cause, but may include numbness, paraesthesia or other sensation changes, or problems with recognizing or identifying sensory stimuli (agnosia), resulting in ‘neglect’ of one side of the body; difficulty in understanding speech, reading or writing; vertigo; swallowing difficulties; personality or emotional changes,

including depression or apathy; loss of bladder or bowel control; and cognitive decline, dementia, ease of distraction, impaired judgment and limited attention.

The four main types of stroke (Table 13.19) are as follows:

- *Cerebral arterial thrombosis*, the most common cause, follows atherosclerosis; it tends to be the least rapid in development and has lowish acute mortality (30%).
- *Intracerebral haemorrhage* mainly affects individuals past middle age and is the most lethal type, with a mortality of 80%. Bleeding into the brain destroys and tears apart the tissue and acts as an expanding lesion, distorting the brain and causing gross cerebral oedema. Predisposing factors are hypertension and atherosclerosis.
- *Subarachnoid haemorrhage* accounts for only about 10% of strokes, originates from a ruptured congenital aneurysm (berry aneurysm) on the arterial circle of Willis (more common in polycystic kidney disease, Ehlers–Danlos syndrome, fibromuscular dysplasia with renal artery stenosis, polyarteritis nodosa and coarctation of the aorta). Hypertension, atherosclerosis, trauma, cocaine or amphetamine abuse, and acute physical or emotional stress may be contributory. Clinically, subarachnoid haemorrhage is characterized by sudden, excruciatingly severe headache, which is quickly followed by coma; unlike other types of stroke, localizing signs, such as hemiplegia, are typically absent. In some cases, slow aneurysm leakage causes headache or minor neurological dysfunction preceding the acute attack. The prognosis is poor: about 30% of patients die from the initial haemorrhage and only 50% survive.
- *Cerebral embolism* is relatively uncommon and usually originates from a fibrillating atrium or intracardiac thrombosis secondary to a myocardial infarct, and rarely from endocarditis or a thrombosed prosthetic heart valve. Embolic strokes are *not* associated with activity levels, can occur at any time, and typically are dramatically sudden and may affect a younger person.

General management

Diagnosis of a CVA is essentially clinical, based upon a history and clinical features. Specific neurological, motor and sensory deficits often correspond closely to the location of the brain damage. Neck stiffness, Brudzinski sign (flexing the neck causes the patient to flex knees and hips) and Kernig sign (flexing the hip 90° and straightening the knee causes pain) become positive in subarachnoid haemorrhage. Examination may also show changes in vision or visual fields, abnormal eye movements, muscle weakness, impaired sensation and other changes. A ‘bruit’ may be heard over the carotid arteries in the neck.

Table 13.18 Disability following stroke^a

	Right-sided brain lesion	Left-sided brain lesion
Side paralysed	Left	Right
Other deficits	Thought, perception	Language, speech
Other problems	Memory Problems with performing tasks and using mirrors	Memory Problems with organization

^aSee Table 13.19.

Table 13.19 Clinical features of different types of stroke

	Haemorrhage		Thrombosis	Embolism
	Intracerebral	Subarachnoid		
Prodrome	–	±	Transient ischaemic attacks (TIAs)	–
Onset	Rapid	Rapid	Gradual	Sudden
First symptom	Headache	Intense headache	Ill-defined	Headache
Progression	Hemiplegia and aphasia	Coma	Gradual and intermittent	Immediate
Underlying diseases	Hypertension Atherosclerosis	Aneurysm	Hypertension Atherosclerosis	Atrial fibrillation, etc.
Prognosis	High mortality	High mortality	From minimal dysfunction to death in a week	80% recur

There may be signs of atrial fibrillation. It is also important to assess risk factors, including co-morbid medical conditions. MRI or CT may localize the site and assess the degree of cerebral damage. However, MRI is not always possible and CT may be normal in the early stages of ischaemic stroke or in patients with minor symptoms. Cardiac investigations (ECG and echocardiogram) help in arrhythmias and valvular heart disease. Carotid duplex scans assess carotid artery stenosis and arterial blood flow to the brain.

Cerebral arteriography can identify a source of haemorrhage. Brainstem evoked response audiometry and clotting, thrombophilia and vasculitic screens may help. Blood biomarkers of stroke, such as S-100b (a marker of astrocytic activation), B-type neurotrophic growth factor, von Willebrand factor, matrix metalloproteinase-9 and monocyte chemoattractant protein-1, have yet to be proved superior to conventional investigations.

Virtually all stroke victims or those with developing stroke should be admitted early to hospital for assessment and management, the goal being to prevent a stroke or to prevent its spread, and to maximize the patient's ability to function. The time of the stroke, progression and conscious level (using the Glasgow Coma Scale; Ch. 24) should be recorded. Early treatment in a dedicated stroke unit lowers mortality and morbidity. Supportive care includes protection of the airway with appropriate ventilatory support; speech and language assessment; keeping the patient nil by mouth if swallowing is impaired, and placing a nasogastric tube to reduce the risk of an aspiration pneumonia; pressure-sensitive nursing to avoid the development of bed sores; urinary catheterization and incontinence pads if urethral and anal sphincteric reflexes are impaired; physiotherapy to reduce muscle wasting and disuse atrophy; and occupational therapy for long-term rehabilitation. The airway must be protected during the acute phase and, for virtually all strokes, hospitalization is required, possibly including intensive care, life support and oxygen.

It is essential to establish the type of stroke since patients under good care have mortality reduced by 25% and recurrence by a similar amount. The degree of disability can be assessed according to one of several scales (e.g. the Barthel Index, Glasgow Outcome Scale, Hunt and Hess Classification of Subarachnoid Hemorrhage, Modified Rankin Scale or NIH Stroke Scale). Anticoagulation may be useful if it is certain that the stroke is thrombotic or embolic. Alteplase is recommended for ischaemic stroke. Recombinant tissue plasminogen activator (rtPA) lyses clots and potentially restores blood flow to the affected area to prevent further cell death and permanent damage, but there are strict criteria because of the risk of serious bleeding for those who can receive it. The most important is that the stroke victim be evaluated and treated by a specialized stroke team within 3 hours of onset of symptoms. Aspirin and other antiplatelet drugs are also used to prevent non-haemorrhagic strokes.

Antihypertensive medication is frequently indicated. Control of atrial fibrillation is needed to prevent recurrent strokes. Analgesics are required to control severe headache. Nimodipine (a calcium antagonist) helps reduce intracranial vasospasm.

Surgical treatment may include emergency neurosurgery or interventional neuroradiology to clip or glue a leaking aneurysm, or evacuate a large intracerebral bleed. Carotid endarterectomy facilitates removal of atheroma to improve blood flow to the cerebral arteries.

Precautions must be taken in the later care of the comatose patient, to prevent pressure sores and sometimes urinary catheterization or bladder/bowel control programmes are needed to control incontinence. If the person has swallowing difficulties, nutrients and fluids may be given through an intravenous line or via a nasogastric or gastrostomy tube. Longer-term care involves rehabilitation, based on the symptoms,

and prevention of future strokes. Recovery is possible as other areas of the brain take over functioning for the damaged areas. Depression and other symptoms should be treated. People should stay active within their physical limitations but safety must be considered, since some stroke victims appear to have no awareness of their surroundings on the affected side. Friends and family members should repeatedly reinforce important cues, like name, age, date, time and where they live, to help reduce disorientation. Communication may require pictures, demonstration, verbal cues or other strategies, depending on the type and extent of language deficit. In-home care, nursing homes, adult day care or convalescent homes may be needed to provide a safe environment, control aggressive or agitated behaviour, and meet physiological needs. Visiting nurses or aides, volunteer services, homemakers, adult protective services and other community resources may be helpful. Speech therapy, occupational therapy, physical therapy, positioning, range-of-motion exercises, and other therapies may prevent complications and promote maximum recovery of function. Legal action may make it easier to make ethical decisions regarding the care of the person with organic brain syndromes such as stroke.

For TIAs or RIND, aspirin reduces the chance of progression to full stroke. Antihypertensive medication is frequently indicated. Otherwise, the investigations are as above for stroke.

Dental aspects

Many patients with a stroke initially suffer confusion and emotional lability; therefore, encouragement is an extremely important motivating factor. Access, mobility and communication may be impaired in many, since they may have cognitive and visual defects, as well as dysarthria, aphasia, confusion, memory loss, and emotional distress and depression. Support with preventive care is critical; oral hygiene tends to deteriorate on the paralysed side, and impaired manual dexterity may interfere with tooth-brushing. Use of an electric toothbrush or adapted holders may help.

Dentists should defer elective and invasive dental care for 3–6 months. It is important to communicate clearly with the patient by not wearing a mask, by facing the patient and by speaking slowly and clearly, using language that is not complex. Short treatment sessions in mid-morning are desirable for these patients, who are best treated in the upright position, with extra care taken to prevent foreign bodies from entering the pharynx. The practitioner needs to monitor blood pressure and anticoagulation status before beginning any dental treatment.

Dental management modifications in a patient with a stroke may also include consideration of problems relating to loss of protective reflexes, such as swallowing and gag reflexes in brainstem lesions. Patients are best treated sitting upright and extra care must be taken to avoid foreign bodies entering the pharynx. Good suction must be at hand.

Subarachnoid or cerebral haemorrhage can be precipitated by acute hypertension and, in the past, has resulted from the use of noradrenaline (norepinephrine) in LA. Cerebral haemorrhage can also stem from hypertension caused by interactions of MAOIs with other drugs, particularly pethidine (meperidine). Opioids are best avoided in strokes, as they may cause severe hypotension and these and benzodiazepines may cause respiratory depression. It is thus important to have short stress-free treatment sessions in mid-morning and to monitor blood pressure; use the minimal amount of adrenaline (epinephrine) in LA; avoid the use of adrenaline-containing gingival retraction cords; and possibly avoid electronic dental analgesia.

Multidisciplinary care is required for modifications related to anticoagulation, hypertension, cardiovascular disease, diabetes mellitus or old age.

After a stroke, patients may have unilateral (UMN) facial palsy. Oral hygiene tends to deteriorate on the paralysed side and impaired manual dexterity may interfere with tooth-brushing. An electric toothbrush may help. Oropharyngeal dysphagia post-stroke in around 50% of patients makes a significant contribution to morbidity and mortality, since it predisposes to respiratory infection, malnutrition and weight loss.

Strokes are a possible cause of sudden loss of consciousness in the dental surgery and should be recognizable, especially by the sudden loss of consciousness and, usually, signs of one-sided paralysis as already described. Protection of the airway and a call for an ambulance are the only useful immediate measures (Ch. 1).

Calcified atherosclerotic plaques may sometimes be detected on dental panoramic radiographs.

LOCKED-IN SYNDROME

Locked-in syndrome is a condition in which a patient is aware and awake, but cannot move or communicate due to complete paralysis of nearly all voluntary muscles. It is usually due to a brainstem lesion, such as a stroke, trauma, infection or tumour, but higher centres remain intact. Some patients can move certain facial muscles, most often some extraocular eye muscles. There is a 90% early mortality. Of survivors, most do not regain motor control but assistive computer interface technologies may help patients to communicate.

MOVEMENT DISORDERS

Muscles may move without the person meaning them to. For example, tiny muscle twitches (fasciculations) may indicate nerve damage to that muscle. Other possible involuntary movements are rhythmic movements of a body part (tremor), twitches (tics), sudden flinging of a limb (hemiballismus), quick fidgety movements (chorea) or snake-like writhing (athetosis), all of which suggest motor incoordination due to basal ganglia disease. Muscle tone that is evenly increased (rigidity) may be due to Parkinson disease. Muscle tone is severely reduced (flaccid) immediately and temporarily after a spinal cord injury produces paralysis. Muscle tone that is uneven and suddenly increased (spasticity) may be due to a stroke or spinal cord injury.

One of the most common involuntary movements is a tremor, which may have many causes – essential tremor, Parkinson disease, Huntington chorea and cerebellar disease (Table 13.20).

PARKINSON DISEASE (PD; PARALYSIS AGITANS)

General aspects

Parkinson disease (PD) is a common but serious brain disorder that causes trembling, muscle rigidity, difficulty in walking, and problems with balance and coordination; its prevalence increases with age. PD affects mainly the basal ganglia with degeneration of the substantia nigra pigmented cells that normally release dopamine – the neurotransmitter that travels between the substantia nigra and corpus striatum, which enables muscles to make smooth controlled movements. Profound depletion of nigrostriatal dopamine results in disequilibrium of the extrapyramidal motor circuits and development of parkinsonism (i.e. tremor, bradykinesia and rigidity).

PD usually affects people over the age of 50. Most cases are idiopathic and people who have an affected first-degree relative are at

three times greater risk of developing it themselves. *PINK1* mutations tend to be diagnosed as the early-onset autosomal recessive form of PD. Parkinsonism may also be caused by cerebrovascular disease, head injury (particularly in boxers), drugs (particularly phenothiazines and butyrophenones [dopamine receptor blockers], valproate, metoclopramide and prochlorperazine), and (rarely) encephalitis lethargica (von Economo disease). Severe parkinsonism has followed the use of an illicitly manufactured opioid (methyl phenyl tetrahydropyridine, MPTP) and this led to the suggestion that many cases of apparently idiopathic disease are due to environmental toxins, such as pesticides, herbicides, manganese, heavy metals or carbon monoxide. PD is more common in people who are engaged in farming, live in rural areas or drink well water. Lower oestrogen levels may also raise the risk of PD; menopausal women who receive little or no hormone replacement therapy (HRT) and those who have had hysterectomies may be at higher risk, while menopausal women using HRT appear to have a decreased risk.

Clinical features

The earliest features of PD can be as subtle as an arm that does not swing when walking, a mild tremor in the fingers, or soft or mumbling speech that is difficult to understand. The primary features are:

- tremor, or trembling in hands, arms, legs, jaw and face
- rigidity, or stiffness of limbs and trunk
- bradykinesia, or slowness of movement
- postural instability, or impaired balance and coordination.

Early symptoms of PD are subtle and often occur gradually. PD is chronic and progressive and, as the disease follows its course, the tremor may begin to interfere with daily activities. As features become more pronounced, patients may have difficulty walking, talking or completing other simple tasks. Other features may include depression

Table 13.20 Motor abnormalities: terms, features and main causes

Disorder	Features	Main causes
Akathisia	Restlessness	Neuroleptic drugs
Akinesia	Lack of movement	Parkinsonism
Athetosis	Dystonia of limbs	Athetoid cerebral palsy
Chorea	Continual flow of jerky movements	Huntington and Sydenham chorea (rheumatic fever)
Clonus	Rhythmic contractions	Upper motor neuron (UMN) lesions
Dyskinesia	Involuntary chewing or grinding	Phenothiazines
Dystonia	Sustained spasms causing abnormal posture	Phenothiazines
Fasciculation	Spontaneous contractions of muscle fibres	Lower motor neuron (LMN) lesions
Hemiballismus	Chorea affecting half of the body	Subthalamic lesion
Rigidity	Limbs resist passive movement	Parkinsonism
Spasticity	Excess tone in arm flexors, leg extensors	Cerebral palsy; UMN lesion
Tremor	Rhythmic movements of a part at rest	Parkinsonism, anxiety, drugs, thyrotoxicosis, benign, or brain lesion. Worse with anxiety; better with alcohol, benzodiazepines or beta-blockers
	On intention to move	Cerebellar disease

and other emotional changes; difficulty in swallowing, chewing and speaking; urinary problems; constipation; skin problems; and sleep disruption (Box 13.6 and Fig. 13.10).

Many people with PD develop voices that become monotonous and very soft, a special problem for older adults because the voice may not be audible to a partner with poor hearing. Even the functioning of the digestive tract may slow down, causing difficulties with swallowing, digestion and elimination, and constipation is often a major problem. PD may cause either urinary incontinence or urine retention, and anticholinergic drugs used to treat the disease make it hard to urinate. Bradykinesia may progress to akinesia and total rigidity.

Complications of PD may include subtle psychiatric disorders, deformities of the hands and feet, ocular abnormalities, urinary and gastrointestinal disturbances, and autonomic dysfunction (which may cause mild postural hypotension, disordered respiratory control and hypersalivation that, with the movement defect, may result in drooling). The face in PD is often expressionless and there is a loss of the blink reflex as a response

to gentle tapping of the bridge of the nose. Oculogyric crises may be seen in drug-induced or post-encephalitic disease.

General management

There are no diagnostic tests for PD.

Supportive care is required. Treatment aims to enhance brain dopamine – but treatment with dopamine itself is impossible, since it fails to cross the blood–brain barrier. Drug treatment with dopaminergic agents aims to increase dopamine by increasing L-dopa; by inhibiting dopamine breakdown; or by using agonists of dopamine (Table 13.21) hopefully with minimal adverse effects such as confusion; may interfere with driving; may cause fibrotic reactions (lungs, heart, retroperitoneal); and may cause impulse control disorders (e.g. gambling, hypersexuality, or binge eating). Symptom relief may be possible with L-dopa combined with carbidopa – which delays the conversion of L-dopa into dopamine until it reaches the brain. Bradykinesia and rigidity respond best, while tremor may be only marginally reduced. Monoamine oxidase inhibitors such as rasagiline or selegiline enhance L-dopa activities (see below). Dopaminergic drugs may cause daytime sleepiness.

Other drugs, such as bromocriptine, pramipexole and ropinirole, mimic dopamine. Anticholinergics (antimuscarinic drugs) reduce tremor and rigidity, and they (or catechol-O-methyl transferase [COMT] inhibitors such as entacapone or tolcapone) may be given together with L-dopa in severe cases.

Box 13.6 Features of parkinsonism

- Tremor – mainly affecting the hands (pill-rolling) and arms, and worst at rest. Tremors also may develop in the head, lips or feet
- Rigidity – the arms are flexed and held stiffly at the sides. Limb movement has a so-called cog-wheel rigidity
- Abnormal posture – the neck and shoulders are rigid, causing a stooping posture
- Restlessness (akathisia) – typical
- Slowness (bradykinesia) – slowness in the initiation and execution of movements and poverty of spontaneous movements. The patient may be slow at starting to walk but then runs forwards (festinant gait) or shuffles with slow short steps. Speech may be affected

Fig. 13.10 Parkinsonism.

Table 13.21 Drug treatment in Parkinson disease		
Drug examples	Action	Comments
L-dopa (levodopa); usually given with inhibitor of degradative enzyme dopa decarboxylase, e.g. carbidopa (co-careldopa) or benserazide (co-beneldopa)	Replaces dopamine	L-dopa is converted into dopamine in the brain and may improve akinesia and imbalance. Adverse effects include involuntary movements (dyskinesia), nausea, arrhythmias, liver dysfunction, depression, psychoses and hallucinations. L-dopa is contraindicated in glaucoma
Bromocriptine Pergolide Lysuride Ropinirole Cabergoline Pramipexole Apomorphine (injection) Amantadine	Dopamine agonists Acts like a dopamine agonist	Useful when L-dopa cannot be tolerated, but can cause hypotension or serious neuropsychiatric adverse effects, and pulmonary, retroperitoneal and pericardial fibrosis An antiviral
Monoamine oxidase B (MAO-B) inhibitor (selegiline)	Inhibits MAO-B and thus dopamine breakdown	Toxic reactions have occurred in some patients who took selegiline with the narcotic pethidine (meperidine)
Catechol-O-methyl transferase (COMT) inhibitors	Block the liver enzyme that breaks down dopamine and dopa	Tolcapone has been linked to liver damage and liver failure. Entacapone may help manage fluctuations in the response to L-dopa in people with Parkinson disease
Trihexyphenidyl/benzhexol Benzatropine Orphenadrine Procyclidine	Anticholinergics (block acetylcholine)	Effective at reducing tremor at rest

Propargylamine MAOIs demonstrate antioxidant and antiapoptotic activity. The physiological role of MAO is to catalyse the biotransformation of a variety of arylalkylamine neurotransmitters, such as dopamine, adrenaline (epinephrine), noradrenaline (norepinephrine) and serotonin, as well as to detoxify biogenic amines, such as tyramine. MAO-B found within glial cells is the predominant isoform responsible for breakdown of dopamine to 3,4-dihydroxyphenylacetic acid and homovanillic acid (HVA), as well as deamination of alpha-phenylethylamine, an endogenous amine that stimulates the release of dopamine and inhibits its neuronal reuptake. Selective inhibition of MAO-B increases synaptosomal dopamine concentrations. Therefore, selective inhibition of brain MAO-B is pharmacologically desirable for treating PD. Rasagiline potently and completely inhibits MAO-B and increases basal synaptosomal levels of striatal dopamine. Rasagiline mesylate (*N*-propargyl-1[R]-aminoindan) is a second-generation, selective and irreversible inhibitor of MAO-B, and is therefore used along with L-dopa for patients with advanced PD or as a single-drug treatment for early PD.

An antiviral, amantadine, also appears to reduce symptoms. Adenosine A(2A) receptor antagonists may prove useful in the future. Rotigotine, a non-ergoline dopamine agonist is available as a transdermal preparation.

Deep brain stimulation (DBS), which involves implanting a brain stimulator, similar to a heart pacemaker, within the subthalamic nucleus, may reduce tremors, slowness of movements and gait problems, as well as the need for L-dopa and related drugs; this in turn decreases the dyskinesias that are a common adverse effect of L-dopa. The device can also be placed in the thalamus for tremor control or the globus pallidus to produce effects similar to pallidotomy. Neurosurgery may reduce tremor but carries a number of risks, including slurred speech, disabling weakness and vision problems, especially when performed bilaterally. Thalamotomy, the destruction of small amounts of tissue in the thalamus, is useful to reduce tremor. Pallidotomy, use of an electric current to destroy a small amount of tissue in the pallidum (globus pallidus), may improve tremors, rigidity and slowed movement but benefits do not always persist.

Experimentally, brain grafts of fetal substantia nigral tissue have been given but their value is as yet unclear; one large study reported that as many as 15% of recipients developed severe dyskinesias as a result of *excess* dopamine.

Dental aspects

It is essential in patients with PD not to let the blankness of expression and apparent unresponsiveness be mistaken for lack of reaction or intelligence. Sympathetic handling is particularly important, as anxiety increases tremor, which may affect the tongue and/or lips. Patients should be raised upright only cautiously and carefully assisted out of the dental chair, since parkinsonism, L-dopa and some other agents may cause hypotension. The movements, drooling and head positioning associated with PD can make the use of sharp and rotating instruments hazardous and may compromise restorative care. L-dopa in combination with a dopa-decarboxylase inhibitor may interact with adrenaline (epinephrine) to cause tachycardia, arrhythmias and hypertension. Adrenaline may interact with COMT inhibitors (tolcapone, entacapone) to cause tachycardia, arrhythmias and hypertension; therefore, LA without adrenaline should be used in these patients. Erythromycin and other macrolides may increase levels of bromocriptine or cabergoline. Pergolide may rarely induce cardiac valvulopathy; pramipexole may cause sudden onset of sleepiness. It is important not to stop anti-Parkinsonian medication, since this might precipitate the neuroleptic malignant syndrome (Ch. 10).

Conscious sedation (CS) should be safe. Pethidine (meperidine) should be avoided in patients receiving selegiline or other MAOIs,

since a serious interaction is possible. Selegiline differs from other MAOIs in that it should not cause acute hypertensive episodes when it is used with most other drugs.

Drooling of saliva may be troublesome; injection of botulinum toxin into salivary glands significantly decreases saliva production, which may be beneficial. Orofacial involuntary movements (dyskinesia), such as 'flycatcher tongue' and lip-pursing, are side-effects of L-dopa and bromocriptine, and may make the use of rotating dental instruments more hazardous.

L-dopa may cause taste disturbances and reddish saliva. Antimuscarinic drugs may produce dry mouth.

Drills and ultrasonic scalers are safe to use in a patient with a DBS pacemaker but check that it is still switched on after treatment.

HUNTINGTON CHOREA

General aspects

Huntington chorea is an autosomal dominant condition related to a gene on chromosome 4 and the protein huntingtin. It is due to atrophy of the caudate nucleus of the basal ganglia and characterized by involuntary movements (chorea), emotional disturbances and progressive dementia; currently, it is incurable.

Clinical features

The name *chorea* comes from the Greek for 'dance' and refers to the characteristic and incessant quick, jerky and involuntary movements.

Signs and symptoms usually appear in early to middle age (30–50 years) and may include: involuntary jerky movements of fingers, feet, arms, neck, trunk and face; hesitant, halting or slurred speech; clumsiness or poor balance; wide, prancing gait; personality changes (moodiness, paranoia); and deterioration in cognitive function (memory, attention, decision-making).

Progress of disease is slow, often leading to difficulty walking so that patients become chair-bound. Life is often ended by intercurrent infection, or sometimes suicide, since patients are usually aware of the family history and poor prognosis.

General management

There is no satisfactory treatment available to stop or reverse Huntington disease and thus genetic counselling, though available, is not always taken up. A high-calorie diet may be advised, as the involuntary movements can burn up considerable calories. Medications may help. Some signs and symptoms may be controlled by neuroleptics (e.g. clonazepam). Antipsychotics (e.g. haloperidol and clozapine) help control movements, violent outbursts and hallucinations. Speech therapy can be valuable. Lithium can help control extreme emotions and mood swings. Fluoxetine, sertraline and nortriptyline can assist in the control of depression and the obsessive-compulsive rituals that some people with Huntington disease develop. Most individuals who have Huntington disease eventually become physically and mentally disabled, and therefore may require short-term psychiatric hospitalization and, as the disease progresses, long-term nursing care.

Dental aspects

Patients can often understand what they are being told but may be unable to respond; this can give a false impression of the degree of dementia.

There may be darting movements of the head and tongue that subside somewhat if physical control is applied. The chorea can make

operative dentistry or the construction and wearing of prostheses difficult or nigh impossible; general anaesthesia (GA) or CS may then help but especial care must be taken to protect the airway at all times. Oral hygiene may be impaired through reduced manual dexterity, and a predilection to caries and periodontal disease is worsened by medications that cause xerostomia or by a high-calorie diet unless thought is given to avoiding cariogenicity. Orofacial trauma may occur.

NEURAL TUBE DEFECTS (SPINA BIFIDA)

See Chapter 28.

POLIOMYELITIS

General aspects

Anterior poliomyelitis (polio) is an enteroviral infection, spread faeco-orally, that may damage the lower motor neurons and sometimes motor cranial nerves. Rare in the developed world since the introduction of an effective vaccine, it is still common in developing countries; it appears in the developed world in some immigrants or where vaccine uptake is poor.

Clinical features

Typically causing wasting and paralysis of a lower limb, polio may affect other areas, including the medulla oblongata, when it can cause bulbar palsy and respiratory paralysis.

General management

Patients with respiratory paralysis must be artificially ventilated (on an 'iron lung') permanently.

Dental aspects

Patients with bulbar palsy or a high-level spinal lesion may also have impaired gag and cough reflexes, and thus their airway must be carefully protected. Good suction must be used. Patients with quadriplegia may benefit from the dentist constructing a mouthstick or bitestick appliance with which they can perform manual functions or operate a computer, telephone and other means of communication. Those with paraplegia require care similar to persons with spina bifida (see Ch. 28).

SPINAL CORD DAMAGE AND PARAPLEGIA

See Chapter 28.

ABNORMAL FACIAL MOVEMENTS

Dystonias

Dystonias are a group of uncommon basal ganglia diseases characterized by abnormal movements associated with muscle spasm, and are focal or generalized. An example of focal dystonia is torticollis. Most dystonias are primary (a neurological disorder cannot be identified). Those that result from defined organic diseases affecting the brain are known as secondary dystonias.

Oromandibular dystonia refers to recurrent spasmodic episodes of lip movement, tongue protrusion and retraction, and jaw clenching or

opening. This may be associated with blepharospasm, and respiratory muscles and speech may be impaired. Over one-third of patients may suffer from depression. Treatment is difficult but benzodiazepines may be helpful.

Acute oromandibular dystonia (drug-induced parkinsonism) can appear within a short time (hours or days) of starting treatment with neuroleptics, such as phenothiazines and butyrophenones. It may resolve after withdrawal of the drug or be improved with antimuscarinics such as benztropine. However, it is made worse by L-dopa, which can itself also cause involuntary spasmodic movements if the dose is too great.

Torticollis

Torticollis (from the Latin *torti* – twisted – and *collis* – neck) refers to the neck being held in a twisted or bent position. It can be congenital or acquired.

Infants born with torticollis appear healthy at delivery, but over days to weeks develop soft-tissue swelling over an injured sternocleidomastoid due to birth trauma or intrauterine malpositioning. This mass, which may be confused with a branchial cleft cyst, regresses and leaves a fibrous band in place of the muscle, causing contracture of the neck.

Acquired torticollis or idiopathic spasmodic torticollis is a focal dystonia known as acute wry-neck; it is the type most frequently encountered and develops overnight in young and middle-aged adults. Symptoms usually resolve spontaneously within 2 weeks with use of heat, massage, supportive cervical collar, muscle relaxants and analgesics. Torticollis may be associated with other forms of focal dystonia, such as blepharospasm, writer's cramp, spasmodic dysphonia or orobuccal dystonia.

Dyskinesias

Dyskinesias are abnormal movements of the tongue or facial muscles, sometimes with abnormal jaw movements, bruxism or dysphagia.

Common dyskinesias are involuntary tongue protrusion and retraction, and facial grimacing. Tardive dyskinesia is usually a late (hence tardive) complication of long-term treatment with neuroleptics. It is somewhat similar to oromandibular dystonia. It rarely responds to withdrawal of the offending drug, is usually made worse by giving antimuscarinics, and may be resistant to treatment.

Facial tics

Most facial tics are benign spasms (habit spasms) and usually affect children. Common tics are blinking, grimacing, shaking the head, clearing the throat, coughing or shrugging. Emotion or fatigue intensifies tics but the natural history is of spontaneous remission. If the tic is persistent, haloperidol may be helpful.

Gilles de la Tourette syndrome

This includes tics and compulsive behavioural rituals, sometimes with coprolalia (utterance of obscenities).

Hemifacial spasm and blepharospasm

Hemifacial spasm (clonic facial spasm) mainly affects adults, particularly older people, with a spasm that involves especially the angle of mouth or the eyelid and worsens towards evening. Many cases of

hemifacial spasm are idiopathic, but some herald a cerebellopontine angle lesion or other lesion and some follow facial palsy. Occasionally, facial paralysis or trigeminal neuralgia follows.

Blepharospasm is a spasm of both eyelids that may be seen in the elderly, either in isolation or with hemifacial spasm.

Local injections of botulinum toxin into the affected muscles may give relief for up to 3 months but must be given with extreme care, as there is a hazard of corneal exposure and glaucoma.

Facial myokymia

Facial myokymia is a rare but serious condition in which there are continuous fine, worm-like contractions of one or more facial muscles, especially the perioral or periorbital muscles. It must be distinguished from facial hemispasm, facial tics or blepharospasm (which involves several muscles synchronously), and from benign fasciculation and myokymia of the lower eyelid, which are quite innocuous.

Facial myokymia starts suddenly, lasts for variable periods and is unaffected by voluntary movements; it is frequently associated with multiple sclerosis, brainstem or posterior cranial fossa tumours, or other neurological disorders. Neurological assessment is crucial.

Myoclonus

Myoclonus refers to a quick, abnormal, involuntary muscle jerk, that usually comes infrequently or many times a minute. In severe cases, it can distort movement and limit the ability to walk, talk and eat. Jerking leg movements while the person is at rest used to be called myoclonus, but they are now referred to as periodic leg movements (restless legs syndrome). Myoclonus can be normal if it only affects persons as they fall asleep (hypnic jerks). However, it can also be a sign of drug adverse effects (e.g. amitriptyline); metabolic disorders, such as hepatic or renal failure or hyponatraemia; or CNS disorders, such as infection, viral encephalitis or Creutzfeldt–Jakob disease, brain damage (trauma or stroke), multiple sclerosis, epilepsy, Parkinson disease or Alzheimer disease.

Treatment of myoclonus is usually with anticonvulsants.

BOTULINUM TOXIN

Botulinum toxins are increasingly used, especially in cosmetic surgery, but they are neurotoxins and severe, life-threatening, respiratory muscle problems and death have occasionally occurred when the toxin has spread through the body.

Botulinum toxin type A (Botox [Allergan]; BTX; Dysport [Ipsen]; Xeomin [Merz Pharma]) is one of seven distinct neurotoxins produced by *Clostridium botulinum*. It has high specificity and potency, and *small* doses of purified, sterilized toxin may be injected to block the release of acetylcholine and thus temporarily paralyse muscles. It is widely used to paralyse facial muscles to improve the appearance of moderate to severe frown lines between the eyebrows (glabellar lines) or other wrinkles for up to 120 days.

Botulinum toxin type A has been used for an extensive range of conditions but there is most evidence that it can be useful to treat blepharospasm, hemifacial spasm and cervical dystonia. It also acts on cholinergic synapses in the autonomic nervous system, and injection into salivary glands significantly decreases saliva production, which may be beneficial for patients with sialorrhoea, such as in Parkinson disease or amyotrophic lateral sclerosis. There are no randomized controlled trials of botulinum toxoid in a range of applications (orofacial

pain syndromes, cluster headache, chronic paroxysmal hemicrania, trigeminal neuralgia) and only a few small-sized trials in others (cervicogenic headache, chronic neck pain, temporomandibular disorders).

Botox should be injected no more frequently than once every 3 months and the lowest effective dose should be used. Botulinum toxin type A is contraindicated for use in pregnancy and neuromuscular disorders. Air travel should be avoided for 72 hours, as a decrease in pressure may affect distribution of the toxin. The most common adverse events following injection of Botox are generally temporary but can last several months, and include headache, respiratory infection, an influenza syndrome, blepharoptosis (droopy eyelids) and nausea. In less than 3%, adverse reactions may include pain in the face, redness at the injection site and muscle weakness. Botulinum toxin type A has occasionally caused severe, life-threatening breathing problems and death. These symptoms occurred as soon as one day and as late as several weeks after botulinum toxin type A injections were given.

Botulinum toxin type B (BoNTB; Myobloc) acts at a slightly different site from toxin A, and is used to treat cervical dystonia. It may cause severe xerostomia and many of the adverse effects seen with botulinum toxin type A. Botulinum toxin type B has occasionally caused severe, life-threatening breathing problems and death as soon as one day and as late as several weeks after injections were given.

DEMYELINATING AND DEGENERATIVE DISEASES

MULTIPLE (DISSEMINATED) SCLEROSIS

General aspects

Multiple sclerosis (MS) is the most common demyelinating disease of young adults, especially women. There is a high prevalence in northern Europe and North America, and there may be a familial predisposition. MS is thought to be an autoimmune disease in genetically susceptible individuals, perhaps of viral aetiology, and possibly due to human herpes virus 6 (HHV-6), with autoantibodies directed against myelin sheath proteins. Vitamin D is possibly associated with some protection against MS and reduced relapse risk in certain patients. It is a chronic relapsing disorder, characterized by the formation of 'plaques' (areas of demyelination) throughout the CNS. Inflammation of and damage to the myelin sheath with multiple areas of scarring (sclerosis) impair muscle coordination, visual sensation and other nerve signals.

Clinical features

The hallmark of MS is a series of neurological deficits, distributed in time and space, that are not explained by any other causes. Up to 35% of cases are subclinical. Clinical features depend on the area of the CNS affected and may include fatigue, dizziness, numbness, weakness or paralysis in a limb, brief pain, tingling or electric-shock sensations, tremor, lack of coordination or unsteady gait, visual disturbances causing diplopia or a moving field of vision and pain on eye movement (optic neuritis), urinary incontinence, constipation and sexual dysfunction, or cognitive changes (memory loss and impaired concentration). Nystagmus, ataxia, jerky (scanning) speech, tremors and loss of muscular coordination develop as a result of cerebellar involvement. Occasionally, mental changes, such as forgetfulness or confusion, occur. MS varies in severity and speed of evolution, ranging from a mild illness to one that results in permanent disability (Table 13.22). As the disease progresses, muscle spasms, vision loss, problems with bladder, bowel or sexual function, and paralysis may develop and,

Table 13.22 Multiple sclerosis (MS) subtypes

Subtype	Frequency	Features
Relapsing–remitting	80%+	Short acute attacks about once each year
Primary progressive	10%	Progressive deterioration from outset
Secondary progressive	Uncommon	Progressive deterioration in patients with relapsing–remitting MS, after approximately 10 years
Progressive–relapsing	Rare	Relapses in patients with primary progressive MS

ultimately, there can be widespread paralysis, loss of sphincter control and urinary incontinence.

General management

Diagnosis is assisted by MRI to identify demyelinating disease (T2-weighted MRI shows demyelinating plaques and gadolinium-enhancing lesions); delayed visual evoked response potentials (VEPs) and CSF examination may demonstrate a slightly raised white cell count, increased protein concentration and oligoclonal bands indicating intrathecal immunoglobulin synthesis.

Management requires a multidisciplinary team. Symptomatic care may include physical and occupational therapy, counselling and drugs.

There is no specific reliably effective treatment for MS, but acute episodes may be ameliorated by disease-modifying agents (DMAs) beta-interferons (interferon-beta-1b and beta-1a) and glatiramer – an immunomodulator that shifts pro-inflammatory T-helper 1 (Th1) cells to regulatory Th2 cells that suppress the inflammatory response. Neither interferon nor glatiramer is recommended by the National Institute for Health and Care Excellence (NICE) for the treatment of MS in England and Wales. Other potent anti-inflammatory agents like natalizumab (a monoclonal antibody that inhibits leukocyte migration in the CNS) and alemtuzumab are increasingly used, particularly in patients with breakthrough disease activity. Mitoxantrone – a topoisomerase inhibitor – may help in severe attacks. Dimethyl fumarate (Tecfidera) is approved for use in adults with relapsing forms of MS. Intravenous immunoglobulin has a positive effect in relapsing and advanced MS. Corticosteroids promote remission in acute episodes but do not influence long-term prognosis. Low-dose methotrexate is also used. Oral fumarate appears to reduce disease activity significantly in relapsing–remitting MS. Experimental approaches include plasma exchange. Muscle relaxants (baclofen, tizanidine, dantrolene and benzodiazepine) may reduce pain from spastic muscle paralysis. Antidepressants (e.g. fluoxetine), the antiviral amantadine or modafinil (a medication used for narcolepsy) may reduce fatigue.

Dental aspects

There are no specific oral manifestations of MS but this diagnosis should always be considered in a young patient presenting with trigeminal neuralgia, particularly if bilateral, or if there have been other neurological disturbances, or if the pain lasts minutes or hours. It may respond to carbamazepine. Other presentations may include cerebellar tremor; abnormal speech; abnormal perioral sensation, such as extreme hypersensitivity or anaesthesia; or facial palsy, myokymia or hemispasm. Atropinics used in the treatment of bladder dysfunction may cause dry mouth, as may tizanidine. Glatiramer may cause facial oedema.

Dental preventive care and treatment are important since oral hygiene may be poor. Limited mobility and psychological disorders may interfere with routine dental treatment. Patients with severe MS are best not treated fully supine, as respiration may be embarrassed. Treatment is best carried out under LA if possible. Nitrous oxide is probably best avoided since it may theoretically cause demyelination. Some patients are on corticosteroids, with attendant complications (Ch. 6).

GUILLAIN–BARRÉ SYNDROME (INFECTIVE OR IDIOPATHIC POLYNEURITIS)

General aspects

Guillain–Barré syndrome (GBS) appears to be an immunologically mediated disorder mainly of peripheral nerves, which may follow bacterial infections (campylobacteriosis, from eating undercooked food, especially poultry); viral infections (approximately two-thirds of people affected by GBS have had an infection, such as sore throat, diarrhoea, cold or influenza, or EBV or CMV infection, up to 4 weeks before the onset); or operations (5–10% of all cases). GBS occasionally follows vaccinations (within 1.5–5 weeks of vaccination).

Clinical features

GBS is a serious neurological disorder characterized by subacute onset of progressive, symmetrical weakness in the arms and legs. There is loss of reflexes, and there may be sensory abnormalities, respiratory paralysis and involvement of the cranial nerves. There is a low mortality, and 20% of hospitalized patients can suffer prolonged disability. GBS can be devastating because of its sudden onset; signs and symptoms usually appear rapidly over the course of a single day, and may include weakness, paraesthesia or loss of sensation in legs and feet, or in arms or upper body, with hypoaesthesia, paraesthesia or moderate pain throughout the body. Difficulty with breathing, eye and facial movement, speaking, chewing or swallowing, and paralysis of legs and arms, may follow. There may be bradycardia, hypotension and difficulty with bladder or intestinal control. Generally, GBS progresses quickly, with most patients experiencing the most profound weakness in the legs, arms, chest and other areas within 3 weeks. In some cases, GBS may progress very rapidly with complete paralysis of legs, arms and respiration over a few hours. Recovery may take as little as a few weeks or as long as a few years, and up to 30% have some residual weakness after 3 years.

Miller Fisher syndrome is a rare variant of GBS, characterized by ataxia, ophthalmoplegia and areflexia.

General management

Diagnosis is confirmed by lumbar puncture and EMG. Hospitalization is required and treatment approaches include plasmapheresis, intravenous immunoglobulin and physiotherapy.

MOTOR NEURON DISEASE

General aspects

Motor neuron disease (MND) comprises a group of uncommon fatal neurodegenerative diseases affecting males, especially in old age, and causing damage to motor neurons (especially anterior horn cells;

Fig. 13.11 Motor neuron disease.

Fig. 13.11). The aetiology is unclear but may be viral; 90% of cases of the most common type are sporadic, while a few others are due to a defect in the gene for superoxide dismutase, which normally protects against free radical damage.

Clinical features

There are three subtypes of MND:

Amyotrophic lateral sclerosis (ALS) is the most common subtype and has an intermediate prognosis. It affects oligodendrocytes and motor neurones in the anterior horn and pyramidal tract, and begins in the hands, feet and limbs, but is rapidly progressive and spreads to the trunk. UMN and LMN damage cause hand wasting and weakness, and leg spasticity. Early signs and symptoms include cramps and twitching in arms, shoulders and tongue (the hypoglossal nerve may be affected); slow loss of strength and coordination in one or more limbs; and weakness in feet and ankles, resulting in a stiff and clumsy gait and in foot-dragging. ALS eventually affects bulbar functions such as chewing, swallowing, speaking and breathing but, even in the late stages, sensory, bowel, bladder and cognitive functions are spared. Involvement of the brainstem may lead to pseudobulbar palsy – bulbar palsy with emotional lability (involuntary weeping or laughing). When muscles in the diaphragm and chest wall fail, individuals lose the ability to breathe without ventilatory support. Riluzole (an ant glutamate) prolongs life by 2–3 months but does not relieve symptoms. Other drugs are available to help individuals with spasticity, pain, panic attacks and depression. Physiotherapy, occupational therapy and rehabilitation may help, as may forms of mechanical ventilation (respirators). ALS is relentless, with respiratory paralysis and death supervening within 5 years.

Progressive bulbar palsy affects brainstem anterior horn cells and thus cranial nerve motor neurons arising in the medulla (IX–XII inclusive). It has the worse prognosis, and is characterized by wasting, weakness and fasciculation of the muscles of the pharynx, tongue, palate, sternomastoid and trapezius.

Progressive muscular atrophy has the best MND prognosis, affecting the anterior horn below the foramen magnum and causing LMN lesions with wasting and weakness starting in small muscles of the hands and spreading proximally.

General management

Diagnosis is clinical, based on the history and findings of muscle fasciculation, weakness, wasting, spastic dysarthria and exaggerated reflexes. Nerve conduction studies and EMG are confirmatory. Riluzole may slow the progress of ALS. Physical and occupational therapy, speech therapy, nutritional support and, eventually, breathing assistance are needed and can be remarkably successful (as in the case of Prof Stephen Hawking). Morphine or pethidine (meperidine) is frequently needed for terminal care.

Dental aspects

Oral hygiene may be impaired, as in other conditions with disability. Weakness or paralysis in the neck and head can lead to dysphagia and drooling. Protection of the airway may also be impaired. Botulinum toxin injection into salivary glands significantly decreases saliva production.

SYRINGOMYELIA

General aspects

Syringomyelia is cavitation of the spinal cord, of unknown aetiology, causing disruption of pain and temperature neurons of the anterior commissure. *Syringobulbia* is the term used if it affects the brainstem (usually the medulla).

Clinical features

Symptoms begin in adolescence or adult life and progress erratically. Syringomyelia leads to segmental loss of pain and temperature but preservation of touch senses, causing painless ulcers, injuries or burns and deranged (Charcot) joints. Damage to sympathetic neurons in the intermediolateral column of the spinal cord can cause Horner syndrome. Later, the pyramidal tracts may be involved, causing leg spasticity. Kyphoscoliosis develops at an early stage.

Syringobulbia may also cause facial or oral sensory changes or paralyses, but medullary damage rarely affects the respiratory or cardiovascular centres significantly.

General management

There is no effective treatment. Patients should be protected from injuries, especially from heat.

Dental aspects

Syringobulbia can cause facial sensory loss with unilateral palatal and vocal cord palsies, nystagmus, weakness and atrophy of the tongue, dysphagia and dysarthria.

PATIENTS WITH RESPIRATORY PARALYSIS

Spinal cord trauma, infarction, haemorrhage, myelitis, tumours or poliomyelitis may cause severe and permanent disablement, but the type of disability depends largely on the level and extent of the lesion within the spinal cord. High-level lesions can be fatal, or cause respiratory paralysis and quadriplegia. Lower-level lesions may cause paraplegia and many of the problems that afflict persons with spina bifida (Ch. 28).

ORGANIC BRAIN DISORDERS

Damage to focal areas of brain from trauma, stroke, tumours or infections may lead to a range of defined neurological defects (Table 13.23) and epilepsy, whilst damage that is more gross may also cause coma or death.

More diffuse cortical damage can lead to acute or chronic organic brain disease (dementia) and widespread brain dysfunction. *Acute organic brain disease* can have many causes (Table 13.24). Characterized by disorientation, anxiety, fear, hallucinations, delusions and impaired consciousness, patients with acute organic brain disease must be handled carefully with tact and reassurance, and may need sedation and psychiatric help (Ch. 10).

Chronic organic brain disease (dementia) is more common than acute, and probably affects 1% of those aged 60 years, doubling every 5 years thereafter so that, by age 85 years, up to 50% are affected. Dementia is not a feature of old age *per se* but has many causes; almost two-thirds is Alzheimer disease and one-quarter is multi-infarct (vascular) dementia (Table 13.25).

Everyone has occasional lapses in memory, especially with advancing age, and it is often quite normal to forget the names of people whom you rarely see, but it is not a normal part of ageing to forget the names of familiar people and objects.

Dementia is an acquired progressive loss of cognitive functions, intellectual and social abilities, severe enough to interfere with daily functioning, and characterized by amnesia (especially for recent events), inability to concentrate, disorientation in time, place or person, and intellectual impairment (including loss of normal social awareness; Box 13.7). Other less specific symptoms include mood changes or paranoia. Anxiety, fear, hallucinations and delusions can be features.

Dementia is often accompanied by disruptive behaviour, and may be mimicked by acute organic brain disease, confusional states, drug-induced disorders and psychiatric disease.

Informed consent is a fraught issue in patients with dementia. They themselves are rarely able to give informed consent and, in many countries, relatives and staff have no legal right to give such consent on the patient's behalf. If a person is not capable of giving or refusing consent, and has not validly refused such care in advance, treatment may still be given lawfully if it is deemed to be in the patient's best interests. However, this should happen only after full consideration of its potential benefits and unwanted effects, and consultation with the carer(s), relatives and other people close to the patient.

DEMENTIA

Dementia may be caused by systemic disorders such as metabolic syndrome, in which the combination of high blood pressure, high cholesterol, and diabetes causes confusion and memory loss, or by Alzheimer disease.

Table 13.23 Defects resulting from brain cortex damage

Area damaged	Examples of resulting defects
Frontal	Anosmia, abnormal affect, difficulty in motivation/planning, aphasia, perseveration, personality changes
Occipital	Cortical blindness, homonymous hemianopia, visual agnosia, impaired visual perception
Parietal	Astereognosis (failure to recognize common objects by feel), disorders of learned movements such as writing
Temporal	Memory impairment, cortical deafness, auditory agnosia, impaired musical perception

Table 13.24 Possible causes of acute organic brain disorders

Causes	Mental complications that may result
Chemicals	Various
Drugs	Various
Endocrine disease	
Acromegaly	Emotional lability
Addison disease	Apathy, mild recent amnesia
Corticosteroid therapy	Euphoria
Cushing syndrome and disease	Euphoria or depression, psychoses with delusions or hallucinations
Hypoglycaemia (in treated diabetes mellitus)	Confusion, dementia
Hypothyroidism	Impaired concentration, amnesia, depression, paranoia, acute confusion
Hyperparathyroidism with hypercalcaemia	Apathy, depression
Thyrotoxicosis	Anxiety and agitation, depression
Infections	See text
Trauma	Ch. 24
Tumours	See text

Table 13.25 Causes of dementia

Common causes	Uncommon causes
Alcoholism	Brain-occupying lesion
Alzheimer disease	Chronic traumatic encephalopathy
Hydrocephalus	Creutzfeldt–Jakob disease
Lewy body dementia	HIV infection/AIDS
Multi-infarct dementia	Hypothyroidism
Tumours	Huntington chorea
	Pick disease (frontal lobar atrophy)
	Syphilis
	Vitamin B ₁₂ deficiency
	Wernicke–Korsakoff syndrome

Alzheimer disease (Alzheimer dementia)

General aspects

Alzheimer disease (AD) is the most common form of dementia. It may affect 10–15% of those over 65, 20% of those over 80 years of age and nearly half of those aged 85 and older. AD involves parts of the brain that control thought, memory and language, and can seriously affect a person's ability to carry out daily activities.

It seems likely that a combination of factors is responsible:

- *Age* – This is a major factor.
- *Gender* – Women are more likely to develop AD, even allowing for their longer life expectancy.
- *Head injury* – Severe head injury or whiplash, or trauma over an extended period (e.g. boxing), increases the risk.
- *Lifestyle* – Smoking, hypertension, low folate and high blood cholesterol increase the risk. Aluminium or mercury appears not to be causal. Evidence for physical, mental and social activities as protective factors against AD is growing.
- *Genetic* – Abnormalities on chromosome 1, 14 or 21 account for a small number of cases of early-onset dementia. Down syndrome is also caused by an abnormality of chromosome 21 and, as these individuals age, 50% will show the physical brain changes and behavioural symptoms of AD. A gene on chromosome 19 that controls apolipoprotein E4 has been implicated in later-onset AD. The genes involved in AD (*ApoE4*, *TREM2* or *Fad*) seem responsible for a common pathogenic pathway centred around cellular trafficking, maturation and abnormal processing of beta-amyloid precursor protein (β -APP), and the subsequent generation, aggregation and intracellular deposition of toxic beta-amyloid ($A\beta$: $A\beta$ 1–42) peptides.

The three major pathological hallmarks of AD are:

- *amyloid plaques* – These are made of beta-amyloid peptide and other fragments
- *neurofibrillary tangles* (NFTs) – Damage to tau proteins in neurons causes malfunction and loss of microtubule stabilization, and neuronal atrophy
- *loss of connections between neurons responsible for memory and learning* – Neurons die throughout the brain, and affected regions atrophy.

The brain degenerates, with reduced neurotransmitter levels, creating signalling problems and a progressive decline in memory and mental abilities. Similar brain changes can be seen in Down syndrome; both have a defect on chromosome 21, where the *APP* gene is located. Mutations in this *APP* gene, or the pre-senilins PS-1 or PS-2, or inheritance of the ApoE allele, are responsible for some cases of AD.

Clinical features

AD may manifest with slight memory loss and confusion, and an inability to perform previously simple tasks, but eventually leads to decreasing cognitive skills and severe, irreversible mental impairment that destroys a person's ability to remember, reason, learn and imagine (Box 13.8). Initially, people with AD experience memory loss and confusion, which may be mistaken for age-related memory changes ('senior moments'). However, there are gradual behavioural and personality changes, a decline in cognitive abilities such as decision-making and language skills, and problems recognizing family and friends. AD ultimately leads to a severe loss of mental function. In most people with AD, features include:

Box 13.8 Changes in cognition (mental ability) in Alzheimer disease

- Dementia (dysfunction of multiple cognitive functions)
- Difficulty performing common motor skills, such as combing one's hair, despite normal strength (apraxia)
- Difficulty in understanding or using language to speak or write (aphasia)
- Failing memory
- Inability to recognize familiar objects (agnosia)
- Inability to perform simple arithmetic (acalculia)
- Inability to sustain concentration when performing a task
- Inability to distinguish right from left
- Poor visual-spatial comprehension (e.g. getting lost driving in a familiar area)

- memory loss – one of the most common signs is forgetting recently learned information
- challenges in planning or solving problems, such as ability to develop and follow a plan or work with numbers
- difficulty completing familiar daily tasks
- confusion about time or place
- trouble understanding visual images and spatial relationships, such as difficulty reading, judging distance and determining colour or contrast
- trouble following or joining a conversation
- misplacing things and losing the ability to retrace steps
- decreased or poor judgment
- withdrawal from work or social activities
- changes in mood and personality, such as becoming confused, suspicious, depressed, fearful or anxious
- features of anxiety and depression – these may also be present, often contributing to social difficulties and self-neglect.

In advanced dementia, individuals may be disoriented in time, place and person. The ability to recognize family or friends, or carry out the simplest, once-routine tasks that require sequential steps, such as combing the hair or tooth-brushing, decreases. There are also general deteriorations in motor skills and difficulties with abstract thinking, decision-making and finding the right word. People with AD may initially have trouble balancing their cheque book, a problem that progresses to trouble understanding and recognizing numbers. Eventually, reading and writing are also affected and inability to solve everyday problems, such as knowing what to do if food on the stove is burning, makes independent living impossible. Ultimately, there can be disorientation and grossly inappropriate or bizarre behaviour, in which loss of a sense of time and dates, personality changes, delusions, mood swings or depression, and disordered behaviour of many kinds may be associated. Patients may express distrust in others, show increased stubbornness and withdraw socially. Restlessness is also a common sign and eventually patients may even wander from home.

General management

No definitive test is available. The diagnosis depends on evidence of a progressive decline in cognitive function in the absence of focal neurological deficits and the exclusion of other organic disease, such as hypothyroidism and vitamin B₁₂ deficiency. Investigations include full blood count, renal and liver profiles, serum vitamin B₁₂ and folate levels, syphilis serology, infection screen and MRI. Additional diagnostic studies included serial neurocognitive testing, NeuroSPECT, ApoE genotyping, and a CSF assay of tau and beta-amyloid. AD differs from multi-infarct dementia, as shown in Table 13.26.

Table 13.26 Comparison of Alzheimer disease and multi-infarct dementia

	Alzheimer disease	Multi-infarct dementia
Gender	F > M	M > F
Age at onset	70–90 years	60–80 years
Aetiopathogenesis	? Possibly environmental/familial	Transient ischaemic attack (TIA) or stroke
Hypertension and ischaemic heart disease	±	+ + +
Onset	Slow, progressive deterioration	Acute and stepwise deterioration
Main symptoms	Cognitive loss	Emotional disturbance
Cognitive loss	Global	Patchy
Insight	Lost	Preserved
Personality	Lost	Preserved
Focal signs	±	+ + +

Medications used to treat AD, to assist individuals carry out activities of daily living by maintaining thinking, memory or speaking skills, and which can also help some of the associated behavioural and personality disturbances, include drugs that stabilize acetylcholine levels (donepezil, rivastigmine, galantamine) and an antagonist of glutamate, a neurotransmitter present at abnormally high levels in AD (mefenazine). Oestrogens, NSAIDs, and antioxidants such as vitamin E may improve cognition. Ginkgo biloba may improve memory. An unexpected benefit of statins (inhibitors of 3-hydroxy-3-methyl-glutaryl-CoA [HMG-CoA]) has been their effect on enzymes that generate A β peptides. Glutamatergic agonist and A β -peptide immunization, however, have had little impact. Methylene blue is an innovation and looks promising in early clinical trials. Sedatives and antidepressants may help manage associated anxiety and depression.

Patients with dementia should be managed in the community if possible, although a detailed assessment by a psychogeriatrician is often needed. People with AD are individuals with their own likes and dislikes, struggling to make sense of a world they can no longer fully understand. It is essential to treat them with respect and dignity, using good verbal and non-verbal communication:

- Engage their attention. Eliminate distractions, such as traffic noise or other people's conversations. Make eye contact. Be relaxed and calm.
- Gently hold their hand or put your arm around their shoulder to comfort them.
- Give verbal cues: 'I'm your dentist,' rather than the more challenging 'Do you remember who I am?' Use simple short sentences. Ask questions one at a time in such a way that they can answer 'yes' or 'no'. Repeat or rephrase your words if they do not understand.
- Listen carefully to what the person says. If you have to interpret their meaning, check that you have guessed correctly.
- Never speak down to someone with dementia, or speak across them as if they were not there. Even if you get no response, include them in your conversations.
- Reassure them constantly. Use gentle humour to form a bond between you.

Once you know them, it may be appropriate to call them by their first name, which they will recall long after they have forgotten their surname.

Nothing is worse than delivering treatment that the patient neither understands nor appreciates, and struggles to avoid. Treatment planning should be realistic and patient-centred, aiming to maintain

quality of life. When the many complex issues are evaluated, there are essentially four choices:

- Comprehensive routine care, including aesthetic and prosthodontic treatments
- Monitoring and maintaining the existing dentition by restoring new cavities and implementing prevention
- Emergency care only, relieving pain and infection, and implementing prevention if possible
- No dental treatment at all because of poor general health or inability to cooperate.

As AD progresses, the person must be constantly reassessed, and individualized care plans revised to take into account physical and cognitive changes.

Treatment may involve management of concurrent problems, which may make dementia worse (e.g. respiratory or urinary tract infections); social services (supportive interventions for both patients and carers – long-term residential or nursing home care may become necessary); and drugs.

In advanced AD, the inability of patients to care for themselves leads to: difficulty eating, incontinence and health problems, such as pneumonia and other infections; urinary incontinence, which may require catheterization and raises the risk of infections; and falls and their complications. Prolonged immobilization, which may be necessary to recover from injuries related to a fall, raises the risk of deep vein thrombosis and pulmonary embolism.

Dental aspects

Up to 75% of patients with AD require dental attention but the chief problems are behavioural. It is crucial to anticipate future decline in oral hygiene. Carers must be involved. Attention to diet, oral hygiene and preventive care are important but after a time may no longer be practicable. Dental treatment should be planned with the knowledge that the patient may sooner or later become unmanageable for treatment under LA. In the early stages, dental appointments and instructions are forgotten. Later, there is progressive neglect of oral health as a result of forgetting the need, or even how, to brush the teeth or clean dentures. Dentures are also frequently lost or broken, or cannot be tolerated. Deterioration of dental care, together with hyposalivation, can lead to destruction of the dentition by caries and periodontal disease, and increase the problems of management because of difficulty in eating and halitosis. Periodontitis has even been suggested as an aetiological factor in AD. Injuries are also common in demented patients. Drugs, such as phenothiazines used to manage behavioural problems, may aggravate xerostomia and may cause dyskinesias. Loss of taste is common. Salivary substitutes may give some symptomatic relief.

Treatment should, as far as possible, be carried out in the morning, when cooperation tends to be best, and with the usual carers present in a familiar environment; care is needed to explain every procedure before it is carried out and to avoid discomfort. Time-consuming and complex treatments should be avoided.

Access can be a serious handicap. Preoperative sedation with a short-acting benzodiazepine or haloperidol may be required.

Frontotemporal dementia (Pick's disease)

Frontotemporal dementia (FTD) is a progressive dementia, which is typically associated with shrinking of the frontal and temporal anterior lobes of the brain. The current designation of the syndrome groups together Pick's disease, primary progressive aphasia and

semantic dementia as FTD. Some doctors propose adding corticobasal degeneration and progressive supranuclear palsy to frontotemporal dementia and calling the group Pick complex.

Symptoms of FTD fall into two groups: changes in behaviour or problems with language. The first type features behaviour that can be either impulsive (disinhibited) or bored and listless (apathetic) and includes:

- inappropriate social behaviour
- lack of social tact
- lack of empathy
- distractibility
- loss of insight into the behaviours of oneself and others
- an increased interest in sex
- changes in food preferences
- agitation or, conversely, blunted emotions
- neglect of personal hygiene
- repetitive or compulsive behaviour
- decreased energy and motivation.

The second type primarily features symptoms of language disturbance, including difficulty making or understanding speech, often in conjunction with symptoms of the behavioural type of FTD. Spatial skills and memory remain intact.

BRAIN TUMOURS

Brain (cerebral) tumours are second only to cerebrovascular lesions as a cause of neurological disease. Most are metastatic from carcinomas of the lung, breast, gastrointestinal tract and kidney, but primary cerebral tumours are also usually malignant. A possible relationship between brain tumours and dental radiography has been reported but not as yet confirmed. Intracranial lymphomas are a well-recognized feature of HIV disease and are rising in prevalence. In children, brain tumours account for approximately 2% of all cancer deaths but are second only to leukaemia as a cause of death.

Epileptiform fits developing for the first time in an adult are strongly suggestive of a cerebral tumour. Typical features of a tumour are localizing signs dependent on the site (e.g. convulsions or paralysis), and signs of raised intracranial pressure (headache, vomiting, papilloedema, lapsing consciousness, rising blood pressure and slowing pulse). Cerebral tumours, even those that are histologically benign, have a poor prognosis if not amenable to surgery.

Acoustic neuroma (neurofibroma)

Acoustic neuroma is usually a benign tumour that arises from the neural axon or sheath of the vestibular part of cranial nerve VIII, where it leaves the brainstem in the posterior cranial fossa. Bilateral acoustic neuromas are characteristic of neurofibromatosis type II (Fig. 13.12). Clinically, this causes tinnitus (ringing in the ears), deafness and rotational vertigo (a sensation of spinning), and then post-auricular pain, disturbance of balance, facial twitching or weakness and paraesthesia; as the trigeminal, facial, glossopharyngeal and vagus nerves become stretched over the tumour, there is difficulty in speaking and swallowing – a highly characteristic picture. The neuroma can be completely removed surgically in about 60% of cases.

Meningioma

Ionizing radiation is a risk factor for meningioma, the most common primary brain tumour. An increased risk of meningioma is associated

Fig. 13.12 Neurofibromatosis.

with bitewing examination on a yearly or more frequent basis, and was also linked to Panorex films® taken at a young age or on a yearly or more frequent basis. Exposure to some dental X-rays performed in the past, when radiation exposure was greater than in the current era, appears to be associated with an increased risk of intracranial meningioma.

The American Dental Association's statement on the use of dental radiographs (American Dental Association 2006) highlights the need for dentists to examine the risk/benefit ratio associated with the use of dental X-rays and confirms that there is little evidence to support the use of dental X-rays to search for occult disease in asymptomatic patients or to obtain routine dental X-rays from all patients at preset intervals.

Pituitary tumours

Adenomas are the most common pituitary tumours. Their endocrine effects dominate the clinical picture (Ch. 6) but they may compress the gland and cause hypopituitarism, or produce signs common to other cerebral tumours.

The craniopharyngioma arises from Rathke's pouch, an upgrowth from the primitive stomatodeum, may resemble an ameloblastoma or calcifying odontogenic cyst microscopically. Most manifest in childhood with headache, vomiting, papilloedema and visual defects. Short stature, delayed sexual development and diabetes insipidus may be associated. Suprasellar calcification may be seen, especially on CT.

Pituitary tumours can be removed, often through a trans-sphenoidal approach.

CENTRAL NERVOUS SYSTEM INFECTIONS

Meningitis

Meningitis is infection of the membranes (meninges) that surround the brain and spinal cord, and has a number of possible causes and

Table 13.27 Causes and sequelae of meningitis

Causes		Comments
Infective		
Viral	Enteroviruses: Coxsackie viruses, ECHO viruses and mumps	Thousands of cases occur each year, mostly affecting babies and children. Most common; usually self-limited to 10 days or less and a mild disease. Although most recover fully, some remain with serious and debilitating after-effects. Specific treatment rarely available
Bacterial	<i>Neisseria meningitidis</i> (meningococcus)	Most cases in babies and young children. Uncommon. Around 7% die and 15% left with severe disability. Meningococcal disease describes meningitis and septicaemia, which can occur alone or more commonly together. Treat urgently with antimicrobials (benzyl penicillin or cefotaxime)
	<i>Streptococcus pneumoniae</i> (pneumococcus)	Most cases in babies and young children under 18 months of age. Increasingly important in adult life, particularly in those with impaired resistance (e.g. alcoholism or sickle cell disease). A life-threatening infection; 20% die and 25% are left with severe and disabling after-effects. Treat with intravenous ceftriaxone or cefotaxime (often penicillin-resistant), or if cause is unclear. Vaccine is available
	<i>Haemophilus influenzae</i>	Usually in babies and children under the age of 4. Hib vaccine significantly reduced cases. Treat with cefotaxime
	<i>Listeria monocytogenes</i>	Treat with amoxicillin plus gentamicin
	<i>Mycobacterium tuberculosis</i>	Usually originates from lungs but in about 2% is haematogenous. Develops slowly. Difficult to diagnose and treat
	Group B streptococcus (<i>Streptococcus agalactiae</i>) and <i>Escherichia coli</i>	The most common causes in newborn babies. Risks higher for premature babies. Fatality rates as high as 20%
	<i>Staphylococcus aureus</i>	May complicate neurosurgical procedures
	<i>Listeria monocytogenes</i>	Associated with malnutrition and alcoholism
Fungal	<i>Cryptococcus neoformans</i> , <i>Candida albicans</i>	Rare. Typically seen in immunocompromised people. Often develop slowly. Difficult to diagnose and treat
Non-infective		
Physical injury		–
Cancer		
Drugs		
Systemic lupus erythematosus		

sequelae (Table 13.27; see also Ch. 21). Viral meningitis is usually fairly inconsequential and self-limiting. However, high fever, severe and persistent headache, stiff neck, nausea and vomiting may appear suddenly and require prompt medical attention since some forms of meningitis, notably bacterial, are potentially fatal.

Bacterial (suppurative) meningitis

General aspects

A number of bacteria may cause meningitis, notably *Neisseria meningitidis* (meningococcus), *Streptococcus pneumoniae* (pneumococcus)

and *Haemophilus influenzae* B (Hib; see Table 13.27). *N. meningitidis* (12 serotypes are known) is carried in the nasopharynx and sometimes causes meningitis epidemics, mainly in children or adolescents. Most cases are caused by serogroups A, B and C, less commonly by serogroups W-135 and Y. Recent outbreaks have been caused by groups B and C. Group B, type 15 meningococcus, in particular, causes a severe form of the disease. Spread of bacteria to the meninges is by the bloodstream or occasionally results from a maxillofacial fracture involving the ethmoid cribriform plate (Ch. 24).

Clinical features

Meningitis is characterized by severe headache, nausea or vomiting, pain and stiffness of the neck, drowsiness, photophobia, fever, stupor or coma and, occasionally, convulsions. A purpuric rash is characteristic of meningococcal septicaemia, which, as a result of bleeding into the adrenal cortex, can go on to adrenocortical failure with vasomotor collapse, shock and death (Waterhouse–Friderichsen syndrome).

General management

Diagnosis is confirmed with a Gram-stained smear, culturing and examining for meningococci by the polymerase chain reaction (PCR) from throat, lumbar puncture (CSF) specimen and blood. Antibiotic treatment should start immediately, even before microbiology results are available. If treatment is prompt, the overall mortality is low, but about 20% suffer permanent neurological damage (e.g. cranial neuropathies – blindness, deafness or palsies, epilepsy or learning impairment).

Patients with middle third maxillofacial injuries should be given prophylactic antimicrobials because of the danger of meningitis (Ch. 24). Family contacts of patients with contagious meningitis require chemoprophylaxis with rifampicin or ciprofloxacin. ACWY Vax is a meningitis quadrivalent vaccine that contains inactivated polysaccharide extracts of meningococci types A, C, W-135 and Y.

Brain abscess

General aspects

Brain abscesses usually arise secondary to middle ear, sinus or pulmonary infections, head trauma or infective endocarditis. Bacteria from periodontal pockets, particularly anaerobes, or periapical periodontitis are also a recognized focus for cerebral abscess; inhalation of a tooth fragment or materials used in dentistry can cause a lung abscess, which can metastasize to the brain with serious consequences. Patients with congenital heart disease, particularly those with right-to-left shunts, and those with hereditary haemorrhagic telangiectasia are also at risk of brain abscess.

In immunocompetent persons, frontal lobe abscesses often result from sinusitis and contain a heavy growth of *Streptococcus milleri*. Sphenoidal sinusitis is notorious in this respect and can be difficult to diagnose. Post-traumatic or postoperative brain abscesses are often related to *Staphylococcus aureus*.

Temporal lobe abscesses frequently arise from middle ear mixed bacterial infections, with large numbers of anaerobes. In immunocompromised persons, brain abscesses may also be fungal (mainly *Candida*, *Aspergillus* or *Cryptococcus*) or protozoal (*Toxoplasma*).

Clinical features

Cerebral abscess causes signs and symptoms similar to those of other space-occupying lesions of the brain (i.e. headache, nausea, vomiting,

diminished level of consciousness, hypertension, bradycardia and respiratory changes).

General management

CT and MRI are valuable in the diagnosis. Treatment is by immediate high doses of antibiotics (usually penicillin or metronidazole, or both), followed, where necessary, by aspiration or drainage. The mortality is still between 10% and 20%.

Encephalitis

Encephalitis (inflammation of the brain) is usually caused by viral infection. Symptoms include sudden fever, headache, vomiting, photophobia (abnormal visual sensitivity to light), stiff neck and back, confusion, drowsiness, clumsiness, unsteady gait and irritability.

Some cases are mild, short and relatively benign, and patients recover fully; others are severe, and permanent impairment or death is possible. The acute phase of encephalitis may last for 1–2 weeks, with gradual or sudden resolution of fever and neurological symptoms. Neurological symptoms may require many months before full recovery. No specific treatment is available unless infection is caused by herpes simplex virus.

Herpetic simplex encephalitis

Herpetic simplex encephalitis is rare, although still the most frequent cause of encephalitis in temperate climates. Evidence as to whether it is a primary or reactivation infection is conflicting. Clinical effects are highly variable, ranging from early symptoms, such as disorientation, personality changes, hallucinations and ataxia (which can be mistaken for drunkenness or psychosis) to stupor, fits, paralyses and sensory loss. Coma is often pre-terminal.

Herpetic simplex encephalitis has often been fatal, particularly because confirmation of the diagnosis has had to be by brain biopsy, but the prognosis has improved greatly as a result of treatment with aciclovir and related antiviral drugs, which are frequently given on suspicion. The incidence of neurological damage among survivors has also declined.

Neurosyphilis

See Chapter 32.

HIV-associated neurological disease

See Chapter 21.

Prion disease (transmissible spongiform encephalopathies)

Transmissible spongiform encephalopathies (TSEs) are a group of fatal degenerative brain diseases (encephalopathies) characterized by the appearance of microscopic vacuoles in the brain grey matter, giving a sponge-like (spongiform) appearance. TSEs were originally termed slow virus infections – though no virus has ever been associated and current evidence points to the specific association with an abnormal form of a host-encoded protein termed a prion (proteinaceous infectious particle).

Prions are composed of a cell-surface glycoprotein PrP, and accumulation in the brain of a protease-resistant isoform (PrP^{sc}) is the

common mechanism of pathogenesis of TSEs. PrP^{sc} is remarkably resistant to inactivation by sterilization methods, and this presents significant infection control problems when patients with TSEs undergo health interventions.

All TSEs have prolonged incubation periods of months to years, gradually leading to death over months or years, with varying amounts of PrP^{sc} accumulating in the CNS.

There are several animal TSEs, including bovine spongiform encephalitis (BSE; also known as ‘mad cow disease’) in cattle, and scrapie in sheep and goats. The classic example of a human TSE is Creutzfeldt–Jakob disease (CJD). Incubation periods in humans, after peripheral or oral exposure, range from at least 4 years to 40 years, with a mean of 10–15 years.

Infectivity in TSEs is highest in brain tissue but is also present in some peripheral tissues; it is not found in most body fluids, including saliva. Animal studies show prions in the trigeminal nerve, tooth pulp, gingiva and salivary glands, and the potential for prion transmission via the dental route. Prions do not evoke a protective immune response or detectable diagnostic antibodies. Nevertheless, attempts at vaccine production are under way.

Human TSE types are inherited, acquired or sporadic (Table 13.28), but are frequently referred to collectively as CJD. The acquired forms include kuru, and iatrogenic and variant CJD. Overall, CJD affects approximately 1 per 1 000 000 of the population per annum across the world.

Creutzfeldt–Jakob disease (CJD)

Creutzfeldt–Jakob disease is a rare illness and is one of a group of diseases called prion diseases, which affect humans and animals. Prion diseases exist in different forms, all of which are progressive, currently untreatable and ultimately fatal. Their name arises because they are associated with an alteration in a naturally occurring protein: the prion protein.

CJD was first described in 1920. The commonest form is called sporadic CJD and occurs worldwide, causing around 1 death per million population per year. A new form of CJD (variant CJD; see below), linked to BSE in cattle, was identified in 1996. There are also inherited forms of human prion disease associated with mutations of the prion protein gene (*PRNP*) and cases caused by infection via medical or surgical treatments (iatrogenic CJD).

Sporadic CJD (sCJD) accounts for about 85% of all cases of CJD. The underlying cause is unknown but the disease commonly develops in middle to late life as a rapidly progressive multifocal dementia. Up to a third of patients have non-specific prodromal symptoms, such as insomnia, fatigue, depression, weight loss, headache, malaise and pain. Over weeks there is rapid progression to akinetic mutism, with mental deterioration, myoclonus, extrapyramidal and pyramidal signs,

Table 13.28 Types of Creutzfeldt–Jakob disease (CJD)

Type	Abbreviation	Source
Sporadic	sCJD	–
Familial	fCJD	Autosomal dominant
Kuru	–	Ritualistic cannibalism
Iatrogenic	iCJD	Contaminated surgical instruments; dura mater grafts or pituitary hormones
Variant; sometimes termed new-variant CJD	vCJD; nvCJD	Consumption of material infected with bovine spongiform encephalopathy (BSE)

cerebellar ataxia and cortical blindness. The EEG shows characteristic changes.

Familial CJD (fCJD), which accounts for around 10% of cases, includes rare autosomal dominant disorders that manifest in early to middle adult life. *Fatal familial insomnia* is characterized by progressive insomnia, dysautonomia, disruption of circadian rhythms, motor dysfunction and deterioration in cognition. *Gerstmann–Straussler–Scheinker syndrome* is distinct, with many PrP^{Sc}-positive plaques throughout the brain.

Kuru, first described in the 1950s, was endemic among the Fore ethnic group in the eastern highlands of Papua New Guinea and spread by cannibalism. Most cases were in children and women, who ritually consumed brains from deceased relatives. Typically, there was progressive cerebellar ataxia but, unlike in CJD, dementia was not common.

Iatrogenic CJD (iCJD) can be transmitted mainly by exposure to cadaver-derived growth hormone, pituitary gonadotropins, dura mater homografting, corneal grafts or inadequately sterilized neurosurgical equipment. There is no evidence to suggest that any patients who have received dura mater allografts for the management of maxillofacial defects have developed iCJD. Concerns exist about the theoretical risk of the use of non-human animal-derived graft materials and heterologous human graft materials in oral or periodontal surgery.

Variably protease-sensitive prionopathy (VPSPr) is a relatively newly described (in 2008) human prion disease of unknown aetiology. Its precise relationship with other prion diseases is uncertain but no mutations have been found in the *PRNP* coding sequence and the patients have no (known) risk factors for iatrogenic CJD. The reported cases have clinicopathological profiles and protein biochemical characteristics that differ from those seen in variant or sporadic CJD. The clinical features are not yet fully characterized but the reported cases have been middle-aged to elderly with relatively longer disease durations than for sporadic CJD.

Variant Creutzfeldt–Jakob disease (vCJD)

General aspects

BSE was first recognized in UK cattle in 1986, and it was eventually established that the infective agent was spread by the use of meat and bonemeal in cattle food. Then, in 1990, TSE appeared in domestic cats in the UK, suggesting that TSE was transmitted in pet foods and that the causative agent was by no means species-specific. In 1996, a variant of sporadic CJD (variant or vCJD) was first observed in humans in the UK, and linked with the consumption of infected bovine offal. Pathological examination of the CNS revealed plaques of PrP^{Sc} and a specific genetic predisposition, with all vCJD patients analysed being homozygous for methionine at codon 129 of the *PrP* gene. CNS, posterior orbit and (unusually for prion diseases) lymphoreticular tissue are, in descending order of risk, the tissues most likely to be infective. Transfusions of blood or blood derivatives can also transmit the prion; plasma products were banned in the UK in 1998 and all donor blood has been leukodepleted since 1999. To avoid the possibility of transmission via infected brain tissue, recipients of human growth hormone were excluded from blood donation in 1989, and recipients of other human-derived pituitary hormones have been excluded since 1993. There may also be other potential but unproven sources of infection, such as products from cell lines grown in the presence of fetal bovine serum, some vaccines, and bovine products such as collagen.

Clinical features

Persons with vCJD have prominent early psychiatric symptoms (severe depression and behavioural manifestations), together with

paraesthesias and dysaesthesias, followed by dementia, cerebellar and other neurological signs, myoclonus or other involuntary movements and, finally, akinetic mutism.

General management

The clinical course of vCJD is much longer than that of sCJD and affected patients do not have the same typical EEG changes. Tests and investigations that can contribute to a diagnosis include MRI, which shows characteristic bilateral symmetrical high signals in the thalamic pulvinar nuclei ('the pulvinar sign'). Other investigations include blood tests for the genetic mutations, EEG, psychometric tests, and CSF analyses to show a rise in the specific CSF proteins 14-3-3 and to exclude other infections. Tonsillar biopsy may help confirm a diagnosis of CJD.

There is no effective treatment for vCJD or other prion diseases. *In vitro*, some success has been achieved with mepacrine (quinacrine) and chlorpromazine.

Dental aspects

Conventional dental treatment has no proven association with transmission of any form of CJD. However, PrP^{Sc} is remarkably resistant to inactivation with heat, most disinfectants, and ionizing, ultraviolet and microwave radiations. Concentrated bleach does appear to achieve inactivation and 20 000 ppm available chlorine of sodium hypochlorite for 1 hour or 2M sodium hydroxide for 1 hour are considered effective (Box 13.9), as is an enzyme (prionzyme).

Effective cleaning to remove adherent tissue, coupled with autoclaving, significantly reduces infectivity levels on contaminated instruments if a non-porous load steam sterilizer is used at 134–137°C for a single cycle of 18 minutes or six successive cycles of 3 minutes each.

For management purposes, it is useful to divide patients with TSEs into three main groups, as follows:

- Confirmed cases of CJD – all instruments used for invasive procedures should be destroyed after use.
- Suspected cases of CJD (patients who present with a clinical history that is suggestive of CJD but a confirmed diagnosis is unavailable) – the instruments used for invasive procedures should be quarantined pending a confirmation of diagnosis.
- Cases 'at risk' of CJD who are clinically well, including those 'at risk' by virtue of an inheritable defect in the prion protein gene producing fCJD, and those who have been exposed to infectious material through the use of human cadaveric derived pituitary hormones, and dural and corneal homografts (iatrogenic CJD) – most guidelines recommend that surgical instruments used to operate on 'high-risk' tissues (CNS, spinal cord and eye) in patients 'at risk' of CJD should be disposed of by incineration. For interventions such as routine dental treatment, which do not involve 'high-risk' tissues, some national guidelines recommend the use of stringent instrument decontamination.

Dental health care staff infected or potentially infected with prion disease should not practise invasive clinical procedures in view of the risk of motor and cognitive dysfunction.

Box 13.9 Recommended methods of inactivation of human and transmissible spongiform encephalopathy (TSE) agents

- 20 000 ppm available chlorine of sodium hypochlorite for 1 h
- 2M sodium hydroxide for 1 h
- Non-porous load steam sterilizer 134–137°C for a single cycle of 18 min, or six successive cycles of 3 min each

Orofacial manifestations of human TSEs comprise dysphagia and dysarthria (due to pseudobulbar palsy); in vCJD patients, there may be orofacial dysaesthesia or paraesthesia or abnormal taste sensation.

BRAIN DAMAGE

Trauma, hypoxia, infections and hypoglycaemia are the main causes of brain damage.

Traumatic brain injury (TBI)

TBI can occur when the head suddenly and violently hits an object, or when an object penetrates the skull and enters the brain. Consequences can be mild, moderate or severe, depending on the extent of brain damage.

A person with a mild TBI may remain conscious or may experience a loss of consciousness for a few seconds or minutes. Other symptoms may include headache, confusion, light-headedness, dizziness, blurred vision or tired eyes, tinnitus, a bad taste in the mouth, fatigue or lethargy, a change in sleep patterns, behavioural or mood changes, and trouble with memory, concentration, attention or thinking.

A person with a moderate or severe TBI may show the same symptoms but also have a headache that increases or does not resolve, repeated vomiting or nausea, convulsions or seizures, an inability to awaken from sleep, dilatation of one or both pupils, slurred speech, weakness or numbness in the extremities, loss of coordination, and increased confusion, restlessness or agitation.

Patients with moderate or severe TBI should receive urgent medical attention to prevent further injury by ensuring proper oxygen supply to the brain, maintaining adequate blood flow and controlling blood pressure. Patients with mild to moderate injuries may receive skull and neck imaging (usually CT) to check for fractures or spinal instability.

Disabilities resulting from a TBI depend upon the severity of the injury, the location of the injury, and the age and general health of the individual; they can include problems with cognition (thinking, memory and reasoning), sensory processing (sight, hearing, touch, taste and smell), communication (expression and understanding), and behaviour or mental health (depression, anxiety, personality changes, aggression, acting out and social inappropriateness). More serious head injuries may result in stupor – an unresponsive state but one in which an individual can be aroused briefly by a strong stimulus, such as sharp pain; coma – a state in which an individual is totally unconscious, unresponsive, unaware and unarousable; vegetative state – in which an individual is unconscious and unaware of their surroundings but continues to have a sleep–wake cycle and periods of alertness; and a persistent vegetative state (PVS; see below) – in which an individual stays in a vegetative state for more than a month. Approximately half of severely head-injured patients will need surgery to remove or repair haematomas or contusions.

Cerebral palsy

See Chapter 28.

Hypoxic encephalopathy

Acute cerebral hypoxia is particularly important, as it can readily cause brain damage. Some patients can die and others suffer damage leading, depending on the age, duration and degree of hypoxia, to cerebral palsy, epilepsy or a persistent vegetative state.

Hypoxia can follow head injuries, airway obstruction, severe hypotension (e.g. cardiac arrest, shock syndrome, severe bradycardia, stroke) or impaired oxygenation (e.g. respiratory failure or the situation during

GA, when the anaesthetic agent can depress respiration but there may also be partial, often unnoticed, respiratory obstruction). Cerebral hypoxia can remain unrecognized if the patient is already unconscious.

Cerebral hypoxia causes loss of consciousness in less than a minute but, if the blood circulation and oxygenation are restored within about 3 minutes, recovery should be complete. Hypoxia for longer than about 3 minutes causes brain damage and coma, with dilated pupils unresponsive to light, inert or rigid limbs, unresponsiveness to all stimuli, abolition of brainstem reflexes and, ultimately, no electrical activity on EEG (brain death). *The most vigilant supervision of all patients with head injuries, and other patients undergoing or recovering from GA or sedation, is, therefore, essential.* Special care must be taken to ensure that the patient is breathing effectively, that oxygen supplies are adequate and maintained, and that no hypoxia, however slight, develops.

Persistent vegetative state

‘Persistent vegetative state’ (PVS) is a term that describes the condition of patients with severe brain damage. Patients with PVS have no cerebral cortical function (they are unconscious and unaware), but exhibit irregular circadian sleep–wake cycles with either full or partial hypothalamic and brainstem autonomic functions, and persisting reflexes. PET scan studies have shown metabolic activity to be decreased by approximately 50% in the cerebral cortex and cerebellum of patients in PVS.

Patients in a PVS may be aroused by certain stimuli, opening their eyes if they are closed, changing their facial expressions, or even moving their limbs, and they may grind their teeth, swallow, smile, shed tears, grunt, moan or scream without reason. They may move their eyes, but this is merely reflexive and does not indicate awareness if they neither fixate on a visual object nor track a moving target with their eyes. Nevertheless, despite no evidence of awareness, their heads and eyes can follow a moving object or move towards a loud sound.

PVS is considered permanent when a diagnosis of irreversibility can be established, based on the fact that the chances of the patient regaining consciousness are exceedingly small.

Patients with PVS need close medical and nursing support, similar to that for stroke victims, including attention to oral health.

EPILEPSY

General aspects

Epilepsy, or seizure disorder, refers to a tendency to recurrent seizures. A seizure (fit) is a convulsion or transient disturbance in consciousness, caused by abnormal cerebral cortical electrical activity. Different causes prevail at different ages (Table 13.29). Disturbances of nerve cell activity produce symptoms that vary, depending on which part (and how much) of the brain is affected. Seizures may produce changes in awareness or sensation, involuntary movements, or other changes in

Table 13.29 Causes of fits at different ages of onset

Age at onset	More common causes
Young child	Birth trauma, fevers, metabolic disease, congenital disease or idiopathic
Adolescent	Idiopathic or traumatic
Young adult	Traumatic, neoplastic, idiopathic, alcoholism or barbiturate abuse, acquired immune deficiency syndrome (AIDS)
Middle-aged	Neoplastic, traumatic, cerebrovascular disease, AIDS or drug abuse
Older	Cerebrovascular disease or neoplasm

behaviour. In general, seizures do not indicate epilepsy but may only occur as a result of a temporary medical condition, such as a high fever, hypoglycaemia, alcohol or drug use or withdrawal, or following brain injury.

Typically, a seizure lasts from a few seconds to a few minutes. There are many seizure types but they fall into two main groups:

- *Primary generalized seizures* – seizures begin with widespread involvement of both sides of the brain.
- *Partial seizures* – seizures begin with involvement of a smaller, localized area of the brain, though in some the disturbance spreads within seconds or minutes to involve widespread areas of the brain (secondary generalized seizure).

Some people have an absence seizure, a type of primary generalized seizure called petit mal – rapid blinking or a few seconds of staring into space, and this may be hardly noticeable to others. In contrast, a person having a complex partial seizure may appear confused or dazed and unable to respond to questions for up to a few minutes. Finally, a person having a generalized tonic–clonic seizure, often called grand mal, may cry out, lose consciousness, fall to the ground, and have rigidity and muscle jerks for up to a few minutes, with an extended period of confusion and fatigue afterward.

In nearly two-thirds of the cases of epilepsy, a specific underlying cause is not identified but some known conditions and events that may lead to epilepsy are:

- oxygen deprivation
- brain infections (e.g. meningitis, encephalitis, cysticercosis or brain abscess)
- traumatic brain injury or head injury
- stroke
- other neurological diseases (e.g. Alzheimer disease)
- brain tumours
- certain genetic disorders.

Epilepsy is a predisposition for *recurrent* seizures; it affects approximately 1% of the adult population and may reflect underlying brain pathology (injury, tumours or infections). A total of 10% of the population suffer at least one seizure in their lifetime, but mainly in childhood when it may be caused by febrile convulsions. Epilepsy is more prevalent in the young and in the mentally or physically impaired. Most cases begin between the ages of 5 and 20 years.

Epilepsy is occasionally secondary (symptomatic epilepsy) to cerebral hypoxia; metabolic disturbances (hypoglycaemia or hyperglycaemia) and drugs (alcohol, amphetamines, anticonvulsants, barbiturates, benzodiazepines, cocaine and opioids) may predispose to epilepsy. Many cases, however, have no detectable structural or metabolic cause and are known as idiopathic – when there is likely to be a positive family history and a genetic predisposition (Box 13.10).

Many seizures in epileptic people have no clear trigger but, in some instances, food and sleep deprivation, hormonal changes (e.g. pregnancy or menstruation), concurrent illness, metabolic disturbances, sensory stimuli (flashing lights, sounds and touch – even, very rarely, an electric toothbrush), and prescribed or illicit drugs (alcohol, chlorpromazine, enflurane, flumazenil, fluoxetine, ketamine, methohexitone, tramadol, tricyclic antidepressants) or their withdrawal may be implicated.

Clinical features

The International League Against Epilepsy (ILAE) Classification of Epileptic Seizures 1981 and 1989 are the two systems in use. ILAE 1981 classifies seizures as:

Box 13.10 Causes of epilepsy

- Metabolic abnormalities
 - Diabetes mellitus or hypoglycaemia
 - Electrolyte imbalances
 - Renal failure
 - Nutritional deficiencies
 - Inborn errors of metabolism, e.g. phenylketonuria (PKU)
 - Use of, intoxication from or withdrawal from alcohol
 - Use of, intoxication from or withdrawal from illicit drugs, especially cocaine and amphetamines; also anticonvulsants, barbiturates, benzodiazepines, ecstasy, opioids
- Brain trauma
 - May affect any age, highest incidence in young adults
 - Most likely if the brain membranes are damaged
 - Seizures usually begin within 2 years of injury
 - Early seizures (within 2 weeks of injury) do not necessarily indicate that chronic seizures (epilepsy) will develop
- Brain tumours and other space-occupying brain lesions (such as haematomas)
 - May affect any age, more common after age 30
 - Partial (focal) seizures most common initially
 - May progress to generalized tonic–clonic seizures
- Cerebrovascular disease
 - Most common cause of seizures after age 60
- Degenerative disorders (senile dementia, Alzheimer disease or similar organic brain syndromes)
 - Mostly affect older people
- Drugs
- Infections, which may affect all ages
 - Meningitis
 - Encephalitis
 - Brain abscess
 - Acute severe systemic infections
 - Chronic infections (e.g. neurosyphilis)
 - HIV/AIDS or other immune disorders

- partial (seizures involving only part of the brain)
- generalized (seizures involving both sides of the brain)
- unclassifiable.

A problem presented by this simple classification is that the same patient may have more than one type of seizure, either together or in sequence. ILAE 1989 is meant to supplement the 1981 classification and describes epilepsies as:

- localization-related (involving one or more distinct parts of the brain)
- generalized (involving both sides of the brain at the same time)
- undetermined whether localized or generalized
- special syndromes (Table 13.30).

In addition to seizures, there may be other features, such as headache, changes in mood or energy level, confusion and memory loss.

The main types of epilepsy are generalized seizures (grand mal [tonic–clonic]), when consciousness is typically lost, and partial seizures, which include simple seizures during which the person remains alert, along with abnormal movements or sensations. Generalized seizures are the most dramatic but partial seizures are the most common.

Generalized: grand mal (tonic–clonic) epilepsy

Grand mal epilepsy usually begins in childhood, or sometimes at about puberty. There is a warning (aura), followed by loss of consciousness, tonic and clonic convulsions, then, finally, a variably

Table 13.30 Classification and features of generalized and focal/partial epilepsy

Type	Subtype	Clinical features
Generalized seizures	Tonic-clonic (grand mal)	Loss of consciousness, tonic phase, clonic phase, tongue-biting, incontinence Seizure lasts <5 min
	Absence seizure (petit mal)	Brief period of unresponsiveness Duration of absences <30s
Partial seizures	Simple (Jacksonian epilepsy)	No impairment of consciousness Motor, sensory and autonomic features
	Complex (temporal lobe epilepsy)	Impaired consciousness Automatic repetitive acts

Fig. 13.13 Results of trauma in a person with epilepsy.

prolonged recovery. The aura may consist of a mood change, irritability, brief hallucination or headache. The attack then begins suddenly, with total body tonic spasm and loss of consciousness. The sufferer falls to the ground and is in danger of injury. Initially, the face becomes pale and the pupils dilate, the head and spine are thrown into extension (opisthotonos), and glottic and respiratory muscle spasm may cause an initial brief cry and cyanosis. There may also be incontinence and biting of the tongue or lips. The tonic phase passes, after less than a minute, into the clonic phase, when there are repetitive jerking movements of trunk, limbs, tongue and lips. Salivation is profuse with bruxism, sometimes tongue-biting and, occasionally, vomiting. There may be urinary or faecal incontinence, and autonomic phenomena such as tachycardia, hypertension and flushing. Clonus is followed by a state of flaccid semi-coma for a further 10–15 minutes. Confusion and headaches are common afterwards and the patient may sleep for up to 12 hours or more before full recovery. The attack may occasionally be followed by a transient residual paralysis (Todd palsy) or by automatic or aggressive behaviour. This full sequence is not always completed.

Complications of major convulsions can be trauma (Fig. 13.13), respiratory embarrassment or brain damage; seizures may progress to *status epilepticus* but most end without mishap. A major fit is so dramatic that it seems to be of longer duration than is in fact the case, but if it lasts more than 5 minutes (by the clock) or starts again after apparently ceasing, the patient must be regarded as being in *status epilepticus*, which is particularly dangerous – the mortality rate can be up to 20%. Brain damage may result from cerebral hypoxia, when tonic and clonic phases alternate repeatedly without consciousness being regained and there can also be inhalation of vomit and saliva. *Status*

epilepticus is a medical emergency because it causes severe hypoxia, and is potentially fatal.

Partial seizures

Petit mal seizures come most often during childhood and are characterized by minimal or no movements (except for eye-blinking) and an apparently blank stare, with a brief sudden loss of awareness or of conscious activity that may last only seconds. Seizures may recur many times and may involve learning difficulties (the child is often thought to be day-dreaming). Most patients who have petit mal also have grand mal attacks.

Simple partial (focal) seizures can be motor, sensory or behavioural, typically remain confined to one area, and include muscle contractions of a specific body part – focal motor epilepsy, which may take the form of clonic movements of a limb or group of muscles, usually in the face, arm or leg, though the clonus may spread (march) to adjacent muscles on the same side of the body (Jacksonian epilepsy). There are abnormal sensations; sometimes nausea, sweating, skin flushing and dilated pupils; and sometimes other focal (localized) symptoms.

Partial complex seizures, or temporal lobe epilepsy (psychomotor epilepsy), are characterized by automatism (automatic performance of complex behaviours), such as lip-smacking and chewing movements, or facial grimacing; recalled or inappropriate emotions; changes in personality or alertness; sometimes disorientation, confusion and amnesia, or loss of consciousness; and sometimes olfactory (smell) or gustatory (taste) hallucinations or impairments.

General management of epilepsy

Having a single seizure as the result of a high fever (febrile seizure) or head injury does not necessarily mean that a person has epilepsy. Only when individuals have had two or more seizures are they considered to have epilepsy, and the diagnosis requires careful review.

Disorders that may show features resembling seizures include transient ischaemic attacks, rage or panic attacks, and any disorder that causes loss of consciousness, tremors or tics. Witness accounts are invaluable. A physical examination, including a detailed neurological component, is indicated to confirm the diagnosis; it may show focal neurological deficits but often is normal. CT and MRI are used to screen for cerebral pathology. An EEG records brain electrical activity and may aid in the diagnosis, usually confirming the seizures and possibly, in some cases, indicating the location of a lesion. It displays 3-Hz spike-and-wave activity in primary generalized absence seizures. However, a normal EEG does not completely rule out a seizure disorder. Tests for the cause may also include a full blood picture, blood glucose, liver function tests, renal function tests, inflammatory markers (erythrocyte sedimentation rate [ESR], C-reactive protein [CRP]), and CSF analysis to exclude infection.

Management of a seizure is outlined in Ch 1. Management of epilepsy includes patient education; identification and avoidance of precipitating or trigger factors; treatment of any identifiable predisposing pathology or disease; and prophylactic anticonvulsants. Antiepileptic drugs (AEDs) are the treatment modality used for most people (Table 13.31) and are of two broad groups – GABA or receptor potentiators, and neuronal inhibitors. Therapy is typically started with a single drug, raising doses until the disorder is controlled. A second-line drug is then substituted and some 50% will eventually be able to relinquish medication. However, most patients with major epilepsy having more than one attack in a year need to be maintained on AEDs.

A second drug should only be given *additionally* if a single agent in maximal dosage fails to control fits or causes undesirable toxic effects. Plasma levels may sometimes need to be monitored, particularly with phenytoin, where small changes in dosage can cause disproportionately large changes in plasma levels and toxic effects. Since treatment

Table 13.31 AED treatment of epilepsy

Type of epilepsy	Drugs	Adverse effects ^a
Tonic-clonic seizure	Carbamazepine	Skin rashes
	Phenytoin	Blood dyscrasias
	Sodium valproate	Liver impairment
	Gabapentin	
Absence seizure	Sodium valproate	Sleep disturbance
	Ethosuximide	
Partial seizures	Carbamazepine	As above
	Sodium valproate	

^aSodium valproate is best avoided in women of childbearing age because of significant risk (5–7%) of fetal malformation. Phenytoin and carbamazepine may also be teratogenic.

Box 13.11 Possible adverse effects of phenytoin apart from teratogenicity

- In large doses, nystagmus, ataxia and, possibly, cerebellar damage
- Gingival swelling, thickening of the facial features, hypertrichosis
- Folic acid deficiency and, occasionally, megaloblastic anaemia
- Enhanced catabolism of vitamin D, causing osteomalacia, usually subclinical
- Lymphadenopathy with lymphoma-like changes histologically
- Slightly enhanced risk of lymphoma
- Allergy – rashes, erythema multiforme or lupus erythematosus-like reactions

of major epilepsy is often lifelong, adverse effects can be a problem (Box 13.11).

Patients with epilepsy who are drowsy from medication should not operate unguarded machinery or drive. Epileptics may not drive a motor vehicle until they have been seizure-free for more than 1 year, or over a 3-year period have only had sleep attacks.

AEDs may interact with other drugs (Tables 13.32 and 13.33); some interfere with the oral contraceptives. Traditional AEDs in pregnancy, particularly phenytoin, are potentially teratogenic but there is a greater risk to the fetus from uncontrolled epilepsy. Phenytoin (Epanutin), carbamazepine (Tegretol) and sodium valproate (Epilim) are all known to be teratogenic and can cause fetal anticonvulsant syndrome (FACS), which affects up to 10% of babies born to women taking anticonvulsants during pregnancy. Folic acid can reduce the risk of some of the congenital problems seen. Anomalies reported in FACS include spina bifida, cleft palate, and heart, kidney and limb malformations. The children also usually have distinctive facial features (prominent forehead, broad flattened nasal bridge, thin upper lip, medial deficiency of the eyebrows and infraorbital grooves); these may be particularly apparent in pre-school children but change, becoming more normal as the children mature. Anticonvulsant medication is also a risk factor for the development of an autistic spectrum disorder.

Valproate depresses platelet numbers and function to produce a bleeding tendency. Valproate may lead to adverse hormone changes in teenage girls and polycystic ovary syndrome in women who start taking the medication before age 20, so young female patients taking it should be monitored carefully by a physician. NSAIDs, erythromycin and benzodiazepines are also contraindicated.

Newer-generation AEDs which are not teratogenic, include:

- Gabapentin
- Lamotrigine
- Levetiracetam
- Oxcarbazepine
- Topiramate.

Table 13.32 Drugs used in dentistry that can increase anticonvulsant activity, leading to overdose

Drug	Comment
Aspirin	Can increase the bleeding tendency induced by valproate
Azole antifungals	Can interfere with phenytoin
	Can increase the bleeding tendency induced by valproate
	Can interfere with carbamazepine
Metronidazole	Can interfere with phenytoin
	Can increase the bleeding tendency induced by valproate
Non-steroidal anti-inflammatory drugs (NSAIDs)	Can increase the bleeding tendency induced by valproate
Propoxyphene	Can interfere with carbamazepine

Table 13.33 Drugs used in dentistry whose activity can be altered by AEDs

Drug	Comment
Paracetamol (acetaminophen)	Hepatotoxicity may be increased by anticonvulsants
Doxycycline	Metabolism may be increased by carbamazepine

Antiepileptic drugs should be continued during breast-feeding. Drug treatment should follow the same principles as for non-pregnant patients but plasma levels need to be monitored, as they may fall during the later stages.

The uses and adverse effects of anticonvulsant drugs are summarized in Appendix 13.2.

With certain types of partial epilepsy, especially when seizures consistently arise from a single area of brain (the 'seizure focus') such as the temporal lobe, surgical removal of that focus may be effective in stopping seizures or making them amenable to medical control.

Other supplemental treatments that are sometimes beneficial include a ketogenic diet (a high-fat, low-carbohydrate diet with restricted calories) and vagus nerve stimulation therapy (VNST). VNST involves the use of an implantable electronic device in the neck to stimulate the vagus nerve intermittently. Little is understood about how vagal nerve stimulation modulates seizure control but about 50% of patients experience a 40% or greater reduction in seizure frequency and severity. Adverse effects may include intermittent decrease in respiratory flow during sleep and up to one-third of patients develop mild obstructive sleep apnoea post treatment. Thus screening for obstructive sleep apnoea (OSA) in patients undergoing a VNST implant is important. VNST may also cause stimulation of the superior and recurrent laryngeal nerves and problems ranging from alteration of voice, coughing, pharyngitis and throat pain, and hoarseness (common) to laryngeal muscle spasm and upper airway obstruction (rare). Transcutaneous vagus nerve stimulation (t-VNS) permits vagal stimulation without surgical intervention (Lisowska and Daly 2012).

Dental aspects

Dental treatment should be carried out in a good phase of epilepsy, when attacks are infrequent. Various factors can precipitate attacks (Box 13.12).

Box 13.12 *Factors sometimes precipitating fits in susceptible subjects*

- Withdrawal of AED medication
- Epileptogenic drugs (see [Box 13.12](#))
- Fatigue, starvation or stress
- Infection
- Menstruation
- Flickering lights (television; strobe lights)

Box 13.13 *Drugs contraindicated in epilepsy*

- Alcohol
- Chlorpromazine
- Enflurane
- Flumazenil
- Fluoxetine
- Ketamine
- Lidocaine (large doses)
- Metronidazole
- Quinolones
- Tramadol
- Tricyclic antidepressants

Those who have infrequent seizures or who depend on others (such as those with a learning impairment) may fail to take regular medication and thus be poorly controlled. When dental treatment is being carried out in a known epileptic, a strong mouth prop should be kept in position and the oral cavity kept as free as possible of debris. As much apparatus as possible should be kept away from the area around the patient. Drugs can be epileptogenic or interfere with anti-convulsants, or can themselves be changed by anticonvulsant therapy and may, therefore, be contraindicated (see [Tables 13.32 and 13.33](#); [Box 13.13](#)).

In the past, particularly, gingival swelling due to phenytoin required treatment by gingival surgery. Carbamazepine or gabapentin obviates this problem.

Aspirin, azoles and metronidazole can interfere with phenytoin. Propoxyphene and erythromycin can interfere with carbamazepine.

Large doses of lidocaine given intravenously for severe arrhythmias may occasionally cause convulsions. An overenthusiastic casualty officer may therefore blame a dental LA for causing a fit. There is no evidence that this can happen, especially as intravenous lidocaine has also been advocated for the control of status epilepticus.

CS in epilepsy should be safe. Stress reduction should reduce the chance of a fit. Benzodiazepines are anti-epileptogenic, but occasionally fits have been recorded in epileptics undergoing intravenous sedation with midazolam. Flumazenil, however, can be epileptogenic. Nitrous oxide can increase the CNS depression in patients on anticonvulsants. It is probably best to avoid electronic dental analgesia.

Temporal lobe (psychomotor) epilepsy, in particular, is associated with paranoid and schizophrenic features. Antisocial and psychopathic behaviour may then make dental management difficult.

Acrylic is probably better used for prostheses than porcelain, as it is more resilient.

Convulsions may have craniofacial sequelae, especially lacerations, haematomas and fractures. Trauma frequently results from a grand mal attack when the patient falls unconscious or from the muscle

Box 13.14 *Peripheral neuropathies*

- Abuse of nitrous oxide
- Alcoholism
- Bell palsy
- Diabetes
- Vitamin B₁₂ deficiency
- Other, less common causes ([Appendix 13.3](#))

spasm, and a range of injuries can result, e.g. fractures of the vertebrae or limbs; dislocations; periorbital subcutaneous haematomas in the absence of facial fractures; injuries to the face from falling (lacerations, haematomas, fractures of the facial skeleton); fractures, devitalization, subluxation or loss of teeth (a chest radiograph may be required); TMJ subluxation; or lacerations or scarring of the tongue, lips or buccal mucosa.

FEBRILE CONVULSIONS (FEBRILE SEIZURES)

Febrile convulsions are more common than epilepsy, usually affect children and result from a rise in body temperature commonly caused by infection; they are seen in about 4% of infants or small children, the child typically losing consciousness and shaking. The seizures characteristically last only last a minute or two; some can be as brief as a few seconds. Risk factors include young age (below 15 months), frequent fevers, and immediate family members who have a history of febrile seizures.

Children who develop high fevers (above 38°C) should therefore be put in a cool environment, bathed with tepid water and given paracetamol (acetaminophen) elixir (*not* aspirin). Children under 18 months should be admitted to hospital since the fit may be due to meningitis. Severe febrile convulsions can cause brain damage and about 3% of children with febrile convulsions go on in later life to develop epilepsy; most do not.

There is no evidence that short febrile seizures cause brain damage – most are harmless and warrant no treatment. However, children who have cerebral palsy, delayed development or other neurological abnormalities, or who have febrile seizures that are lengthy or affect only one part of the body, may have an increased risk of developing epilepsy.

PERIPHERAL NEUROPATHIES

Mononeuropathies are commonly caused by nerve compression (e.g. carpal tunnel syndrome) or by vascular disease. Polyneuropathies have a wide range of causes, as seen in [Box 13.14](#).

AUTONOMIC DYSFUNCTION

Many disorders can be associated with autonomic dysfunction, most importantly ageing, alcoholism, amyloidosis, diabetes, familial dysautonomia, liver failure, parkinsonism, porphyria and renal failure. Autonomic dysfunction manifests with: abnormal sweating (sometimes gustatory sweating), bladder dysfunction, dry mouth and eyes, gastrointestinal dysfunction, impotence and orthostatic (postural) hypotension. Autonomic dysfunction may also underlie sialosis.

Patients with autonomic dysfunction are sensitive to any agent causing hypotension, such as those used in GA, and to being raised quickly from the supine position. Some have mitral valve prolapse.

HORNER SYNDROME

Horner syndrome comprises unilateral:

- miosis (constricted pupil), unreactive to mydriatics
- ptosis (drooping eyelid)
- loss of sweating of the face
- apparent enophthalmos (because of ptosis).

Horner syndrome is usually caused by post-ganglionic interruption of sympathetic nerve fibres, or interruption at the cervical sympathetic trunk or in the spinal cord or brainstem. It may result, for example, from surgery or trauma to the neck, or bronchogenic or metastatic breast carcinoma infiltrating the sympathetic supply from the superior cervical sympathetic ganglion.

CHOLINERGIC DYSAUTONOMIA

Post-ganglionic cholinergic autonomic dysfunction may be autoimmune, characterized by impaired lacrimation and salivation, mydriasis, decreased gastrointestinal motility, bladder atony, sweating and taste disturbance.

RILEY-DAY SYNDROME (FAMILIAL DYSAUTONOMIA)

Familial dysautonomia, a rare autosomal recessive disorder found almost exclusively in Ashkenazi Jews, is characterized by selective damage to the sensory, motor and autonomic peripheral nervous system.

The main features are depressed pain sensation and impaired regulation of temperature and blood pressure. Aspiration pneumonias and episodes of acute abdominal pain are common.

Orthostatic hypotension can occur, so patients should be raised upright only cautiously. The other most important dental aspect is self-mutilation of hard and/or soft tissues. Splints may be used to protect the soft tissues.

Hypersalivation may be seen, the lingual fungiform papillae and taste sensation are diminished, and oral hygiene may be poor.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

MYASTHENIA GRAVIS

See Chapter 16.

SLEEP

Sleep affects daily functioning and physical and mental health. Sleep and wakefulness are controlled by neurotransmitters; brainstem serotonin (5-hydroxytryptamine; 5HT) and noradrenaline (norepinephrine) keep parts of the brain active during wakefulness, while other neurons at the base of the brain begin signalling during sleep and 'switch off' signals that maintain wakefulness. Adenosine accumulates throughout waking hours, causing drowsiness, but gradually breaks down during sleep.

Sleep passes through stages 1, 2, 3, 4 and rapid eye movement (REM) sleep; then the cycle starts all over again with stage 1. A complete sleep cycle takes 90–110 minutes on average, the first REM period usually occurring about 70–90 minutes after falling asleep. It manifests with more rapid, irregular and shallow breathing, rapidly

jerking eyes, temporary paralysis of limb muscles and increase in heart rate; blood pressure rises and males can develop erections. REM sleep stimulates the brain regions used in learning, which may be important for normal brain development; this would explain why infants spend much more time in REM sleep than adults.

In stage 1, light sleep, the person can be awakened easily, the eyes move slowly and muscle activity slows. In stage 2 sleep, eye movements stop and brain electrical activity subsides, with occasional bursts of rapid waves called *sleep spindles*. In stage 3, extremely slow brain waves called *delta waves* begin to appear, interspersed with smaller, faster waves. By stage 4, the brain produces delta waves almost exclusively. Stages 3 and 4 are called *deep sleep* and this is typified by lack of eye movement and muscle activity; people awakened during deep sleep do not adjust immediately and often feel disoriented for several minutes after they wake up. Some children experience bed-wetting, night terrors or sleepwalking during deep sleep. Deep sleep coincides with growth hormone release in children and young adults, and increased production and reduced breakdown of proteins. Activity in parts of the brain that control emotions, decision-making processes and social interactions is drastically reduced during deep sleep, suggesting that this type of sleep may help people maintain optimal emotional and social functioning while awake.

The first sleep cycles each night contain relatively short REM periods and long periods of deep sleep; as the night progresses, REM sleep periods lengthen while deep sleep decreases so that, by morning, most people spend nearly all their sleep time in stages 1, 2 and REM.

Circadian (from the Latin for 'around a day') rhythms are regular changes in mental and physical characteristics that occur in the course of a day; they are usually controlled by the body's biological 'clock' – the hypothalamic suprachiasmatic nucleus (SCN). The SCN receives information about the amount of light or darkness, and connects with the pineal gland, which produces melatonin. Tryptophan is converted to serotonin and finally to the hormone melatonin (*N*-acetyl-5-methoxytryptamine). The less light there is, the more melatonin is released, and nocturnal melatonin secretion may be involved in physiological sleep onset. At sunset, light cessation triggers the pineal to begin releasing melatonin and this rises, peaking around 2.00 a.m. (3.00 a.m. for the elderly), after which it steadily declines to minimal levels by morning. Melatonin regulates many neuroendocrine functions. The SCN has melatonin receptors, and melatonin may have a direct action on the SCN to influence circadian rhythms. The SCN also governs functions synchronized with the sleep–wake cycle, including temperature, hormone secretion, urine production and changes in blood pressure.

SLEEP DISORDERS

The amount of sleep each person needs depends on many factors, including age. Children generally require about 12 hours a day, teenagers need about 9 hours and most adults 7–8 hours. Women in the first 3 months of pregnancy often need more. The amount of sleep needed also increases if a person has been deprived of sleep previously – a dangerous situation when operating machinery or driving. Too little sleep causes drowsiness and inability to concentrate, impaired memory and physical performance, and reduced ability to carry out calculations. If it continues, hallucinations and mood swings may develop. Reduced sleep duration is associated with increased body mass and obesity; sleep restriction to 4 hours of sleep per night increases blood pressure, decreases parasympathetic tone, increases evening cortisol and insulin levels, and promotes increased appetite, possibly through the elevation

of ghrelin, a pro-appetitive hormone, along with decreased levels of leptin. Moreover, proinflammatory cytokine levels are increased with sleep deprivation, along with decreased performance in tests of psychomotor vigilance, and this has been reported to result from a modest sleep restriction.

Foods can change neurotransmitters and affect sleep, as can drugs (e.g. alcohol, amphetamines, antidepressants, caffeine, cocaine, decongestants, dopaminergic drugs, ecstasy, hypnotics, pramipexole, sedatives, statins and valproate). Antidepressants may suppress REM sleep. Heavy smokers often sleep lightly, have reduced amounts of REM sleep and tend to wake after 3–4 hours due to nicotine withdrawal.

The ability to thermoregulate is lost during REM, so abnormally hot or cold environmental temperatures can disrupt sleep.

Sleep and sleep-related problems play a role in a large number of disorders (Table 13.34).

Insomnia

The best measure of the amount of sleep needed is how a person feels, if they awaken feeling refreshed, they are getting enough sleep. Insomnia can affect almost everyone occasionally because of stress, jet lag, diet or many other factors, and insomnia tends to increase with age. It affects about 40% of women, 30% of men and over 50% of older people. Insomnia is a key symptom of depression and often the major disabling symptom of an underlying medical disorder (Table 13.35).

Insomnia can be a chronic and persistent difficulty in either:

- falling asleep (initial insomnia)
- remaining asleep through the night (middle insomnia)
- waking up too early (terminal insomnia).

Insomnia almost always affects well-being and job performance the next day. Those who have insomnia frequently or for extended periods of time can develop even more serious sleep deficits.

Mild insomnia often can be prevented or cured by practising good sleep hygiene habits (Box 13.15). For short-term insomnia, hypnotics may help. Counselling may be valuable for psychological disorders that lead to insomnia; antidepressants such as amitriptyline or trazodone can often be helpful. Antihistamines and long-acting or high-dose sedatives can increase daytime drowsiness, making the problem worse over time, not better.

Table 13.34 Effects of disease on sleep

Disorder	Sleep-related problems
Depression	Often causes early morning wakening. Extreme sleep deprivation can lead to a seemingly psychotic state of paranoia and hallucinations in otherwise healthy people and disrupted sleep can trigger episodes of mania (agitation and hyperactivity) in people with manic depression
Epilepsy	Rapid eye movement (REM) sleep seems to help prevent seizures, while deep sleep may promote the spread of these seizures. Sleep deprivation may trigger seizures
Infectious diseases	Cytokines are powerfully sleep-inducing
Pain	Hospital routines may disrupt sleep, and patients who are unable to sleep also notice pain more
Sleep apnoea	Ch. 15
Stroke and asthma	Attacks tend to occur more frequently during the night and early morning, perhaps due to changes in hormones and heart rate

Jet lag

Jet lag is the result of long-distance travel east/west, crossing time zones at a rapid rate, and consists of symptoms such as sleep disturbance, loss of appetite, reduced psychomotor efficiency and general malaise. Circadian rhythms need about 1 day to adapt for each time zone crossed; people adapt more easily after a flight westward because there is a longer day. Melatonin will almost certainly have a role in the treatment but the exact dose regime still requires to be worked out. Benzodiazepines are the current treatments; they appear to suppress melatonin secretion.

Delayed sleep phase syndrome

This is the condition when people are only able to fall asleep late into the night or early in the morning. It is quite common among adolescents.

Somnambulism (sleepwalking)

This disorder falls under the parasomnia group – undesirable motor, verbal or experiential events that occur during sleep. Sleepwalking occurs most commonly in middle childhood and pre-adolescence, with a peak incidence around puberty. There are no specific diagnostic tests. Reassurance usually suffices. Parents may need to lock windows and

Table 13.35 Causes of insomnia^a

Causes	Detail
Disrupted waking hours	Jet lag, shift work, wake–sleep pattern disturbances, excessive sleep during day
Disturbance of sleep	Bed or bedroom not conducive to sleep, noise, interference with sleep by diseases, including prostate hypertrophy (men), cystitis (women), chronic obstructive pulmonary disease, arthritis, heartburn and cardiorespiratory problems
Drugs	Nicotine, alcohol, caffeine, food or stimulants at bedtime, medications or illicit ‘street drugs’ (e.g. excessive thyroxine, amphetamines, caffeine-containing beverages, cocaine, ephedrine, phenylpropanolamine, theophylline), withdrawal of medications (such as sedatives or hypnotics), alcoholism or abrupt alcohol cessation
Endocrine	Hyperthyroidism
Light exposure	Inadequate bright-light exposure during waking hours
Others	Ageing, restless legs syndrome (see later)
Psychological factors	Depression, grief, anxiety, stress, exhilaration or excitement, excessive physical or intellectual stimulation at bedtime

^aSee also Table 13.35.

Box 13.15 Sleep hygiene

- Having a routine
- Going to the toilet before retiring
- Taking a warm bath
- Going to sleep at a reasonable time
- Ensuring that the bed is comfortable, warm and in a quiet place
- Avoiding stimulants

^aSee <http://umm.edu/programs/sleep/patients/sleep-hygiene> (accessed 26 May 2013).

doors, remove obstacles and add alarms (if necessary) to decrease the likelihood of injury. Benzodiazepines or tricyclic antidepressants may be useful if necessary.

Seasonal affective disorder (SAD; winter depression)

This is depression occurring in the winter months, associated with hypersomnia, weight gain and carbohydrate craving. Environmental magnetic fields have diminished strength during the winter months and there may be desynchronization of the circadian rhythm. SAD improves with bright-light treatment, or melatonin.

Narcolepsy

Narcolepsy is a disorder of sleep regulation that manifests with 'sleep attacks' lasting from several seconds to more than 30 minutes, at various times, even after a normal night's sleep. Narcolepsy is usually hereditary, linked to HLA-DR2 and the hypocretin receptor 2 gene, but is occasionally caused by brain damage from a head injury or neurological disease. People with narcolepsy also may experience cataplexy (sudden onset of falling or collapse), hallucinations whilst falling asleep, temporary paralysis on awakening and disrupted night-time sleep. Nearly 50% of patients develop a personality or major affective disorder.

Restless legs syndrome

This is one of the most common sleep disorders, especially among older people. A familial disorder causing unpleasant crawling, prickling or tingling sensations in legs and feet and an urge to move them for relief, it may sometimes be linked to anaemia, pregnancy or diabetes. Many restless legs syndrome (RLS) patients also have a disorder known as *periodic limb movement disorder* (PLMD), which causes repetitive jerking movements of the limbs, especially the legs. These movements occur every 20–40 seconds and cause severely fragmented sleep. RLS and PLMD often can be relieved by drugs that affect dopamine.

Snoring

Snoring is caused by the vibration of the uvula and soft palate during breathing whilst asleep. It is at the lower end of a spectrum of sleep-disordered breathing (SDB), which may be related to weak activity of tongue, palate and pharynx muscles. SDB has simple snoring at its minimal level, then upper airways resistance syndrome (UARS) and, finally, obstructive sleep apnoea syndrome (OSAS; Ch. 15). SDB has been associated with insulin resistance and glucose intolerance, and is frequently found in people with type 2 diabetes.

At least 30% of adults snore, more as age increases. Snorers tend to have a higher body mass index and snoring is usually due to nasal or pharyngeal obstruction or weakness. Snoring is usually a minor problem, but complications may include interpersonal difficulties from annoyance to others, mouth-breathing and dryness, headache and daytime tiredness. Almost all treatments for snoring are based on ensuring upper airway patency. Advice includes sleeping on the side, losing weight and stopping smoking. Rarely, single-dose injection snoreplasty with sodium tetradecyl sulfate or surgery (or radiofrequency uvulopalatopharyngoplasty or laser-assisted palatoplasty) is indicated.

Central sleep apnoea is a disorder that may occur particularly in people who have life-threatening brainstem problems, since control of breathing is located there. The condition may be associated with:

- cervical spine disorders:
 - arthritis
 - surgery
 - radiation
- CNS conditions:
 - bulbar poliomyelitis
 - brainstem stroke or encephalitis
 - Parkinson's disease
 - primary hypoventilation syndrome
- use of narcotics.

REPETITIVE MOTION DISORDERS (OVERUSE SYNDROME)

Repetitive motion disorders (RMDs) are muscular conditions that result from repeated motions performed in the course of normal work or daily activities. RMDs most commonly affect the upper limbs (hands, wrists, elbows and shoulders), but can also be seen in the neck, back, hips, knees, feet, legs and ankles. RMDs include carpal tunnel syndrome, bursitis, tendonitis, epicondylitis, ganglion cyst, tenosynovitis and trigger finger.

RMDs are characterized by pain, tingling, numbness, swelling or redness of the affected area, and loss of flexibility and strength.

Treatment for RMDs usually includes reducing or stopping the causative motions. Applying ice to the affected area and analgesics, NSAIDs and steroids can reduce pain and swelling. Splints may relieve pressure on the muscles and nerves. Physical therapy may help. In rare cases only, surgery may be required.

APPENDIX 13.1 CRANIAL NERVE SYNDROMES

Syndrome	Cranial nerves involved	Site of lesion	Other features
Avellis	X	Medulla	Hemiplegia Horner syndrome
Benedikt	III	Midbrain	Cerebellar ataxia Tremor Hemiplegia
Cerebellopontine angle	V, VII, VIII, sometimes IX	Posterior cranial fossa	Cerebellar ataxia
Claude	III	Midbrain	Cerebellar ataxia Tremor
Collet–Sicard	IX, X, XI, XII	Retroparotid space	Paralysed palate, pharynx, tongue
Foix	III, IV, V (ophthalmic), VI	Cavernous sinus	Proptosis
Gradenigo	V, VI	Petrous temporal	Pain
Jackson	X, XII	Medulla	Hemiplegia Horner syndrome
Jacob	II, III, IV, V, VI	Middle cranial fossa	–
Millard–Gubler	VII, VI	Pons	Hemiplegia
Moebius	VI, VII	Pons	Lack of facial expression
Nothnagel	III	Midbrain	Cerebellar ataxia
Parinaud	III, IV, VI	Midbrain	Abnormal eye movements with pupil dysfunction
Sphenoid fissure (superior orbital fissure)	III, IV, V (ophthalmic), VI, sometimes II	Superior orbital fissure	Proptosis
Vernet	IX, X, XI	Jugular foramen Nasopharynx	Paralysed soft palate, pharynx and vocal cords
Villaret	IX, X, XI, XII	Retroparotid space	Horner syndrome
Wallenberg (posterior inferior cerebellar artery [PICA]; lateral medullary)	V, IX, X, XI	Medulla	Ipsilateral cerebellar ataxia and Horner syndrome, loss of pain and temperature sense on face, and paralysis of palate/pharynx/larynx Contralateral loss of pain and temperature sense elsewhere Vertigo, nystagmus
Weber	III	Midbrain	Hemiplegia

APPENDIX 13.2 ANTICONVULSANT DRUGS: USES AND ADVERSE EFFECTS

Drug	Use	Systemic adverse effects	Oral adverse effects
Carbamazepine	Temporal lobe epilepsy (TLE) Grand mal (GM)	Ataxia Drowsiness Leukopenia Lupoid syndrome Syndrome of inappropriate antidiuretic hormone secretion (SIADH; Ch. 6)	Dry mouth Dyskinesias Erythema multiforme
Valproate	GM Petit mal (PM)	Bleeding diathesis Drowsiness	Purpura
Phenytoin	GM TLE	Cerebellar damage Hirsutism Hyperglycaemia Nephrotic syndrome	Cervical lymphadenopathy, dental anomalies Erythema multiforme Gingival swelling Lupoid syndrome or ulcers
Ethosuximide	PM	Eosinophilia Lupoid syndrome Renal damage	–
Primidone	GM TLE PM	Ataxia Drowsiness Oculomotor palsy	Megaloblastic anaemia causing ulcers
Gabapentin	GM PM	Dizziness Drowsiness	Dry mouth
Topiramate	GM PM	Allergic reactions Various others	Dry mouth, oedema

APPENDIX 13.3 PERIPHERAL NEUROPATHIES

Hereditary

- Charcot–Marie–Tooth disease
- Dejerine–Sottas disease
- Refsum disease

Acquired

- Infective
 - Diphtheria
 - Guillain–Barré syndrome
 - Herpes zoster

KEY POINTS

- Upper respiratory infections are ubiquitous
- Voice changes may herald laryngeal cancer

The upper respiratory tract (URT) includes the nose, paranasal sinus, pharynx and larynx but the salivary glands and oral cavity are closely adjacent. Otorhinolaryngology specialists (ear, nose and throat; ENT) deal mainly with the nose, paranasal sinus, pharynx and larynx, and often employ binocular microscopy (Fig. 14.1) and nasendoscopy. Salivary disorders are discussed mainly in this chapter, as well as Chapters 18 and 22, oral disorders in Chapters 11 and 22. The URT may become damaged by pollutants such as smoke, soot, dust and chemicals, or infected with microorganisms from the inspired air. Pain from sinus or aural problems may radiate or be referred to the mouth; equally, oral problems may cause pain in the sinus or ear.

UPPER RESPIRATORY TRACT INFECTIONS (URTI)

A wide variety of respiratory pathogens may cause a single clinical syndrome and, *vice versa*, any one pathogen may cause a range of clinical diseases. Most URTI are viral.

The URT is also colonized by normal bacterial flora, which rarely cause disease, but may under certain circumstances cause upper or lower respiratory tract (LRT) or even systemic or transmissible infections. For example, the normal nasal bacterial flora may include *Staphylococcus aureus*, *S. epidermidis* and aerobic corynebacteria ('diphtheroids'). Some people carry meticillin-resistant *S. aureus* (MRSA) in their nose, which can cause disease (Ch. 21). Bacterial infection caused by a foreign body introduced into the nose of a child (e.g. a small toy) is a well-recognized cause of halitosis, as are tonsillitis and sinusitis. The nasopharyngeal bacterial flora may include non-encapsulated or non-virulent strains of *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae*, which may cause meningitis. Pharyngitis can be caused by group A streptococci (and can rarely lead to rheumatic fever and occasionally rheumatic carditis; Ch. 5) or can be caused by Epstein–Barr virus (Ch. 21).

VIRAL UPPER RESPIRATORY TRACT INFECTIONS

Viruses frequently evade URT defences to produce infections; children have up to eight URTIs per year, and adolescents up to four. Viral URTIs are highly infectious in the early stages and most are contracted by shaking the hands of infected persons or by touching things that they have touched (and then touching the nose, mouth or conjunctivae; Table 14.1); infection may also be spread via sneezes. The incubation periods rarely exceed 14 days. The incubation times of the common agents are:

- rhinoviruses, 1–5 days
- influenza and parainfluenza viruses, 1–4 days
- respiratory syncytial virus (RSV), 7 days
- Epstein–Barr virus (EBV), 4–6 weeks.

The three main clinical patterns of URTI are the common cold syndrome (coryza), pharyngitis and tonsillitis, and laryngotracheitis.

Other URTIs are discussed in Chapter 21.

The common cold syndrome

General aspects

The common cold is caused not by a single organism but usually by rhinoviruses; it can, however, be caused by more than 200 different viruses (Table 14.2), particularly by respiratory syncytial virus (RSV), coronaviruses, and para-influenza and influenza viruses).

Clinical features

Sneezing, mucus overproduction with nasal obstruction, nasopharyngeal soreness and mild systemic upset are common. Bacterial infection may supervene and cause sinusitis or middle ear infection (otitis media), but serious complications are rare in otherwise healthy patients.

General management

Only symptomatic treatment is available.

Dental aspects

Elective dental care is best deferred. General anaesthesia (GA) should be avoided since there is often some respiratory obstruction and

Fig. 14.1 Microscope.

Table 14.1 The main respiratory viruses

Viral respiratory pathogens	Presumed viral respiratory disease
Adenoviruses	Coronaviruses
Influenza viruses	Coxsackie viruses
Para-influenza virus	Cytomegalovirus
Respiratory syncytial virus	ECHO viruses
Rhinoviruses	Epstein–Barr virus
	Herpes simplex viruses
	Severe acute respiratory syndrome (SARS)

Table 14.2 Upper respiratory tract infections and their main causes

Condition	Micro-organisms
Common cold	Coronavirus Coxsackie viruses ECHO viruses Para-influenza virus Respiratory syncytial virus Rhinoviruses
Pharyngitis	Adenoviruses Coxsackie viruses ECHO viruses Epstein–Barr virus Beta-haemolytic streptococci Influenza viruses <i>Candida</i>
Tonsillitis	Adenoviruses Beta-haemolytic streptococci Enteroviruses Epstein–Barr virus Herpes simplex virus Influenza viruses Para-influenza viruses
Influenza	Influenza viruses
Sinusitis	<i>Streptococcus pneumoniae</i> <i>Streptococcus milleri</i> <i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i> <i>Aspergillus</i> Mucorales

infection can spread to the lungs. If a GA is unavoidable, it is best to intubate with a cuffed tube, so that nasal secretions do not enter the larynx. Antimicrobials may be indicated for prophylaxis. Xylitol chewing gum has been shown to reduce the risk of otitis media, presumably by inhibiting pneumococcal superinfection.

Pharyngitis and tonsillitis

General aspects

Most cases of pharyngitis and tonsillitis are caused by viruses (see Table 14.2), some by streptococci.

Clinical features

The throat is sore, with pain on swallowing (dysphagia) and sometimes fever and conjunctivitis. Enlargement of the tonsils with an infected exudate from the crypts, together with cervical lymphadenopathy, is characteristic of tonsillitis. Prominent submucosal aggregates of lymphoid tissue may be evident in those with pharyngitis. Complications are rare but may include peritonsillar abscess (quinsy), otitis media and, rarely, scarlet fever, acute glomerulonephritis or rheumatic fever.

General management

Infectious mononucleosis (glandular fever) or, rarely, diphtheria may need to be considered in the differential diagnosis.

Tonsillitis caused by bacterial infection is best treated with benzyl or phenoxymethyl penicillin, or, if the patient is allergic, by erythromycin

Box 14.1 Factors predisposing to sinusitis

- Diving – water may be forced into the nose and sinuses
- Barotrauma in air flight, conversely
- Foreign body in nose or sinus
- Peri-apical infection of upper posterior teeth
- Oro-antral fistula
- Prolonged endotracheal intubation and mechanical ventilation
- Rhinitis – vasomotor or allergic
- Viral upper respiratory tract infection

or a cephalosporin. Ampicillin and amoxicillin should be avoided, as they tend to cause rashes, especially if the sore throat is misdiagnosed as a streptococcal sore throat but is due to glandular fever.

Pharyngitis is not often treated with antimicrobials, as there is no evidence that they accelerate resolution or reduce complications; an increasing body of opinion advises simple analgesics.

Dental aspects

Elective dental care is best deferred. GA should be avoided since there is often a degree of respiratory obstruction and infection may spread to the lungs.

Laryngotracheitis

General aspects

Various microbes may be involved, such as respiratory syncytial virus (RSV), particularly in children.

Clinical features

Hoarseness, loss of voice and persistent cough are common. In children, partial laryngeal obstruction may cause noisy inspiration (stridor or croup) and is potentially dangerous.

General management

Symptomatic treatment only is available but ribavirin or palivizumab may be appropriate in RSV infection in infants who may otherwise subsequently develop bronchiolitis.

Dental aspects

Dental treatment should be deferred until after recovery. GA must be avoided, as it may exacerbate progression of infection to the lungs. Antimicrobials may be indicated for prophylaxis.

BACTERIAL RESPIRATORY TRACT INFECTIONS

Sinusitis

General aspects

Infection of the paranasal air sinuses (maxillary most commonly, but also ethmoid, sphenoid and frontal) is usually bacterial. It may be preceded by viral or other factors (Box 14.1).

Table 14.3 *Paranasal sinusitis*

Sinus	Location of pain	Other features
Maxillary	Cheek and/or upper teeth, worsened by biting	Tenderness over antra
Frontal	Over frontal sinuses	Tenderness of sides of nose
Ethmoidal	Between eyes	Anosmia, eyelid swelling
Sphenoidal	Ear, neck, and top or centre of head	–

Clinical features

Headache on waking is typical, with pain worse on tilting the head or lying down; there is also nasal obstruction with mucopurulent nasal discharge (Table 14.3).

General management

Diagnosis is from the history, plus tenderness over the sinus, dullness on transillumination, and radio-opacity or a fluid level on plain X-rays of the sinuses (sinus opacity may be due to mucosal thickening rather than infection, but a fluid level is highly suggestive of infection). Antral opacities in children can be difficult to evaluate since they are seen in up to 50% of healthy children under the age of 6 years. Computed tomography (CT) is now the standard care. Ultrasonography may be helpful. However, the gold standard for diagnosis remains sinus puncture and aspiration.

Sinusitis is classified as acute, chronic or recurrent.

In *acute sinusitis*, the bacteria most commonly incriminated are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Infection resolves spontaneously in about 50%, but analgesics are often indicated and antibiotics may be required if symptoms persist or there is a purulent discharge. Treatment is drainage using vasoconstrictor nasal drops, such as ephedrine or xylometazoline. Inhalations of warm, moist air, with benzoin, menthol or eucalyptus, may give symptomatic relief. In adults, a course of antimicrobials for longer than 7 days is indicated, using amoxicillin, ampicillin or co-amoxiclav (erythromycin or azithromycin, if penicillin-allergic), or a tetracycline, such as doxycycline, or clarithromycin. In children, high-dose amoxicillin, cefuroxime or co-amoxiclav is recommended especially if the child has received antibiotics during the 4–6 weeks prior to the infection.

Chronic sinusitis involves anaerobes, especially *Porphyromonas* (Bacteroides), and half are beta-lactamase producers. It may follow acute sinusitis, especially where there are local abnormalities, allergic rhinitis, or impaired defence mechanisms such as cystic fibrosis or human immunodeficiency virus (HIV) disease. Gram-positive cocci and bacilli, as well as Gram-negative bacilli, may also be found – especially in HIV/acquired immunodeficiency syndrome (AIDS) patients and those on prolonged endotracheal intubation. *Pseudomonas aeruginosa* (up to 5% of cases are caused by *Pseudomonas*, especially in cystic fibrosis), *Acinetobacter baumannii* and Enterobacteriaceae are also implicated. In immunocompromised persons, fungi may also be involved, including *Mucor*, *Aspergillus* or other species. Chronic sinusitis responds better to drainage by functional endoscopic surgical techniques (Fig. 14.2), plus antimicrobials, such as metronidazole with amoxicillin, erythromycin, clarithromycin or a cephalosporin.

Recurrent sinusitis should be treated with drainage, plus antimicrobials, and investigation to determine whether there is any underlying cause.

**Fig. 14.2** Nasal pack, used after nasal and antral surgery.

Dental aspects

Dental treatment should be deferred until after recovery. GA should be avoided, since there is often some respiratory obstruction and infection can spread to the lungs. Inhalational sedation may be impeded if the nasal airway is obstructed.

Mycoses may infect the sinuses in immunocompromised persons (Ch. 20).

Otitis media

General aspects

Otitis media is a common middle-ear infection in children; 3 out of 4 experience it by the age of 3 years. Otitis media usually follows a viral URTI, often followed by bacterial superinfection. The most common bacterial pathogen is *Streptococcus pneumoniae*, followed by non-typeable *Haemophilus influenzae* and *Moraxella catarrhalis*.

The most important predisposing factor is Eustachian tube (ET) dysfunction but immune defects and palatal dysfunction, such as cleft palate or submucous cleft, occasionally contribute. Interference with the ET mucosa by inflammatory oedema, adenoidal hypertrophy, negative intratympanic pressure or, rarely, a tumour facilitates direct extension of infections from the nasopharynx to the middle ear. Oesophageal contents regurgitated into the nasopharynx can enter the middle ear through the ET if it is patulous.

Clinical features

When the ears are infected, the ET becomes inflamed and swollen, the mucociliary pathways from the middle ear to the nasopharynx become paralysed or dysfunctional, and fluid is trapped inside the middle-ear cleft. The adenoids can also become infected and can block the openings of the ET, trapping air and fluid.

Acute otitis media is very painful, and is worse when the child is lying down. If the infection is not controlled, the eardrum ruptures and pus escapes through the perforation – otorrhoea – when there is an immediate decrease in pain. It may become evident that the child has diminished hearing in that ear. If ET dysfunction merely prevents the normal drainage of the middle-ear cleft, with or without previous acute infection, a condition referred to as otitis media with effusion or ‘glue ear’ becomes established. This also affects the hearing but is

painless. In either case, temporary speech and language problems may become evident as a result of the hearing loss, but usually resolve spontaneously with time. Complications that are rare but can be serious include mastoiditis, meningitis, brain abscess, lateral sinus thrombosis, otitic hydrocephalus, facial palsy, cholesteatoma and tympanosclerosis.

General management

Medical treatment includes antibiotics (usually penicillin) and decongestants and/or antihistamines together with analgesia. If fluids from otitis media stay in the ear for several months, drainage by surgery, usually myringotomy (incision of the ear drum) and grommets (small drainage tubes placed in the incision), may be recommended. Adenoidectomy may also be indicated.

MALIGNANT NEOPLASMS

Most head and neck cancers are squamous cell carcinomas; other tumour types include lymphoepithelioma, spindle cell carcinoma, verrucous cancer, undifferentiated carcinoma, Kaposi sarcoma and lymphoma. Use of computer guided surgery seems likely to improve outcomes, especially in patients whose anatomy has been altered.

MAXILLARY ANTRAL CARCINOMA

General aspects

Antral carcinoma is a rare neoplasm of unknown aetiology, seen mainly in older people.

Clinical features

From the outset, antral carcinoma presents with severe maxillary pain. As the tumour increases in size, the effects of expansion and infiltration of adjacent tissues also become apparent. There is intraoral alveolar swelling; ulceration of the palate or buccal sulcus; swelling of the cheek; unilateral nasal obstruction, often associated with a blood-stained discharge; obstruction of the nasolacrimal duct with consequent epiphora; hypoaesthesia or anaesthesia of the cheek in the infraorbital nerve distribution; proptosis and ophthalmoplegia consequent on invasion of the orbit; and trismus from infiltration of the muscles of mastication.

General management

Combinations of surgery and radiochemotherapy are usually required. Further details can be found in standard textbooks of otorhinolaryngology or maxillofacial surgery.

NEOPLASMS OF THE PHARYNX

Cancer can develop in the nasopharynx (see below and Ch. 22), oropharynx (consisting of the base of tongue, the tonsillar region, soft palate and back of the oral cavity) or the hypopharynx. Patients with pharyngeal cancer are at greater risk of cancer elsewhere in the upper aerodigestive tract.

Factors that increase the risk of pharyngeal cancers include smoking (both tobacco and marijuana) or chewing tobacco; alcohol use; leukoplakia; human papillomavirus (oropharyngeal carcinoma); Epstein–Barr virus (nasopharyngeal carcinoma); anaemia (Paterson–Brown–Kelly syndrome); radiation; and immune defects.

Pharyngeal cancer is treated by one, or a combination, of radiotherapy, chemotherapy or surgery.

NASOPHARYNGEAL CARCINOMA

General aspects

Nasopharyngeal carcinoma is a rare neoplasm that may be associated with Epstein–Barr virus and dietary nitrosamines; it is especially common amongst the southern Chinese, some Inuit races and people in parts of North Africa, such as Tunisia. A similar tumour, undifferentiated carcinoma with lymphoid stroma, is one of the most common salivary gland cancers in Inuits and southern Chinese.

Clinical features

Nasopharyngeal carcinoma often remains asymptomatic for some time, as it rarely obstructs the nasopharynx. The ways in which it presents include:

- isolated cervical lymph node enlargement
- unilateral conductive deafness (from obstruction of the Eustachian tube)
- abducens nerve palsy
- soft palate elevation and immobility
- ipsilateral pain, sometimes with anaesthesia, in the distribution of the major divisions of the trigeminal nerve, e.g. over the eye (ophthalmic division), tongue, lower teeth and lower lip (mandibular division)
- a combination of the above – known as *Trotter's triad*.

General management

Treatment is usually by radiotherapy.

LARYNGEAL CARCINOMA

Laryngeal cancer is found in the glottis, supraglottis or subglottis. It is most common in males, patients of both sexes over the age of 55 who smoke or drink alcohol, are infected with human papillomavirus or have immune defects. Risk factors may also include genetics (people of African descent are more likely than whites to be affected); a personal history of head and neck cancer; exposure to asbestos, sulphuric acid mist or nickel; or a diet low in vitamin A.

Clinical features

Symptoms and signs may include hoarseness, persistent sore throat, dysphagia, pain referred to the ear when swallowing, haemoptysis and cervical lymphadenopathy.

General management

Laryngoscopy, computed tomography (CT) and biopsy are required to confirm the diagnosis. Laryngeal cancer is treated by one, or a combination, of radiotherapy, chemotherapy or surgery. Laser surgery may be used for very early cancers of the larynx. A cordectomy removes the vocal cord. A supraglottic laryngectomy takes out only the supraglottis. A partial or hemi-laryngectomy removes only part of the larynx. A total laryngectomy removes the entire larynx and commits the patient to a permanent tracheostomy. Despite loss of part or all of the vocal apparatus, most patients are able to communicate by speech with or without further surgical procedures and electronic voice aids.

Box 14.2 Risk factors for salivary neoplasms

- Epstein–Barr virus infection
 - At least in Asian patients and Inuits
- Occupation
 - Rubber manufacturing
 - Plumbing industry
 - Woodworking
 - Hairdressing
 - Asbestos exposure
- Smoking
 - At least for Warthin tumour
- Other malignant disease
 - Breast cancer
 - Nasopharyngeal carcinoma
 - Thyroid cancer
- X-ray repair cross-complementing group 1 (XRCC1) single-nucleotide polymorphisms
- Radiation exposure, as in:
 - sun exposure
 - ionizing radiation exposure
 - survivors of atomic explosions in Japan (mucoepidermoid carcinomas and Warthin tumour)
 - survivors of childhood malignancies treated with radiation and chemotherapy
 - iodine-131 in the treatment of thyroid disease
 - radiotherapy to the head and neck
 - radiographs of the head and neck

ORAL AND OROPHARYNGEAL CARCINOMA

See Chapter 22.

SALIVARY NEOPLASMS**General aspects**

A wide range of different neoplasms can affect the salivary glands but most are uncommon; they are epithelial neoplasms, which present as unilateral swelling of the parotid and are benign. Most salivary gland neoplasms are seen in older people. There is a female predisposition.

Neoplasms in the major salivary glands (parotid, submandibular) are most commonly pleomorphic adenomas but others are usually monomorphic adenomas (such as adenolymphomas), mucoepidermoid tumours or acinic cell tumours. Neoplasms in the minor salivary glands are most commonly pleomorphic adenomas but carcinomas, particularly adenoid cystic carcinomas, account for about 50%.

Salivary gland tumours are more common in certain geographical locations. Inuits, for example, have an increased prevalence. The aetiology is unknown but there are various associations (Box 14.2). A suggested association of parotid tumours with mobile phone use is controversial.

Apart from the above epithelial neoplasms, the next most common salivary neoplasms are lymphomas. Sjögren syndrome is recognized as predisposing to lymphomas, which have arisen in up to 6% of patients over 10 years in some studies.

Clinical features

Salivary gland swelling is the main clinical feature of a neoplasm (Fig. 14.3). A long history of gradual gland enlargement suggests a benign

Fig. 14.3 Salivary gland neoplasms are mainly in the parotid gland.

process, while pain, facial palsy, rapid growth and change in growth pattern are ominous and suggest carcinoma.

General management

On clinical examination, a mass is usually palpable. In the case of the parotid, this will often be in the retromandibular region but is sometimes pre-tragal. Tumours confined to the deep lobe of the parotid present like other parapharyngeal tumours with medial displacement of the palate, tonsil and pharyngeal wall. A few malignant neoplasms may be small and almost impalpable, and present with pain only. Magnetic resonance imaging (MRI) is particularly helpful for diagnosing parotid and submandibular tumours. CT is often degraded in this region by amalgam artefacts. Ultrasonography has utility in determining whether a mass is in the tail of the parotid or posterior pole of the submandibular gland. Regardless of the image appearances, the precise diagnosis can only be firmly established by histological examination of either the operative specimen or, increasingly frequently, by fine-needle aspiration biopsy.

The treatment of choice for salivary gland neoplasms is surgical excision. Most salivary gland neoplasms are relatively radioresistant. Chemotherapy is used only on a very limited basis and as an adjunct in the treatment of some malignant salivary gland neoplasms, such as adenocarcinoma or adenoid cystic carcinoma.

LYMPHOMAS

See Chapter 8.

ORO-ANTRAL FISTULA

Oro-antral fistula is discussed in surgical textbooks. Palatal perforations can be caused by trauma, malignant neoplasms or the use of cocaine.

OBSTRUCTIVE SLEEP APNOEA SYNDROME**General aspects**

Obstructive sleep apnoea syndrome (OSAS) is characterized by periods of prolonged apnoea during sleep. Patients with OSAS snore extremely loudly, often termed 'heroic snoring'!

The cause is airway obstruction, usually in the region of the oropharynx; enlarged tonsils, nasal septum deformity, narrow dental arches and abnormalities in the larynx may contribute. Enlarged tonsils or tongue (macroglossia) are uncommon causes. Alcohol or other sedatives inducing muscle relaxation can aggravate the situation.

As the patient relaxes in the early phase of sleep, the tongue falls back into the oropharynx and causes obstruction. OSAS is the extreme end of a spectrum of sleep-disordered breathing (SDB), which may be related to weak activity of muscles in (or obstruction to) the tongue, palate and pharynx. SDB has as its minimal level simple snoring, then upper airways resistance syndrome (UARS) and, finally, OSAS, in which there are periods of apnoea during sleep; each period lasts for up to a minute and episodes range from the occasional one to hundreds per night, waking the patient. Sleep is lost and patients with significant OSAS have daytime sleepiness that often culminates in road traffic accidents, an increased risk of acute cardiopulmonary complications and stroke.

Oronasal obstruction in weak senile patients results from blockage of the nose and lack of teeth or dentures, causing the mouth to become overclosed. It may cause a dangerous degree of dyspnoea and cyanosis, even when the person is awake. Hypoxia, thus caused, may contribute to the death of these vulnerable patients.

Clinical features

Partial upper airways obstruction during sleep in anyone can cause snoring that is not OSAS. People with OSAS are characteristically obese middle-aged men. In OSAS, snoring is far more severe and, because there is apnoea, arterial oxygen saturation falls, and cardiac arrhythmias and stroke may develop, particularly in obese middle-aged men. In even more severe cases, pulmonary hypertension and right ventricular failure result. There is also a raised mortality rate from road traffic and other accidents, since affected patients are constantly drowsy.

General management

Severity of OSAS is scored by an apnoea/hypopnoea index calculated from the combined number of episodes per night (less than 20 is mild, 20–40 is moderate and more than 40 is classed as severe). Tiredness can be scored on the Epworth scale (Table 14.4); a score of 10 or more is considered ‘sleepy’, while 18 or more is ‘very sleepy’. Diagnosis is assisted by polysomnography and measurement of arterial blood oxygen.

Treatment includes obesity reduction and nasal continuous positive airways pressure (CPAP). Other measures include various appliances (sometimes termed non-sleep apnoea dental orthotics [NADOs], e.g. *Silent Nite*, *Klearway*, *NAPA*, *Snore aid*, *Herbst*, *Silencer*), orthognathic surgery (maxillary–mandibular and hyoid advancement; MMA), or uvulopalatopharyngoplasty (UPPP), adenoidectomy, tonsillectomy or even tracheostomy.

UPPP using scalpel surgery or lasers has been the standard treatment for OSAS, but is often overprescribed and its efficacy is under review.

Dental aspects

Dental appliances that hold the mandible forward are claimed to be as effective as surgical measures and should certainly be tried initially. However, where the obstruction is predominantly hypopharyngeal, surgical advancement of the facial skeleton and hyoid (MMA) may effectively

Table 14.4 Score sheet for Epworth daytime sleepiness scale

Situation	Chance of dozing or sleeping ^a
Sitting and reading	Total = Epworth score
Watching TV	
Sitting inactive in a public place	
Being a passenger in a motor vehicle for an hour or more	
Lying down in the afternoon	
Sitting and talking to someone	
Sitting quietly after lunch (no alcohol)	
Stopped for a few minutes in traffic while driving	

^a0 = would never doze or sleep; 1 = slight chance of dozing or sleeping; 2 = moderate chance of dozing or sleeping; 3 = high chance of dozing or sleeping.

expand the airway. When there is both oropharyngeal and hypopharyngeal obstruction, UPPP may need to be combined with MMA.

Nasal obstruction may also have to be relieved, but staged maxillofacial surgery to assess the degree of improvement may relieve nocturnal hypoxia, snoring and daytime sleepiness.

FREY SYNDROME (GUSTATORY SWEATING)

General and clinical aspects

Parotidectomy or trauma to the parotid region is sometimes followed by sweating and flushing of the pre-auricular skin on that side, in response to stimulation of salivation. Similar conditions may follow surgery to other salivary glands.

Gustatory sweating is due to the joining of the damaged post-ganglionic parasympathetic nerve fibres with the sympathetic nerve endings, so that sweating and flushing occur rather than salivation.

General management

Antiperspirants, such as 20% aluminium chloride hexahydrate, may be effective in controlling the sweating.

DEVELOPMENTAL DISORDERS

By the third week after fertilization, the first of four paired swellings – the branchial arches – at the sides of the head end of the embryo have formed, as well as three germ layers (ectoderm, endoderm and mesoderm). Some craniofacial anomalies result from branchial arch defects and others from the germ layers.

Genes that orchestrate the development of craniofacial structures also direct the development of brain, limbs and some internal organs, such as the heart, lungs and liver. If affected very early in gestation, there may be widespread and devastating consequences. Craniofacial birth defects are rare but fortunately may be ameliorated by surgery, dental care, psychological counselling, and rehabilitation.

CRANIOFACIAL ANOMALIES CAUSED BY BRANCHIAL ARCH DEFECTS

The primary palate forms by merging of the two medial nasal prominences, which arise from the frontonasal process. The primary palate

Table 14.5 Main genes involved in cleft palate development

Defects	Genes implicated
Defects in growth of the palatal shelves	Homeobox-containing transcription factor <i>MSX1</i>
	Paired-related genes <i>Pax-1, 3, 6, 7</i> and <i>9</i>
	<i>Dlx</i> transcription factors
	<i>Activin A</i>
Elevation of palatal shelves	<i>LIM</i> homeobox genes
	<i>Gli</i> transcription factors
	<i>Jagged 1, 2</i>
	<i>BMP7/BMPReceptor1B</i>
Impairment of the midline epithelial seam, adhesion, dispersion	<i>Hox</i> genes
	<i>Tgfβ3</i>
Epithelio-mesenchymal transition	Transforming growth factor (<i>TGF</i>)
	Fibroblast growth factor (<i>FGF</i>)
Cell deficiency (proliferation, differentiation, migration defects)	<i>Twist</i> transcription factor
	<i>SHH</i> (Sonic Hedgehog)
	Endothelin-1 (<i>Et-1</i>)

will fuse laterally with the maxillary processes of the first branchial arch during the sixth and seventh weeks, forming the upper lip. The palate contains the maxillary incisor teeth.

Secondary palate development involves bilateral palatal shelves arising from the maxillary processes in 6.5-week human embryos, which eventually make contact above the tongue. The palatal shelves adhere with each other over the space of about 10 days to form the midline epithelial seam. The epithelial seam disperses to allow merging of the mesenchyme to form fused palatal shelves, by the 10th week of gestation. The midpalatal seam often disappears incompletely, leaving epithelial rests or remnants (Epstein’s pearls) in the midline. Impaired formation of the secondary palate results in cleft palate (CP), usually quickly recognized after birth, especially when associated with a cleft lip (CL). A submucous cleft can be more difficult to diagnose.

Pathogenesis of cleft palate

The development of the face and the upper lip takes place during the fifth to ninth week of pregnancy. Clefts of the lip with or without cleft palate, and cleft palate alone, result from the failure of the first branchial arches to complete fusion processes; they are the most common of all craniofacial anomalies. The male-to-female ratio of cleft lip/palate (CLP) is 2:1; the ratio for CP alone is just the reverse, 1:2.

Failed fusion of the palatal shelves can be caused by different gene defects (Table 14.5), culminating in:

- a problem in the formation of the midline epithelial seam
- small size of the palatal processes
- unsynchronized timing of the elevation or growth of the palatal shelves with the growth of surrounding structures such as the cranial base
- a small mandible preventing the downward relocation of the tongue, which mechanically may prevent palatal fusion.

CP as an isolated malformation behaves as an entity distinct from CL with or without CP. It has an incidence of 0.5 per 1000 births. The risk of recurrence in subsequent children is about 2% if one child has it, 6% if one parent has it, and 15% if one parent and one child have it.

Box 14.3 Drugs used in pregnancy that may induce cleft palate

Drugs most commonly implicated

- Alcohol
- Anticonvulsants
- Cocaine
- Fluconazole
- Heroin
- Phenytoin
- Retinoids
- Tobacco
- Topiramate

Drugs occasionally implicated

- Antihypertensives
- Corticosteroids
- Cytotoxic agents
- Thalidomide

Box 14.4 Genes implicated in non-syndromic cleft palate

- Transforming growth factor (*TGF*)
- Retinoic acid receptor alpha (*RARA*)
- Long arm of chromosome 2 (2q32)
- Chromosome 4
- Short arm of chromosome 6 (*Et-1* gene 6p24)

Non-syndromic cleft palate

Not all cases of clefting are inherited; a number of teratogens (environmental agents that can cause birth defects) have been implicated, as well as defects in essential nutrients. Environmental factors present during the first trimester of pregnancy, and which may generate CP, include maternal URTI in the first trimester, smoking (especially when the mother has glutathione-S-transferase theta 1 [*GSTT1*] – null variants), obesity, diabetes, stress or exposure to the agents shown in Box 14.3. Paternal smoking has also been implicated.

CLP is more prevalent in the lower socioeconomic classes. The teratogens incriminated include isotretinoin, used to treat acne, which causes birth defects such as brain malformations, learning disability and heart problems, as well as facial abnormalities. Thalidomide given to pregnant mothers was, and anticonvulsants (phenytoin, valproic acid, lamotrigine, carbamazepine) and corticosteroids may be, associated with an increased incidence. Phenytoin may act via an effect causing fetal arrhythmias and hypoxia. Systemic corticosteroids have been reported to increase the risk (this is controversial) and there are also concerns about possible effects from topical steroids used in the first trimester. There has been suspicion of aspirin and diazepam as possible causes but there is no real evidence. Folic acid given periconceptually may lower the risk but the evidence is weak.

Inheritance of non-syndromic CP is multigenic, with a number of genes implicated (Box 14.4).

Clefting can occur independently or as part of a larger syndrome that may include the heart and other organs. Affected infants have facial deformity and may have difficulty with feeding, breathing, speaking and swallowing; they are susceptible to respiratory infections.

General aspects

The primary palate or pre-maxilla includes that portion of the alveolar ridge containing the four incisors. The secondary palate forms the remaining hard palate and all the soft palate. Orofacial clefts result from an embryopathy in which there is failure of the frontonasal process and/or fusion of the palatal shelves. In the submucous CP, the palatal shelves may fail to join, but the overlying mucous membranes are intact and the muscle attachments of the soft palate are abnormal, causing velopharyngeal insufficiency. Bifid uvula may signify a submucous CP.

CP is the fourth most common birth defect, affecting approximately 1 in 700–1000 live births. There are also racial differences, with a high incidence in South-East Asians and a low incidence in Afro-Caribbean races. The common clefts are cleft lip with or without cleft palate (CL $\pm$ P) and CP only. The total incidence of facial clefting is between 2 and 3 per 1000 live births. A number of these do not develop as full-term fetuses. Facial clefts are associated with a syndrome in up to 15–60% of cases and are then termed syndromic clefts (see below). More than 400 syndromes may include a facial cleft as one manifestation, and CLP may be associated with many congenital syndromes.

The cause of non-syndromic cleft lip with or without cleft palate (NSCLP) is unclear but there is still a strong genetic component; there may be a family history of clefts and typically the same type of cleft is seen in affected members. In monozygotic twins, there is nearly 40% concordance. No single gene defect appears responsible, however. Several loci have been identified. Candidate genes in CLP include transforming growth factor alpha (*TGF*), poliovirus receptor-like 1 (*PVRL1*), retinoic acid receptor alpha (*RARA*), T-box transcription factor-22 (*TBX22*), specific isoforms of glutamic acid decarboxylase (*GAD*), interferon regulatory factor 6 (*IRF6*), *MSX1* (formerly *homeobox 7* – encodes a member of the muscle segment *homeobox* gene family) and fibroblast growth factor (*FGF*) (see Table 14.5).

Clinical features

Clefts have a major impact from birth from both aesthetic and functional viewpoints, since the neonate with a CP is unable to suckle. Later, speech development is also impaired. A person may have a CL, CP, or both.

A unilateral CL occurs on one side of the upper lip. A bilateral CL occurs on both sides of the upper lip. In its most severe form, the cleft may extend through the nose base.

CP may be incomplete, involving only the uvula and the muscular soft palate (velum). A complete CP extends the entire length of the palate. CP can be unilateral or bilateral. There may also be feeding difficulties and associated congenital defects such as dental, hearing and speech defects.

General management

Health-care providers that frequently participate in a multidisciplinary CP team include: audiologists; maxillofacial, ear, nose and throat, and plastic surgeons; geneticists; neurosurgeons; nurses; dentists (paediatric dentist/orthodontist/prosthodontist); paediatricians; social workers/psychologists; and speech and language pathologists.

A high percentage of patients with CP develop otitis media with effusion. Up to 20% have additional abnormalities that can affect management in various ways (Fig. 14.4). Systemic disorders are more frequent in patients with CP than in those with CL alone, and include especially skeletal, cardiac, renal and central nervous system defects.

Fig. 14.4 Cleft palate.

Newborn to 12 months

Treatment of the airway takes priority and may be managed with positioning but, in severe cases, may need tracheostomy. There can be significant difficulties in management of the airway for anaesthesia in children under the age of 5 years, particularly in young infants and in those with feeding difficulties, bilateral clefts and/or retrognathia. Patients with mandibular dysostoses and those requiring midface advancement (Le Fort II osteotomy) have the greatest problems. Difficulties are common in Pierre Robin, Treacher Collins and Goldenhar syndromes, and the cervical spine may be problematic in Klippel–Feil syndrome. The laryngeal mask has been recommended as a guide to fiberoptic endoscopic intubation. Aesthetics is a major issue for parents (Fig. 14.5). One of the problems for the child is feeding; a Rosti bottle with Gummi teat often helps.

The timing of the initial CLP repair is controversial. In general, when the lip alone is cleft, initial cosmetic repair is carried out at about 3–6 months of age, though earlier operations are becoming popular. Many repair CLP within the first few days of life since, after repair, the appearance is dramatically improved, feeding difficulties are significantly minimized and speech develops better. If the palatal defect is too wide, it can be repaired 3 months later to allow for sufficient palatal growth. In any event, CP is now usually repaired before the child speaks, between 6 and 18 months, and typically at 6–12 months of age.

Years 1 to 18

Age 1–5 years is when it is important to have good hearing and normal appearance to avoid low self-esteem and help speech develop. These children need a hearing assessment; if hearing is impaired, ear ventilation tubes (grommets) may be indicated.

Age 5–13 years is when the orthodontist can help correct malocclusion, and alveolar bone grafting may be needed. Speech, if poor despite the best efforts on the part of the child and the speech pathologist, may be corrected with pharyngoplasty.

Fig. 14.5 Cleft lip.

Age 13–18 years is the time for final adjustments. Fine-tuning, such as scar revisions, rhinoplasty and orthognathic surgery, is carried out to enable the child's appearance and speech to be restored to as near normal as possible.

Dental aspects

Palatal ulcers seen in neonates with CLP appear to result from trauma from the tongue and resolve if a palatal plate is fitted. Dental abnormalities include malocclusion (almost 100%), hypodontia (50%), hypoplasia (30%) and supernumerary teeth (20%). Children may have a higher prevalence of caries in both primary and permanent dentitions, and significantly more gingivitis, especially in the maxillary anterior region. Adult CLP patients may have poorer oral hygiene and more gingivitis. Prevention and continuity of care are essential and a high rate of success can be achieved.

Submucous cleft palate can be recognized by a notched posterior nasal spine, a translucent zone in the midline of the soft palate and a bifid uvula, but not all these features are necessarily present and a bifid uvula may be seen in isolation. About 1 in 1200 births is affected and feeding difficulties, speech defects and middle-ear infections may develop in 90% of affected children. Adenoidectomy is contraindicated, as it may reveal latent velopharyngeal insufficiency. A minority have other issues such as Loeys–Dietz syndrome (similar to Marfan syndrome), where there is a risk of arterial aneurysm and rupture.

Syndromic cleft palate

Current molecular epidemiology investigations have examined both syndromic and non-syndromic (isolated) cleft lip/palate and cleft palate. Linkage studies have identified a number of candidate genes, including *MSX1*, *RAR*, an X-linked locus, and the genes for TGF beta-3 and TGF alpha.

Van der Woude and Waardenberg syndromes are associated with CL, with or without CP. Common syndromes with CP include Apert, Stickler and Treacher Collins syndromes. CLP may also be seen in velocardiofacial, Pierre Robin and Klippel–Feil syndromes and in various chromosome anomalies (Down syndrome, Edwards syndrome; Appendix 14.1).

A small subgroup of patients have CLP with median facial dysplasia and cerebrofacial malformations, while others have laryngotracheal oesophageal clefts (Opitz–Frias or G syndrome) or cranial asymmetry (Opitz or B syndrome).

One of the common syndromic forms of CLP, the van der Woude syndrome, is caused by an autosomal dominant form of inheritance at a locus on chromosome 1.

Other examples include:

- branchial arch syndromes
- craniosynostoses
- diseases associated with mutations in the Sonic Hedgehog pathway (*SHH*).

Branchial arch syndromes

Pierre Robin syndrome

Deficient development of the mandibular portion derived from the first branchial arch results in micrognathia, with the tongue set back and possibly obstructing the airway. CP may be another consequence. The infant is also at risk of cor pulmonale.

Treacher Collins syndrome (mandibulofacial dysostosis)

Treacher Collins syndrome has an autosomal dominant inheritance and is associated with mutation of the *Treacle* gene (5q32-q33.1), which encodes a phosphorylated nucleolar trafficking protein. First branchial arch structures are deficient, and all derivative craniofacial components are affected. Treacher Collins syndrome manifests with cleft palate; downward-sloping eyelids; partial absence of lower eyelashes; depressed cheekbones; a large, fish-like mouth; deformed ears with conductive deafness; a small, receding chin and lower jaw; a highly arched or cleft palate; and severe dental malocclusion. These defects result from defective cranial neural crest cell differentiation, migration and proliferation.

The underdeveloped facial structures can contribute to airway blockage and repeated upper respiratory infections, and maldevelopment of the ears leads to a conductive deafness.

DiGeorge syndrome, velocardiofacial syndrome (Shprintzen syndrome, CATCH 22)

General aspects. Velocardiofacial syndrome (VCFS; from the Latin *velum* – palate, *cardia* – heart, and *facies* – to do with the face) is a genetic disorder involving chromosome 22 (a deletion at 22q11). Its features include cardiac defects, abnormal facies, thymic hypoplasia, cleft palate and hypocalcaemia – hence it is termed ‘CATCH 22’. It affects approximately 5–8% of children born with CP. There is a characteristic facial appearance, minor learning problems and speech and feeding difficulties, and heart defects. It is inherited in only about 10–15% and, usually, neither parent has the syndrome or carries the defective gene.

Also known as Shprintzen syndrome, craniofacial syndrome or conotruncal anomaly unusual face syndrome, at least 30 different defects have been associated with the 22q11 deletion of VCFS. DiGeorge syndrome is similar (Ch. 20).

Box 14.5 Features of velocardiofacial syndrome (CATCH 22)

- Cleft palate, usually of the soft palate
- Heart disease
- Facies (elongated face, almond-shaped eyes, wide nose, small ears)
- Learning difficulties
- Eye defects
- Otitis media
- Hypoparathyroidism
- Immune defects
- Weak muscles
- Short height
- Curvature of the spine (scoliosis)
- Tapered fingers

Clinical features. There is great variation in the features (Box 14.5), although none of these problems occurs in all cases.

Dental aspects. There may be difficulties associated with CLP, cardiac disease and immune defects.

Maldevelopment of the fourth branchial arch and the third and fourth pharyngeal pouches leads to deficiencies affecting the thymus, parathyroid glands and the great vessels. Facial features include a squared-off nasal tip, small mouth and widely spaced eyes. Similar facial features, along with heart defects, are seen in the velocardiofacial syndrome. Both syndromes are associated with deletions on the long arm of chromosome 22 (22q11).

The thymic defect severely compromises cellular immunity. Inadequate or missing parathyroid glands cause severe hypocalcaemia and seizures. The great vessel abnormalities lead to compromised circulation.

Features include:

- cardiac abnormality
- abnormal facies
- T-cell deficit due to thymic hypoplasia
- cleft palate
- hypocalcaemia due to hypoparathyroidism.

Craniosynostoses

The premature fusion of certain skull bones (craniosynostosis) prevents normal skull growth, affects the shape of the head and face, and puts pressure on the developing brain. It is seen in Crouzon, Apert, Saethre–Chotzen and Pfeiffer syndromes and in Boston-type craniosynostosis (Ch. 37).

Crouzon syndrome

Crouzon syndrome is a rare genetic disorder characterized by abnormal skull growth with wide-set, bulging eyes (hypertelorism; proptosis) and visual problems caused by shallow eye sockets; eyes that do not point in the same direction (strabismus); a beaked nose; and an underdeveloped maxilla. In addition, there may be cleft lip and palate, dental problems and hearing loss, which is sometimes accompanied by narrow ear canals. People with Crouzon syndrome are usually of normal intelligence.

Mutations in the fibroblast growth factor receptor 2 (*FGFR2*) gene cause Crouzon syndrome.

Apert craniofacial synostosis

Apert craniofacial synostosis is an autosomal dominant disorder, caused by mutations in the chromosome 10q26 gene encoding *FGFR2*. CP is associated more significantly with the *S252W* mutation.

Features include craniosynostosis, facial dysmorphism, hand and feet defects, and learning impairment.

Diseases associated with Sonic Hedgehog pathway (*SHH*) mutations**Holoprosencephaly**

Holoprosencephaly affects neural crest cells populating the frontonasal mass and the forebrain, with associated midface defects. Some cases are caused by *SHH* mutations.

Features include wide phenotypic variation, a single central incisor, median cleft lip and palate, absent nasal bone, hypertelorism and cyclopia.

Basal cell naevus ('Gorlin') syndrome

This condition is due to a mutation in the *PTC* gene (Ch. 37).

CRANIOFACIAL DEFECTS SECONDARY TO OTHER DEVELOPMENTAL DISORDERS

Craniofacial defects may be secondary to a more generalized structural or biochemical defect.

Osteogenesis imperfecta

See Chapter 16.

Waardenburg syndrome

See Chapter 37.

Cleidocranial dysplasia

The inheritance of a regulatory gene defect in cleidocranial dysplasia leads to features that include delayed tooth eruption, supernumerary teeth, altered or missing collarbones, short stature, and possible failure of cranial suture closure. The exact mechanism of the associated gene, *CBFA1*, located on chromosome 6, has not been determined but appears to be essential for bone development.

APPENDIX 14.1 SYNDROMES THAT MAY INCLUDE CLEFT LIP/PALATE

- Apert syndrome
- Basal cell carcinoma naevoid syndrome
- Carpenter syndrome
- Cleidocranial dysplasia
- Craniosynostosis
- Crouzon syndrome
- Down syndrome
- Edwards syndrome
- Freeman–Sheldon syndrome
- Goldenhar syndrome
- Hallermann–Streiff syndrome
- Hemifacial microsomia
- Hydrocephalus
- Klippel–Feil syndrome
- Microtia
- Miller syndrome

- Moebius syndrome
- Nager syndrome
- Nasal encephalocoeles
- Neurofibromatosis
- Orbital hypertelorism
- Parry–Romberg syndrome
- Pfeiffer syndrome
- Pierre Robin sequence
- Saethre–Chotzen syndrome
- Shprintzen syndrome
- Stickler syndrome
- Treacher Collins syndrome
- van der Woude syndrome
- Velocardiofacial syndrome
- Waardenburg syndrome

KEY POINTS

- Upper respiratory infections are commonplace, especially in young people, and are often contagious
- Lower respiratory infections are often contagious and some are potentially fatal
- Asthma is common and may be life-threatening
- Chronic obstructive pulmonary disease is common and disabling
- Tuberculosis worldwide is an important infection, affecting people with HIV/AIDS or malnutrition particularly
- Lung cancer is common and usually has a poor prognosis

The respiratory tract consists of the upper respiratory tract (URT – nose, paranasal sinuses, pharynx and larynx; discussed in Ch. 14) and the lower respiratory tract (LRT): the respiratory airways (trachea, bronchi and bronchioles) and lungs (respiratory bronchioles, alveolar ducts, alveolar sacs and alveoli), discussed in this chapter.

Protective mechanisms in the respiratory tracts include a mucociliary lining. Particles or pathogens are trapped in the mucus and driven by ciliary action (the ciliary elevator) to the pharynx. Mucociliary transport declines with age but any effect on clinical infection has not been proved. Lymphoid tissues of the Waldeyer ring (adenoids, palatine and lingual tonsils) are important in developing an immune response to pathogens. However, the best respiratory defence mechanism is the cough reflex, the components of which include cough receptors, afferent nerves, the cough centre, and efferent nerves and effector muscles. Impairment of any of these – as may be seen in older patients or those with conditions associated with lowered consciousness (e.g. sedative use and neurological disease) – can weaken protection. Dysphagia or impaired oesophageal motility may exacerbate the tendency to aspirate foreign material. The alveolar defence mechanisms include macrophages, immunocytes, surfactant, phospholipids, immunoglobulin G (IgG), IgE, secretory IgA, complement components and factor B; many immune defects manifest with recurrent respiratory infections.

Lung function is vital to gas exchange – the blood absorbs oxygen and releases carbon dioxide. Normal gas exchange requires adequate alveolar ventilation, normal ventilation/blood flow relationships and adequate alveolar–capillary membrane surface area. Breathing (ventilation) depends on respiratory drive, which reacts to the respiratory load. This process requires work and results in gas exchange.

Oxygen is transported in combination with haemoglobin in erythrocytes and a small amount dissolved in plasma. The oxyhaemoglobin dissociation curve is sigmoidal; once the oxygen saturation falls below 95%, the amount of O₂ transported to the tissues and brain falls rapidly. High temperatures, acidosis, raised CO₂ and raised 2,3-diphosphoglycerate (2,3-DPG) levels encourage oxygen offloading, whereas fetal haemoglobin and carboxyhaemoglobin have the contrary effect. Chronic hypoxaemia (e.g. at high altitudes) stimulates release of erythropoietin from the kidneys, with a rise in red cell production, and raised 2,3-DPG. Athletes have abused erythropoietin to gain competitive advantage (Ch. 33).

LOWER RESPIRATORY DISEASE

The most common LRT disorders are asthma and chronic obstructive pulmonary disease (COPD).

General aspects

Respiratory disorders are common, and are often caused or aggravated by tobacco smoking. They may significantly affect general anaesthesia (GA) and conscious sedation (CS), since they are often a contraindication to use of benzodiazepines, opioids, GA agents and other respiratory depressants.

Clinical features

Impaired gas exchange leads to laboured breathing and can cause significant incapacity. Features include cough, sputum production, wheeze, dyspnoea, chest pain, cyanosis, finger-clubbing (Fig. 15.1), use of accessory muscles of respiration with indrawing of the intercostal spaces (hyperinflation), and abnormalities in chest shape, movements, respiratory rate and breath sounds.

Cough may be a feature of any respiratory problem but, if chronic, may herald serious disease – for example, COPD, cancer or infection such as tuberculosis. Muroid or mucopurulent sputum is often a feature (Fig. 15.2); purulent sputum indicates acute bronchitis, bronchiectasis or lung abscess. Blood (haemoptysis) or blood-stained sputum, though common in acute infections (especially in pre-existing COPD), bronchiectasis and pulmonary embolism, may herald an even more serious condition – for example, possibly one due to carcinoma or tuberculosis. Wheezing is caused by airways obstruction and is a typical sign of asthma or COPD. Breathlessness (dyspnoea) is distressing, and may be caused by respiratory or cardiovascular disease, or by anaemia, and is particularly ominous if it persists at rest.

Fig. 15.1 Tobacco smoker with clubbing in lung cancer.

Fig. 15.2 Muroid sputum from chronic obstructive pulmonary disease.

Fig. 15.3 Spirometry.

Excessive resistive load, such as in asthma, COPD and cystic fibrosis, impairs airflow. Elastic load increases because of, for example, interstitial fibrosis, muscle paralysis and obesity.

General management

Diagnosis of respiratory disorders is from the clinical features supported by imaging (especially chest radiography). Spiral computed tomography (CT) can now scan the lungs in a quick 20–30-second breath-hold and therefore, instead of producing a stack of individual CT slices, which may be misaligned due to patient movement or breathing in between slices, provides high-resolution three-dimensional images.

Respiratory function tests can measure individual components of the respiratory process. *Spirometry* is the basic screening test for assessing mechanical load problems, the quantification involving determination of the vital capacity (VC) – slow vital capacity (SVC) and/or forced vital capacity (FVC) – and the speed of maximal expiratory flow (MEF; Fig. 15.3). In health, about 75% of a normal-sized VC is expelled in 1 second (FEV₁). The peak flow meter, which measures the peak expiratory flow rate (PEFR; the earliest portion of forced

Table 15.1 Adult values for PaO₂ and oxygen saturation^a

	PaO ₂ (kPa)	SaO ₂ (%)
Normal (range)	13 (≥10.7)	97 (95–100)
Hypoxaemia	<10.7	<95
Mild hypoxaemia	8–10.5	90–94
Moderate hypoxaemia	5.3–7.9	75–89
Severe hypoxaemia	<5.3	<75

^aFrom Williams AJ. Assessing and interpreting arterial blood gases and acid–base balance. BMJ 1998; 317:1213. <http://www.bmj.com/cgi/content/full/317/7167/1213> (accessed 30 September 2013).

expiration), is a simple measure of airflow obstruction, when the FEV₁ is a much smaller fraction of the VC. In lung restriction, the diminished VC can be mostly expelled in about 1 second. Serial measurements (e.g. in asthma) provide valuable information about disease progress. The reversibility of airways obstruction is usually assessed by spirometry before and after use of a bronchodilator agent.

Arterial blood gas analysis yields considerable information about gas exchange efficiency. Arterial hypoxaemia in adults is defined as PaO₂ below 10.7 kPa breathing room air, although it is not usually treated as clinically important unless below 8 kPa, when oxygen saturation will be 90% or less (Table 15.1).

Arterial carbon dioxide tension (PaCO₂) is used as an inversely proportional index of ‘effective’ alveolar ventilation. Hence, a high PaCO₂ is taken to indicate poor alveolar ventilation. Alveolar hypoventilation (raised PaCO₂) with a normal pH probably represents a primary ventilatory change present long enough for renal mechanisms to compensate, as in chronic ventilatory failure. Ventilation/blood flow relationships are most simply assessed by considering the size of the difference between the amounts of oxygen and carbon dioxide in the blood and in the air; the differences are small if the lungs are working efficiently. Disparity between ventilation/blood flow ratios results in abnormally wide differences – and then alveolar–arterial PO₂ and arterial–alveolar PCO₂ gradients will be abnormal.

Alveolar capillary surface area is assessed by measuring the uptake of carbon monoxide – usually abnormal in diffuse interstitial inflammatory and fibrotic processes and in emphysema.

Assessing bronchial reactivity and the exercise response can help evaluate breathlessness. Simple exercise testing provides information about overall fitness and the appropriateness of cardiorespiratory responses. Radionuclide lung scanning, blood gas analysis and sputum cytology or culture are sometimes needed in addition.

Management can include oxygen administration by mask or nasal cannula (Figs 15.4 and 15.5).

Dental aspects

LRT disorders can cause significant incapacity and are often a contraindication to GA, and even to CS.

ASTHMA

General aspects

Asthma is common, affecting 2–5% of the overall population; it is on the increase, particularly in childhood, with a frequency of up to 20% in some high-income countries. Asthma usually begins in childhood or early adult life; about half the patients with asthma develop it before age 10 years.

Fig. 15.4 Oxygen by mask in a patient with severe bronchospasm.

Fig. 15.5 Nasal catheter.

Bronchial hyper-reactivity causes reversible airway obstruction from smooth muscle constriction (bronchospasm), mucosal oedema and mucus hypersecretion. There are two main types, extrinsic (allergic) and intrinsic asthma (Table 15.2).

Extrinsic (allergic) asthma, the main childhood type, may be precipitated by allergens in animal dander, feathers or hair, drugs (e.g. non-steroidal anti-inflammatory drugs [NSAIDs] and some antibiotics), food (e.g. eggs, fish, fruit, milk, nuts), house dust (mite allergens) or moulds. Patients frequently have or develop other allergic diseases, such as eczema, hay fever and drug sensitivities. Extrinsic asthma is associated with IgE overproduction on allergen exposure, and release of mast cell mediators (histamine, leukotrienes, prostaglandins, bradykinin and platelet activating factor), which cause bronchospasm and oedema. About 75% of asthmatic children lose their asthma or improve by adulthood.

Intrinsic asthma is usually of adult onset and not allergic, but appears rather to be related to mast cell instability and

Table 15.2 Types of asthma		
	Extrinsic asthma	Intrinsic asthma
Frequency	Most common	Least common
Aetiopathogenesis	Allergens causing IgE-mediated mast cell degranulation	Mast cell instability and airway hyper-responsivity
Association with atopy	+	–
Typical age of onset	Child	Adult

airway hyper-responsivity. Triggers include emotional stress, gastro-oesophageal reflux or vagally mediated responses.

Either type of asthma can be triggered by: infections (especially viral, mycoplasmal or fungal); irritating fumes (e.g. traffic or cigarette smoke); exercise (possibly due to cold air); weather changes; emotional stress; foods (e.g. nuts, shellfish, strawberries or milk) or additives (such as tartrazine); and drugs (e.g. aspirin and other NSAIDs, beta-blockers and angiotensin-converting enzyme inhibitors [ACEIs]).

Clinical features

In well-controlled patients with asthma, clinical features may be absent. During an asthmatic episode, symptoms may include dyspnoea, cough and paroxysmal expiratory wheeziness with laboured expiration. The frequency and severity of attacks vary widely between individuals (Table 15.3). Patients may become distressed, anxious and tachycardic, have reduced chest expansion and be using accessory respiratory muscles to increase their ventilatory effort. Nasal polyps are common, especially in aspirin-sensitive asthmatics. Children with asthma initially suffer from repeated ‘colds’ with cough, malaise and fever, often at night.

Asthma is typically diagnosed when the patient has more than one of the following – wheeze, cough, difficulty breathing and chest tightness – particularly if these are frequent and recurrent; are worse at night and in the early morning; occur in response to, or are worse after, exercise or other triggers, such as exposure to pets, cold or damp air, or with emotions or laughter; or occur without an association with colds. There is often:

- a personal history of atopic disorder
- a family history of atopic disorder and/or asthma
- widespread wheeze, heard on chest auscultation
- a history of improvement in symptoms or lung function in response to adequate therapy.

A prolonged asthmatic attack, which is refractory to treatment, may lead to life-threatening *status asthmaticus* (persisting for more than 24 hours). Failure of the patient to complete a sentence, indrawing of the intercostal muscles, a rapid pulse, a silent chest and signs of exhaustion are suggestive of impending respiratory arrest.

General management

Diagnosis of asthma is from the clinical history and presentation, based on recognizing a characteristic pattern of episodic symptoms in the absence of an alternative explanation. Investigations include a chest radiograph (to exclude other diagnoses, such as a pneumothorax), spirometry (serial PEFR), skin tests and blood examination (usually eosinophilia, raised total IgE and specific IgE antibody concentrations, which may help identify allergens). Occasionally, a histamine or methacholine challenge is used if the diagnosis is unclear.

Table 15.3 Severity of asthma

Severity of asthma	Symptom duration	Attack frequency per week	Other comments	Typical therapy
Mild	<1 h	<2	Attacks follow exercise or exposure to trigger	Beta-agonist as required
Moderate	Days	>2	Activity restricted	Beta-agonist plus steroid
Severe	Persistent	Persistent	Audible wheezing. Tachypnoea. Activity and sleep severely restricted	Beta agonist plus steroid plus theophylline

Table 15.4 Medical management of asthma^a

Drug group	Examples	Comments
Beta-agonists	Selective β_2 -agonists or stimulants (e.g. salbutamol). Others include: Terbutaline, fenoterol, rimiterol Pirbuterol, reproterol, tulobuterol Bambuterol, salmeterol, formoterol	Safest and most effective bronchodilators for routine control of asthma Relax bronchial smooth muscle with little cardiac effect Act for 3–6 h Act for at least 12 h
Antimuscarinic bronchodilators	Ipratropium or oxitropium bromide	Useful particularly for those with asthma associated with bronchitis Act for up to 8 h Contraindicated in glaucoma and prostatic disease
Methylxanthines	Theophylline preparations (oral sustained release)	Prolonged action and useful for controlling nocturnal asthma
Corticosteroids	Corticosteroid (beclometasone, betametasone valerate, budesonide or fluticasone) aerosol inhalations	Effective inhaled along with a bronchodilator but must be taken regularly High-dose corticosteroid inhalants can cause some adrenal suppression
Mast cell stabilizers	Sodium cromoglicate or nedocromil	Occasionally used as inhalants for prophylaxis, mainly in children, but some fail to respond
Leukotriene receptor antagonists	Montelukast, zafirlukast	May impair liver function and increase INR
5-Lipoxygenase inhibitor (impairs leukotriene release)	Zileuton	Given orally Effective when used alone or with inhaled steroids but may precipitate, and should not be used in Churg–Strauss syndrome, where deterioration and cardiac complications may be seen
Recombinant humanized monoclonal anti-immunoglobulin E (IgE) antibody	Omalizumab	Safe, effective treatment for allergic asthma

^aIn addition to oxygen.

In children with an intermediate probability of asthma, who can perform spirometry and have evidence of airways obstruction, assess the change in FEV₁ or PEF_R in response to an inhaled bronchodilator (reversibility) and/or the response to a trial of treatment for a specified period; if there is significant reversibility, or if a treatment trial is beneficial, a diagnosis of asthma is probable.

Management includes patient education, smoking cessation advice, avoidance of identifiable irritants and allergens, and use of drugs. Home use of peak flow meters allows patients to monitor progress and detect any deterioration that may require urgent modification of treatment. Treatment should be based on the amount by which peak flow is reduced (a PEF_R diary should be kept).

Drugs used for asthma management (Table 15.4) include oxygen, short-acting β_2 agonists (SABAs; such as salbutamol), corticosteroids, leukotriene receptor antagonists and omalizumab (a recombinant humanized monoclonal anti-IgE antibody that reduces the antigen-specific IgE).

Inhaled long-acting β_2 agonists (LABAs) may be needed (Fig. 15.6). Deaths from asthma are usually a result of failure to recognize deterioration or reluctance to use corticosteroids.

Other factors that have been studied include:

- **air pollution** – There is an association between air pollution and aggravation of existing asthma
- **allergen avoidance** – There is no consistent evidence of benefit
- **breast-feeding** – There is evidence of a protective effect in relation to early asthma
- **electrolytes** – There is no consistent evidence of benefit
- **fish oils and fatty acid** – There is no consistent evidence of benefit
- **house dust mites** – Measures to reduce the numbers of house dust mites do not affect asthma severity
- **immunotherapy** – Allergen-specific immunotherapy is beneficial in allergic asthma
- **microbial exposure** – There is insufficient evidence to indicate that the use of probiotics in pregnancy reduces the incidence of childhood asthma
- **modified milk formulae** – There is no consistent evidence of benefit

Fig. 15.6 Inhaler.

- **nutritional supplementation** – There is limited, variable-quality evidence on the potential preventative effect of fish oil, selenium and vitamin E intake during pregnancy
- **pets** – There are no controlled trials on the benefits of removing pets from the home
- **tobacco** – Exposure to cigarette smoke adversely affects quality of life, lung function, need for rescue medications and long-term control with inhaled steroids. There is an association between maternal smoking and an increased risk of infant wheeze
- **weight reduction** – There is an association between increasing body mass index and symptoms of asthma.

Dental aspects

Elective dental care should be deferred in severe asthmatics until they are in a better phase; this can be advised by the patient’s general practitioner.

Asthmatic patients should be asked to bring their usual medication with them when coming for dental treatment. Local anaesthesia (LA) is best used; occasional patients may react to the sulphites present as preservatives in vasoconstrictor-containing LA, so it may be better, where possible, to avoid solutions containing vasoconstrictor. Adrenaline (epinephrine) may theoretically enhance the risk of arrhythmias with beta-agonists and is contraindicated in patients using theophylline, as it may precipitate arrhythmias.

Relative analgesia with nitrous oxide and oxygen is preferable to intravenous sedation and gives more immediate control. Sedatives in general are better avoided as, in an acute asthmatic attack, even benzodiazepines can precipitate respiratory failure.

GA is best avoided, as it may be complicated by hypoxia and hypercapnia, which can cause pulmonary oedema even if cardiac function is normal, and cardiac failure if there is cardiac disease. The risk of post-operative lung collapse or pneumothorax is also increased. Halothane

Box 15.1 Agents that may precipitate asthmatic attack

- Acrylic monomer
- Aspirin and other NSAIDs
- Barbiturates
- Beta-blockers
- Colophony
- Cyanoacrylates
- Histamine-releasing agents
- Mefenamic acid
- Opioids
- Pancuronium

- Suxamethonium
- Tubocurarine

Table 15.5 Management complications from anti-asthmatic drugs

Anti-asthmatic drug	Possible complications
β ₂ -agonists	Dry mouth
Corticosteroids	Steroid complications and adrenal crisis. Corticosteroid inhalers occasionally causes oral or pharyngeal thrush and, rarely, angina bullosa haemorrhagica
Ipratropium bromide	Dry mouth
Leukotriene antagonists	Bleeding tendency (and prolonged INR) because of impaired liver metabolism
Theophylline	Levels increased by epinephrine, erythromycin, clindamycin, azithromycin, clarithromycin or ciprofloxacin

or, better, enflurane, isoflurane, desflurane and sevoflurane are the preferred anaesthetics, but ketamine may be useful in children.

Allergy to penicillin may be more frequent in asthmatics. Drugs to be avoided, since they may precipitate an asthmatic attack (see later), include those listed in Box 15.1.

Acute asthmatic attacks may also occasionally be precipitated by anxiety; it is important to attempt to lessen fear of dental treatment by gentle handling and reassurance. Even routine dental treatment can trigger a clinically significant decline in lung function in approximately 15% of asthmatics. Acute asthmatic attacks are usually self-limiting or respond to the patient’s usual medication, such as a beta-agonist inhaler, but status asthmaticus is a potentially fatal emergency (Ch. 1). There may be complications caused by the anti-asthmatic drugs (Table 15.5).

Gastro-oesophageal reflux is not uncommon, with occasional tooth erosion. Periodontal inflammation is greater in asthmatics than in those without respiratory disease. Persons using steroid inhalers may develop oropharyngeal candidosis or, occasionally, angina bullosa haemorrhagica.

Guidelines on the management of asthma may be found at: <http://www.sign.ac.uk/guidelines/fulltext/101/index.html>, <http://www.nice.org.uk/guidance/qualitystandards/indevelopment/Asthma.jsp> and <http://www.brit-thoracic.org.uk/Portals/0/Guidelines/AsthmaGuidelines/qrg101%202011.pdf> (all accessed 30 September 2013).

Box 15.2 Features of Churg–Strauss syndrome

- Asthma
- Eosinophilia >10%
- Extravascular eosinophils
- Mono- or polyneuropathy
- Pulmonary infiltrates (non-fixed)
- Paranasal sinus abnormality

CHURG–STRAUSS SYNDROME (ALLERGIC GRANULOMATOSIS OR ANGIITIS)**General aspects**

Churg–Strauss syndrome (CSS) is a rare, potentially fatal, systemic vasculitis similar to polyarteritis nodosa (PAN), characterized by severe asthma-like attacks with peripheral eosinophilia, and intravascular and extravascular granuloma formation with eosinophil infiltration and skin lesions in 70%. Cardiopulmonary involvement is the main cause of death.

Clinical features

CSS is diagnosed if at least 4 of the 6 criteria listed in [Box 15.2](#) are positive.

General management

The 5-year survival of untreated CSS is 25%. Combination treatment with cyclophosphamide and prednisolone (prednisone) provides a 5-year survival of 50%.

Dental aspects

Management problems relating to patients with CSS may include respiratory impairment and corticosteroid treatment (Ch. 6).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)**General aspects**

Chronic obstructive pulmonary disease (COPD; chronic obstructive airways disease, COAD) is a common, chronic, slowly progressive, irreversible disease (most frequently a combination of chronic bronchitis and emphysema), characterized by breathlessness and wheeze (airways obstruction), cough and sputum. *Chronic bronchitis* is defined as the excessive production of mucus and persistent cough with sputum production, daily for more than 3 months in a year over more than 2 consecutive years. It leads to production of excessive, viscous mucus, which is ineffectively cleared from the airway, obstructs and stagnates, and becomes infected, usually with *Streptococcus pneumoniae*, *Moraxella catarrhalis* and *Haemophilus influenzae*. Patchy areas of alveolar collapse can result. *Emphysema* is dilatation of air spaces distal to the terminal bronchioles with destruction of alveoli, reducing the alveolar surface area available for respiratory exchange. COPD is now the preferred term for conditions with airflow obstruction because of a combination of airway and parenchymal damage; patients were previously diagnosed as having chronic bronchitis or emphysema.

Table 15.6 Clinical features differentiating COPD and asthma

	COPD	Asthma
Smoker or ex-smoker	Nearly all	Possibly
Symptoms under age 35	Rare	Often
Chronic productive cough	Common	Uncommon
Breathlessness	Persistent and progressive	Variable
Night-time waking with breathlessness and/or wheeze	Uncommon	Common
Significant diurnal or day-to-day variability of symptoms	Uncommon	Common

Table 15.7 Additional investigations in suspected COPD

Investigation	Comments
Alpha ₁ -antitrypsin	If COPD has an early onset, or there is a minimal smoking history or positive family history
CT scan of thorax	To investigate symptoms that seem disproportionate to spirometric impairment To investigate chest radiograph abnormalities To assess suitability for GA and surgery
Echocardiogram	To assess cardiac status, if cor pulmonale is present
Electrocardiogram	To assess cardiac status, if cor pulmonale is present
Peak flow measurements (serial domiciliary)	To exclude asthma, if any diagnostic doubt
Pulse oximetry	To assess need for oxygen therapy, if cyanosis or cor pulmonale is present, or if FEV ₁ is <50% predicted
Sputum culture	To identify organisms, if sputum is persistently present and purulent
Transfer factor for carbon monoxide (T _L CO)	To investigate symptoms that seem disproportionate to spirometric impairment

COPD is characterized by airflow obstruction – defined as an FEV₁/FVC ratio reduced to less than 0.7. If FEV₁ is 80% or more, a diagnosis of COPD should only be made if there are respiratory symptoms (e.g. dyspnoea or cough). The airflow obstruction is not fully reversible, does not change significantly over months, and is usually progressive in the long term.

The most important causes of COPD include cigarette smoking, environmental pollution, dusts, chemicals or occupational exposures to various substances. Exposure to smoke from home cooking or heating fuels may contribute. Deficiency of the antiproteolytic enzyme alpha₁-antitrypsin is a rare cause of emphysema.

Clinical features

There is often significant airflow obstruction before the person is aware of it and so COPD typically remains undiagnosed until patients are in their fifties. Differentiation from asthma is important ([Table 15.6](#)).

A diagnosis of COPD should be considered in patients over the age of 35 who have a risk factor (e.g. smoking) and exertional breathlessness, chronic cough, regular sputum production, frequent winter ‘bronchitis’ or wheeze. Clinical judgment is based on history, physical examination, confirmation of airflow obstruction using spirometry (post-bronchodilator spirometry) and assessment of the severity of dyspnoea ([Tables 15.7 and 15.8](#)).

COPD is characterized by breathlessness and wheeze (airways obstruction), cough and an early morning mucoid sputum production.

Table 15.8 *MRC dyspnoea scale*

Grade	Degree of breathlessness related to activities
1	Not troubled by breathlessness except on strenuous exercise
2	Short of breath when hurrying or walking up a slight hill
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath when walking at own pace
4	Stops for breath after walking about 100 metres or after a few minutes on level ground
5	Too breathless to leave the house, or breathless when dressing or undressing

Adapted from Fletcher CM, et al. The significance of respiratory symptoms and the diagnosis of chronic bronchitis in a working population. *Br Med J* 1959; 2:257.

Table 15.9 *Comparison of chronic bronchitis and emphysema*

	Chronic bronchitis	Emphysema
Cough	Chronic	Minimal
Sputum	Copious and mucoid	Minimal
Infections	Common	Uncommon
Dyspnoea	Mild	Severe
PO_2	Low	Low
PCO_2	Raised	Normal
Forced expiratory volume (FEV)	Low	Low
Clinical appearance	Blue bloater	Pink puffer

Progressive dyspnoea, low oxygen saturation, carbon dioxide accumulation (hypercapnia) and metabolic acidosis mean that patients may ultimately become dyspnoeic at rest ('respiratory cripples'), especially when recumbent (orthopnoea), and eventually develop respiratory failure, pulmonary hypertension, right ventricular hypertrophy and right-sided heart failure (cor pulmonale).

Two clinical patterns of COPD are recognized:

- '*Pink puffers*' – patients with emphysema who manage to maintain normal blood gases by hyperventilation, and are always breathless but not cyanosed; rather they are pink from vasodilatation
- '*Blue bloaters*' – patients with chronic bronchitis who lose their CO_2 drive, fail to maintain adequate ventilation and become both hypercapnic and hypoxic with central cyanosis, cor pulmonale and oedema (for these patients, the respiratory drive is from the low PO_2 and thus oxygen administration is contraindicated) (Table 15.9).

General management

The diagnosis of COPD is based upon clinical history and presentation. Investigations include a chest radiograph (which may show hyperinflated lung fields with loss of vascular markings); arterial blood gases (which should be measured if pulse oximetry shows oxygen saturation less than 92%); spirometry; and lung function tests. FEV₁ is reduced in all cases (FEV₁ of less than 40% signifies severe COPD) and the flow–volume curve shows a typical pattern, with reduced flow rates at mid- and lower-lung volumes. A ratio of FEV₁:FVC of less than 70% confirms airways obstruction.

Patients with COPD and their family should be educated about the disease, and about required lifestyle changes and medication.

Non-drug therapy includes: stopping smoking (nicotine replacement therapy or bupropion may help); exercise by pulmonary rehabilitation – of proven benefit; weight loss (improves exercise tolerance); and vaccination (pneumococcal and influenza vaccines). Drug therapy includes short-acting bronchodilators (anticholinergic drugs [ipratropium bromide]) and β_2 agonists (salbutamol) to treat the reversible component of airway disease; corticosteroids (inhaled or systemic); and antibiotics (amoxicillin, trimethoprim or tetracycline). Mucolytics, such as carbocisteine, reduce acute exacerbations by almost one-third. Long-term oxygen therapy (LTOT) reduces mortality.

People with stable COPD who remain breathless or have exacerbations, despite using short-acting bronchodilators, should be offered the following as maintenance therapy:

- If FEV₁ is 50% of predicted or more: use either a long-acting β_2 agonist (LABA) or long-acting muscarinic antagonist (LAMA).
- If FEV₁ is less than 50% predicted: either a LABA with an inhaled corticosteroid (ICS) in a combination inhaler, or a LAMA.

Offer a LAMA in addition to a LABA plus ICS to people with COPD who remain breathless or have exacerbations, despite taking LABA plus ICS, irrespective of their FEV₁.

Provide pulmonary rehabilitation for all who need it; non-invasive ventilation (NIV) is the treatment of choice for persistent hypercapnic ventilatory failure during exacerbations not responding to medical therapy. The frequency of exacerbations should be reduced by appropriate use of inhaled corticosteroids and bronchodilators, and vaccinations.

Inhaled therapy

Bronchodilators (short-acting β_2 agonists [SABA] and short-acting muscarinic antagonists [SAMA]) should be the initial empirical treatment for the relief of breathlessness and exercise limitation. ICS have potential adverse effects (including non-fatal pneumonia) in people with COPD. Offer a once-daily LAMA in preference to four-times-daily SAMA to people with stable COPD who remain breathless or have exacerbations, despite using short-acting bronchodilators as required, and in whom a decision has been made to commence regular maintenance bronchodilator therapy with a muscarinic antagonist (see above).

Most patients – whatever their age – are able to acquire and maintain an adequate inhaler technique. Bronchodilators are usually best administered using a hand-held inhaler device (including a spacer device if appropriate).

Patients with distressing or disabling dyspnoea, despite maximal therapy using inhalers, should be considered for nebulizer therapy. They should be offered a choice between a face mask and a mouthpiece to administer their nebulized therapy, unless the drug specifically requires a mouthpiece (for example, anticholinergic drugs).

Oral therapy

Some patients with advanced COPD may require maintenance oral corticosteroids when these cannot be withdrawn following an exacerbation. These individuals should be monitored for the development of osteoporosis and given appropriate prophylaxis.

Theophylline should only be used after a trial of SABA and LABA, and only to those who are unable to use inhaled therapy, as there is a need to monitor plasma levels and interactions. The dose of theophylline prescribed should be reduced at the time of an exacerbation if macrolide or fluoroquinolone antibiotics (or other drugs known to interact) are given. There is insufficient evidence to recommend

prophylactic antibiotic therapy in the management of stable COPD. Mucolytic drug therapy should be considered in patients with a chronic cough productive of sputum.

Combined inhaled and oral therapy

If patients remain symptomatic on monotherapy, their treatment should be intensified by combining therapies from different drug classes, such as:

- β_2 agonist and theophylline
- anticholinergic and theophylline.

Oxygen

Long-term oxygen therapy (LTOT). Inappropriate oxygen therapy in people with COPD may depress respiration. LTOT is indicated in patients with COPD who have a PaO_2 of less than 7.3 kPa when stable, or a PaO_2 greater than 7.3 kPa and less than 8 kPa when stable, and one of: secondary polycythaemia, nocturnal hypoxaemia (oxygen saturation of arterial blood [SpO_2] of less than 90% for more than 30% of the time), peripheral oedema or pulmonary hypertension.

To reap the benefits of LTOT, patients should breathe supplemental oxygen for at least 15 hours per day. To ensure that all those eligible for LTOT are identified, pulse oximetry should be available in all health-care settings. The assessment of patients for LTOT should comprise the measurement of arterial blood gases on two occasions at least 3 weeks apart in patients who have a confident diagnosis of COPD, who are receiving optimum medical management and whose COPD is stable.

Patients should be warned about the risks of fire and explosion and told not to smoke when using oxygen.

Ambulatory oxygen therapy. Ambulatory oxygen therapy should be considered in patients on LTOT who wish to continue oxygen therapy outside the home, and who have exercise desaturation, are shown to have an improvement in exercise capacity and/or dyspnoea with oxygen, and are motivated to use oxygen.

Non-invasive ventilation (NIV). Adequately treated patients with chronic hypercapnic respiratory failure who have required assisted ventilation during an exacerbation, or who are hypercapnic or acidotic on LTOT, should be referred to a specialist centre for consideration of long-term NIV. Advanced emphysema is occasionally treated with surgery – excision of large acquired bullae or, rarely, lung transplantation.

Dental aspects

Patients with COPD who need dental care can be classified as follows:

- Patients at low risk – experience dyspnoea on effort but have normal blood gas levels. These patients can receive all dental treatment with minor modifications.
- Patients at moderate risk – experience dyspnoea on effort, are chronically treated with bronchodilators or recently with corticosteroids, and PaO_2 lowered. A medical consultation is advised to determine the level of control of the disease before any dental treatment.
- Patients at high risk – have symptomatic COPD that may be end-stage and poorly responsive to treatment. With these patients, a medical consultation is essential before any dental treatment is carried out.

Patients with COPD are best treated in an upright position at mid-morning or early afternoon, since they may become increasingly

dyspnoeic if laid supine. It may be difficult to use a rubber dam, as some patients are mouth-breathers and not able to tolerate the additional obstruction. LA is preferred for dental treatment, but bilateral mandibular or palatal injections should be avoided. Patients with COPD should be given relative analgesia only if absolutely necessary, and only in hospital after full preoperative assessment. CS with diazepam and midazolam should not be used, as benzodiazepines are respiratory depressants. Patients should be given GA only if absolutely necessary, and intravenous barbiturates are contraindicated. Secretions reduce airway patency and, if lightly anaesthetized, the patient may cough and contaminate other areas of the lung.

Postoperative respiratory complications are more prevalent in patients with pre-existing lung diseases, especially after prolonged operations and if there has been no preoperative preparation. The most important single factor in preoperative care is cessation of smoking for at least 1 week preoperatively. Respiratory infections must also be eradicated; sputum should first be sent for culture and sensitivity, but antimicrobials such as amoxicillin should be started without awaiting results.

The medical management of COPD should be optimized prior to surgery. The ultimate clinical decision about whether or not to proceed with surgery should rest with a consultant anaesthetist and consultant surgeon, taking account of co-morbidities, functional status of the patient and necessity for the surgery.

Composite assessment tools, such as the American Society of Anesthesiologists (ASA) scoring system, and not just lung function, are the best criteria for the assessment of patients with COPD before surgery. Those taking corticosteroids should be treated with appropriate precautions (Ch. 6). Interactions of theophylline with other drugs, such as adrenaline (epinephrine), erythromycin, clindamycin, azithromycin, clarithromycin or ciprofloxacin, may result in dangerously high levels of theophylline. Ipratropium can cause dry mouth.

Guidelines for the management of COPD may be found at: <http://publications.nice.org.uk/chronic-obstructive-pulmonary-disease-cg101> (accessed 30 September 2013).

INFECTIONS

General aspects

Respiratory viruses usually spread by touch or airborne transmission and the very small particles (2–0.2 micrometres) can avoid the upper respiratory tract defences and the mucociliary elevator to reach the lung alveoli. A range of viruses can cause lower respiratory tract infections (LRTIs; Table 15.10). Some viruses (e.g. influenza and respiratory syncytial) can spread from the upper to the lower respiratory tract via infection of the respiratory epithelium and can lead to bacterial superinfection and pneumonitis (pneumonia). Mycoplasmal (atypical) pneumonia and tuberculosis (TB) may be direct infections. Epidemics of a potentially fatal severe acute respiratory syndrome (SARS) have been caused by a coronavirus that originated in China and spread worldwide; H5N1 bird influenza also arose as an epidemic; and a similar epidemic, but of swine influenza (H1N1), emanated from Mexico (see later).

Bacterial infections, such as pneumonia or lung abscess, can also result from material aspirated into the lungs, and are usually unilateral. Those who aspirate more than others have, as a result, more frequent LRTI and this is seen in alcohol and other drug abusers, as well as comatose patients. Exogenous penetration and contamination

Table 15.10 Lower respiratory tract infections and their main causes^a

Condition	Microorganisms
Laryngo-tracheo-bronchitis (croup)	Influenza viruses <i>Mycoplasma pneumonia</i> Para-influenza viruses Respiratory syncytial virus
Acute bronchiolitis	Human metapneumovirus (HMPV) Influenza viruses Respiratory syncytial virus
Acute bronchitis	Adenovirus <i>Bordetella pertussis</i> <i>Chlamydia pneumoniae</i> (Taiwan acute respiratory [TWAR] agent) Coronaviruses Coxsackie virus <i>Haemophilus influenzae</i> (non-typeable) Herpes simplex virus Influenza viruses <i>Moraxella catarrhalis</i> <i>Mycoplasma pneumonia</i> Para-influenza virus Respiratory syncytial virus Rhinovirus
Acute pneumonitis (pneumonia)	<i>Escherichia coli</i> <i>Haemophilus influenza</i> <i>Klebsiella</i> species <i>Pseudomonas aeruginosa</i> Severe acute respiratory syndrome-associated coronavirus (SARS-CoV) <i>Streptococcus pneumoniae</i> (pneumococcus)

^aThe most frequent are shown in bold.

of the lung can result from trauma (e.g. a stab wound or road traffic accident) or surgery. *Entamoeba histolytica* can occasionally cause pneumonia – by direct extension from an amoebic liver abscess (Table 15.11). Patients with endocarditis, or septic pelvic or jugular thrombophlebitis, may experience LRTI acquired haematogenously and then it is often bilateral.

Immunocompromised persons (e.g. those with human immunodeficiency virus/acquired immune deficiency syndrome [HIV/AIDS] and transplant recipients) and people with bronchiectasis or cystic fibrosis are also susceptible to respiratory infections by a range of opportunistic microbes. *Pneumocystis jiroveci* (*P. carinii*), for example, is a common cause of potentially fatal pneumonia in immunocompromised patients – especially those with HIV/AIDS (Chs 20 and 21).

Clinical features

Clinical features of LRTI vary according to the part of the respiratory tract mainly affected:

- *Bronchiolitis* causes rapid respiration, wheezing, fever and dyspnoea – but is restricted mainly to infants.
- *Bronchitis* causes cough, wheezing and sometimes dyspnoea.
- *Pneumonia* causes cough, fever, rapid respiration, breathlessness, chest pain, dyspnoea and shivering.

Table 15.11 Causes of pneumonia

Infective route	Microorganisms
Inhalation	<i>Streptococcus pneumoniae</i> , <i>Streptococcus pyogenes</i> <i>Mycobacteria</i> , <i>Legionella</i> , <i>Coxiella burnetii</i> (Q fever) Influenza, measles virus, adenovirus <i>Coccidioides</i> , <i>Histoplasma</i> , <i>Cryptococcus</i>
Aspiration	Anaerobes, <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> , Gram-negative bacilli
Haematogenous spread	<i>Staphylococcus aureus</i> , Gram-negative bacilli (<i>Pseudomonas aeruginosa</i>) <i>Candida</i> <i>Strongyloides</i> , <i>Ascaris</i>
Contiguous spread	Anaerobes, Gram-negative bacilli <i>Entamoeba histolytica</i>
Reactivation	<i>Mycobacteria</i> Cytomegalovirus <i>Coccidioides</i> , <i>Histoplasma</i> , <i>Blastomyces</i> <i>Toxoplasma</i> , <i>Strongyloides</i> , <i>Pneumocystis jiroveci</i> (<i>P. carinii</i>)

General management

Antimicrobial therapy is indicated, particularly for pneumonia. Antivirals have not been highly effective. Oxygen may be needed. Pneumococcal vaccine is indicated for older people.

Dental aspects

The majority of LRTIs are severe illnesses, and are contraindications to all but emergency dental treatment. GA is hazardous and absolutely contraindicated. Dental treatment should be deferred until recovery, or be limited to pain relief.

INFLUENZA ('FLU)

Influenza is mainly a community-based infection transmitted in households and communities. Health-care-associated influenza infections can arise in any health-care setting, most commonly when influenza is also circulating in the community.

General aspects

Influenza is a contagious disease caused by influenza virus types A, B or C. Type A has two main subtypes (H1N1 and H3N2); it causes most of the widespread influenza epidemics and can occasionally be fatal. Type B viruses generally cause regional outbreaks of moderate severity, and type C viruses are of minor significance.

A person can spread influenza starting 1 day before they feel sick and for another 3–7 days after symptoms start. Influenza can be prevented or ameliorated by vaccination each autumn; this is especially indicated for older people and those with cardiorespiratory disease.

Clinical features

Influenza attacks virtually the whole respiratory tract; symptoms appear suddenly after 1–4 days and include fever, sore throat, nasal congestion, headache, tiredness, dry cough and muscle pains (myalgia).

Most people recover in 1–2 weeks but infection can be life-threatening, mainly because primary influenzal viral pneumonia can lead to secondary bacterial pneumonia or can exacerbate underlying conditions (e.g. pulmonary or cardiac disease). The old and very young, and those with chronic disorders, are more likely to suffer complications, such as pneumonia, bronchitis, sinusitis or otitis media. Influenza has also been followed by depression, encephalopathy, myocarditis, myositis, pericarditis, Reye syndrome and transverse myelitis.

General management

Rest, maintenance of fluid intake, analgesics, antipyretics, and avoidance of alcohol and tobacco help relieve symptoms. Aspirin must *never* be given to children under the age of 16 years who have 'flu-like' symptoms, and particularly fever, as this can cause Reye syndrome.

Zanamivir (an antiviral that works against influenza types A and B) can shorten the symptoms by approximately 1 day, if treatment is started during the first 2 days of illness. Other antiviral drugs include amantadine, oseltamivir and rimantadine; they may be helpful but their use is restricted mainly to immunocompromised persons, since they can cause adverse effects.

Dental aspects

Influenza can be a severe contagious illness so all but emergency dental treatment should be deferred until recovery. GA is hazardous and absolutely contraindicated.

Bird 'flu

Influenza type A subtype H5N1 can cause an illness known as 'avian influenza' or 'bird 'flu' in birds, humans and many other animal species. HPAI A(H5N1) – 'highly pathogenic avian influenza virus of type A of subtype H5N1' – is the causative agent and is enzootic in many bird populations, especially in South-East Asia. It has spread globally and resulted in the deaths of over 100 people and the slaughter of millions of chickens. A vaccine that could provide protection (Prepandrix) has been cleared for use in the European Union. H5N7 is a more recent emergent infection, similar in many respects.

Swine 'flu

Swine influenza is common in pigs in the midwestern United States, Mexico, Canada, South America, Europe (including the UK, Sweden and Italy), Kenya, China, Taiwan, Japan and other parts of eastern Asia. Transmission of swine influenza virus from pigs to humans is not common, but can produce symptoms similar to those of influenza. A 2009 outbreak in humans ('swine 'flu') was due to an apparently new strain of H1N1 arising from a reassortment produced from strains of human, avian and swine viruses. It can pass from human to human. Antiviral agents such as oseltamivir may help. Vaccines are now available.

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

General aspects

An outbreak of a life-threatening febrile respiratory infection appeared in 2003, originating from Guangdong, China, and was named severe acute respiratory syndrome (SARS). Caused by a newly recognized coronavirus (SARS-associated coronavirus, SARS-CoV), SARS spread via close contact to many countries across the world. According to the

World Health Organization, 8437 people worldwide became sick with SARS during the course of the first recognized outbreak and 813 died.

Clinical features

The incubation period of 2–7 days is followed by a high fever (above 38.0°C), malaise, headache and myalgia. Some people also experience mild upper respiratory symptoms and, after 2–7 days, lower respiratory signs – a dry cough and dyspnoea, potentially progressing to hypoxaemia. SARS can cause a pneumonia with a mortality approaching 10%, particularly in older or immunocompromised people.

General management

Artificial ventilation has been needed in 10–20% of cases. Antiviral agents, such as oseltamivir or ribavirin, may help. Inactivated vaccines, virally and bacterially vectored vaccines, recombinant protein and DNA vaccines, as well as attenuated vaccines, are under development.

Dental aspects

SARS is a severe illness, and all but emergency dental treatment should be deferred until recovery. GA is hazardous and absolutely contraindicated. For all contact with suspect SARS patients, careful hand hygiene is important, including hand-washing with soap and water; if hands are not visibly soiled, alcohol-based handrubs may be used as an alternative to hand-washing. If a suspected SARS patient is admitted to hospital, infection control personnel should be notified immediately. Infection control measures (www.cdc.gov/ncidod/hip/iso-lat/isolat.htm; accessed 30 September 2013) should include standard precautions (e.g. hand hygiene): health-care personnel should wear eye protection for all patient contact; contact precautions (e.g. gown and gloves for contact with the patient or their environment); and airborne precautions (e.g. an isolation room with negative pressure relative to the surrounding area and use of an N-95 filtering disposable respirator for persons entering the room).

BACTERIAL PNEUMONIA

General aspects

Pneumonia is classed as 'primary' if it occurs in a previously healthy individual, and is usually lobar; it is called 'secondary' if it follows some other disorder, such as previous viral respiratory infections, aspiration of foreign material, lung disease (bronchiectasis or carcinoma), depressed immunity (e.g. alcoholism or immunosuppression), or aspiration of oral bacteria (Table 15.12). It is usually bronchopneumonia.

Community-acquired pneumonia is often associated with *Streptococcus pneumoniae* or *Haemophilus influenzae* but Enterobacteriaceae, such as *Klebsiella* species, *Escherichia coli* and *Pseudomonas aeruginosa*, are especially likely in the very old and infirm (Table 15.13). Poor oral hygiene and periodontal disease may promote oropharyngeal bacterial colonization. Early on, hospital-acquired pneumonia is often associated with *Strep. pneumoniae* or *H. influenzae*. In late hospital-acquired pneumonia, polymicrobial infections or methicillin-resistant *Staphylococcus aureus* (MRSA) are particular hazards.

Clinical features

Pneumonia causes cough, fever, rapid respiration, breathlessness, chest pain, dyspnoea and shivering. Complications can include lung abscess or empyema (pus in pleural cavity).

Table 15.12 Factors predisposing to pneumonia

Exogenous	Endogenous
Viral respiratory infections, particularly influenza	Old age
Suppression of the cough reflex	Immobility
Aspiration of foreign material	Respiratory depression or chest injury
Mortality in patients in intensive care units (ventilator-associated pneumonia; VAP) – can range from 20% to 50%	Neurological disorders permitting aspiration of foreign material
Prolonged endotracheal intubation (increases risk by up to 20-fold)	Underlying pulmonary disease, such as carcinoma or emphysema
	Alcoholism
	Immunodeficiency (especially HIV/AIDS)
	<i>Pneumocystis jiroveci</i> (carinii) pneumonia – Chs 20 and 21

Table 15.13 Main causes of bacterial pneumonia

Pathogen	Comments
<i>Chlamydia pneumoniae</i>	Seen in persons in institutions
<i>Chlamydia psittaci</i>	Seen after contact with psittacine birds (parrots, etc.)
<i>Coxiella burnetii</i>	Seen after contact with farm animals
Gram-negative anaerobes	Seen after aspiration
<i>Haemophilus influenzae</i>	Seen at extremes of life
<i>Klebsiella pneumoniae</i>	Seen in the elderly and debilitated, and in nursing homes
<i>Legionella pneumoniae</i>	Seen after exposure to water aerosols
<i>Mycoplasma pneumoniae</i>	Epidemics every 4 years
<i>Staphylococcus aureus</i>	Follows influenza
<i>Streptococcus pneumoniae</i>	Most common pathogen

General management

It is important to avoid alcohol and tobacco, but use analgesics and antipyretics to relieve the symptoms. Broad-spectrum antimicrobials given promptly and empirically usually include a macrolide (azithromycin, clarithromycin or erythromycin), quinolone (moxifloxacin, gatifloxacin or levofloxacin), or doxycycline for outpatients. For inpatients, cefuroxime or ceftriaxone plus a macrolide is used.

Prophylaxis includes immunization against influenza and pneumococci.

Dental aspects

Pneumonia is a severe illness and all but emergency dental treatment should be deferred until recovery. GA is hazardous and absolutely contraindicated.

Ventilator-associated pneumonia (VAP) is discussed later.

LEGIONELLOSIS

General aspects

Legionellosis is a bacterial respiratory infection caused by one of the family Legionellaceae, Gram-negative aerobic bacilli, ubiquitous in water and soil but particularly preferring warm aquatic environments. The term Legionnaire's disease was coined as a result of an outbreak of the previously unrecognized respiratory disease in an American Legion meeting in Philadelphia in 1976, but it is now recognized

Table 15.14 Differentiation of Legionnaire's disease from Pontiac fever

	Legionnaire's disease	Pontiac fever
Isolation of bacterium	+	–
Incubation period	2–14 days	24–48 h
Percentage of persons who, when exposed to the source of an outbreak, become ill	<5%	>90%
Clinical features	Pneumonia: cough, fever, chest pain	'Flu-like illness (fever, chills, malaise) without pneumonia
