Radiographic pneumonia	+	–
Case-fatality rate (%)	5–80	~0

worldwide, many infections being contracted during travel abroad, particularly to Spain, Turkey and some other Mediterranean areas.

Legionella bacteria can be found in natural freshwater environments, usually in insufficient numbers to cause disease. *Legionella* grow best in warm water, as in hot tubs, cooling towers, hot water tanks, large plumbing systems, or the air-conditioning systems of large buildings. Though there are over 30 Legionellaceae, most infections are caused by *Legionella pneumophila*. Disease is contracted by inhalation of contaminated mist or vapour, mainly (approximately 46%) through aerosolization of infected water in air-conditioning systems, hot-water systems, humidifiers, nebulizers, showers and spa pools. Outbreaks have mostly been linked to aerosol sources in the community, cruise ships and hotels, with the most likely sources being whirlpool spas, air-conditioning units in large buildings, potable (drinking) water systems, and water used for bathing. Risk factors include:

- exposure to:
 - recent travel with an overnight stay outside of the home (outbreaks of travel-associated legionellosis are infrequently identified but more than 20% of cases are thought to be associated with recent travel)
 - whirlpool spas
 - recent repairs or maintenance work on domestic plumbing
- systemic ill-health:
 - alcohol use
 - chronic kidney disease
 - diabetes
 - immune defects
 - liver disease
 - malignancy
 - smoking.

Illness mainly affects males over 45, smokers, heavy drinkers, older people and the immunocompromised. Also vulnerable are travellers, especially middle-aged and older tourists, and conference or business groups, possibly because of tiredness or age. Many young people have been exposed to infection and become seropositive, but remained healthy.

There is no evidence of person-to-person transmission of legionellosis.

Clinical features

Legionellosis manifests as one of two clinical syndromes (Table 15.14). *Legionnaire's disease* is typically a lobular type of pneumonia, which

Table 15.15 Sensitivity and specificity of *Legionella* diagnostic tests

Test	Sensitivity (%)	Specificity (%)
Culture	80	100
Urine antigen	70	100
Paired serology ^a	70–80	>90
Direct fluorescent antibody stain	25–75	95

^aA single antibody titre of any level is not diagnostic of legionellosis.

can be fatal but is fortunately rare; infection can range from discrete patches of inflammation and consolidation to involvement of whole lobes. *Pontiac fever* is milder and usually subsides rapidly, often without treatment.

People who should be tested for Legionnaire's disease include those with pneumonia in the following groups:

- Hospitalized patients with enigmatic pneumonia
- Patients who require care in an intensive care unit
- Compromised hosts
- Individuals who contract disease in the setting of a legionellosis outbreak
- Those who fail to respond to a beta-lactam or cephalosporin
- Patients who have travelled away from home within the preceding 2 weeks.

Because *Legionella* is commonly found in the environment, clinical isolates are necessary to interpret the findings of an environmental investigation. Diagnosis can be by rapid urine molecular testing for *L. pneumophila* antigen, and culture of respiratory secretions on selective media. Sensitivity and specificity of the diagnostic tests are shown in Table 15.15.

General management

Pontiac fever is a self-limited illness; most cases recover within 1 week and few benefit from antibiotic treatment. Overall mortality in Legionnaire's disease may be as high as 10%, and over 25% in older people and up to 80% in the immunocompromised. Erythromycin is standard treatment; cephalosporin is an alternative.

Dental aspects

Legionella species are present in roughly two-thirds of potable water samples collected from domestic and institutional taps and drinking fountains, and from a similar percentage of dental units, but water from these dental units often has higher bacterial concentrations (Ch. 31). There are reports of *Legionella* infections in dental unit water lines, and antibodies and occasionally frank infection demonstrated in dental staff; at least one patient appears to have contracted and died from infection emanating from a dental practice.

Prevention is crucial, involving (Ch. 31):

- continuous circulation water systems
- independent water reservoirs
- flushing lines
- regular disinfection of waterlines, handpieces and power scalers
- waterline filters
- regular water quality testing.

Further information on infection control measures is available at: <http://www.legendellacontrol.com/legionella-control-association.htm> (accessed 30 September 2013).

TUBERCULOSIS (TB)

General aspects

Tuberculosis (TB), an infection caused by mycobacteria, affects approximately one-third of the world's population (1.5 billion people); it is a major global health problem, some 2 million people dying from it annually. TB disproportionately affects the poorest persons in both high-income and developing countries. In high-income countries, most human TB arises from *Mycobacterium tuberculosis*, transmitted from person to person through the air. TB usually affects the lungs initially (pulmonary TB) but can also involve brain, kidneys, spine and other parts. From Victorian times to about the Second World War, *Mycobacterium bovis* infection from infected cows' milk (bovine or bTB) was a major cause of morbidity and mortality; it was clinically and pathologically indistinguishable from infection caused by *M. tuberculosis*. Cattle-testing and a slaughter programme became compulsory in 1950 and, by the 1980s, the incidence of TB in cattle had been substantially reduced. Tuberculosis from *M. bovis* in cows' milk was virtually eliminated in high-income countries by the tuberculin testing of cattle and pasteurization of milk. In the developing world, many cattle still have TB, and bTB is still seen. bTB has also increased in high-income countries over the last two decades and an infection rate of up to 38% in badgers – and transmission to cattle – may explain this.

TB is not spread by touch or by drinking glasses, dishes, sheets or clothing. It is usually transmitted by infected sputum, typically from close contacts such as family members, but is unlikely to be transmitted between normal social contacts. TB can present an occupational risk to health-care professionals, including dental staff. One outbreak of drug-resistant TB in New York involved at least 357 patients, most of whom contracted TB in one of 11 hospitals; nearly 90% of the patients were also HIV-positive, and most were young males of Hispanic or African heritage. TB has been transmitted between passengers during long-haul airline flights. The risk of transmitting TB though air circulation is now low because the high-efficiency particulate air (HEPA) filters on newer commercial aircraft are of the same type as those used in hospital respiratory isolation rooms; indeed, the number of times air is cleaned each hour exceeds the recommendation for hospital isolation rooms.

Sub-Saharan Africa has the highest rates of active TB per capita, driven primarily by the HIV epidemic. The absolute number of cases is highest in Asia, with India and China having the greatest burden of disease globally. In the USA and most Western European countries, the majority of cases occur in foreign-born residents and recent immigrants from countries in which tuberculosis is endemic. Immunocompromised people – such as diabetics and severely immunodeficient patients, like those with HIV/AIDS (about 30% of South Africans with HIV/AIDS also have TB) – and patients in prisons or institutions are at risk. TB also mainly affects medically neglected persons, such as vagrants, alcoholics, intravenous drug abusers or older homeless people. The main groups at increased risk for infection therefore include people who are resource-poor or immunoincompetent, especially:

- alcoholics
- older people
- people with cancer, diabetes mellitus, HIV/AIDS or liver disease
- people taking immunosuppressive or biological agents
- young children.

TB in developing countries is particularly widespread and is increasing, the highest rises in incidence being in South-East Asia, sub-Saharan Africa and Eastern Europe. In high-income countries,

Table 15.16 Tuberculosis: differentiation of latent and active infections

	Latent	Active
Mycobacteria present	+	+
Mycobacteria active	–	+
Contagious	–	+
Symptoms	–	+
Mantoux test	+	+
Chest radiograph	Normal	Abnormal
Sputum culture	–	+

the incidence is also rising, probably because of worsening social deprivation, homelessness, immigration, HIV infection and intravenous drug abuse. It is now as common in London as in the developing world, and is seen especially in immigrants, such as those from the Indian subcontinent, Africa and South Asia. This increase appears to be a result of the development of TB disease in individuals who may have been infected for some time and of new infections acquired in the UK, or as a result of travel to other countries where TB is common. London accounted for the highest proportion of cases in the UK in 2011 (39%), followed by the West Midlands region (11%); 74% of these were born outside the UK and mainly originated from South Asia and sub-Saharan Africa. In 2011, there was a rise in the number of TB cases compared to 2010, as well as an increase in drug resistance.

More information on TB, including statistics, can be found at: <http://www.hpa.org.uk/Publications/InfectiousDiseases/Tuberculosis/> and <http://www.tbfacts.org/tb-statistics.html> (both accessed 30 September 2013).

Clinical features

Initial infection with TB is usually subclinical. About 10% of those infected develop overt disease; of these, half will manifest within 5 years (primary TB), while the remainder will develop post-primary disease. Inhaled mycobacteria may cause subpleural lesions (primary lesion) and lesions in the regional lymph nodes (primary complex). Body defences usually localize the mycobacteria, though these remain viable; infected persons are not obviously ill and are unlikely to know they are infected (latent; Table 15.16). Latent TB infection (LTBI) usually becomes active only after many years, if body defences become weakened (Box 15.3). However, active TB can develop shortly after mycobacteria enter the body, if body defences are impaired such as in ageing, drug or alcohol abuse, or HIV/AIDS. Also, in massive infections, acute active TB can result, typically causing a chronic productive cough, haemoptysis, weight loss, night sweats and fever. Erythema nodosum may be associated. Extrapulmonary TB is less common; it may appear as glandular involvement in the neck or elsewhere, and is less infectious than pulmonary TB. Lymph node TB may lead to lymphadenopathy, caseation of the nodes and pressure symptoms – for example, on the bronchi.

Post-primary TB follows reactivation of an old primary pulmonary lesion and results in features ranging from a chronic fibrotic lesion to fulminating tuberculous pneumonia. The pulmonary lesions may extend and lead to a pleural effusion. Reactivation or progression of primary TB may also result in widespread haematogenous dissemination of mycobacteria – ‘miliary TB’. Multiple lesions may involve the central nervous system, bones, joints, and cardiovascular, gastrointestinal and genitourinary systems.

Box 15.3 Conditions in which tuberculosis may become activated

- Alcohol abuse
- Cancer
- Chronic kidney disease
- Diabetes
- Drug abuse
- Gastric bypass/gastrectomy
- HIV
- Immunosuppression
- Leukaemia
- Recent infection
- Silicosis
- Young age at infection

Clinical presentation in TB is thus variable, depending on the extent of spread and the organs involved. As it frequently passes unrecognized for so long, the mortality is high.

Similar illnesses to TB may also be caused by atypical (non-tuberculous) mycobacteria, such as *M. avium* complex (MAC; see below).

General management

The diagnosis of TB is suggested by the history and confirmed by physical examination, a massively raised erythrocyte sedimentation rate (ESR), positive tuberculin skin tests (TSTs; Mantoux or Heaf test for a delayed hypersensitivity reaction to protein from *M. tuberculosis* [purified protein derivative; PPD]) and chest imaging. Hypersensitivity develops with 2–8 weeks of infection and can be detected by conversion of the TST from negative to positive, but TSTs are neither 100% sensitive nor specific. A positive Mantoux reaction indicates previous immunization (BCG; bacille Calmette–Guérin – live attenuated *M. bovis*) or current infection – not necessarily disease. Chest radiography may show scarring and hilar lymphadenopathy. Computed tomography (CT) may show areas of calcification or highlight a tuberculous abscess. Smears and culture of sputum, blood, laryngeal swabs, bronchoalveolar lavage, gastric aspirates or pleural fluid may be tested for mycobacteria.

Polymerase chain reaction (PCR) techniques have greatly accelerated the diagnosis and speciation, though Ziehl–Neelsen, auramine or rhodamine microbial stains are still used. The mycobacteria growth indicator tube (MGIT) system gives results as early as 3–14 days. Blood assay for *M. tuberculosis* (BAMT) may be positive by interferon-gamma release assay (IGRA). Some 15% of people over 65 years have a positive IGRA. The IGRA can be used in place of (but not in addition to) TST. IGRAs measure the immune reactivity to *M. tuberculosis*. White blood cells from most persons that have been infected with *M. tuberculosis* will release interferon-gamma (IFN- γ) when mixed with *M. tuberculosis* antigens. A positive test result suggests that *M. tuberculosis* infection is likely; a negative result suggests that infection is unlikely.

Latent infection (LTBI) can be diagnosed with either a tuberculin skin test or an IGRA (more specific). IGRA gives a result within 24 hours and should be used biological therapy is given, such as for rheumatoid arthritis or inflammatory bowel disease. Prior BCG vaccination does not cause a false-positive IGRA test result. More information on the IGRA is available at: <http://www.cdc.gov/tb/publications/factsheets/testing/igra.htm> (accessed 30 September 2013).

Active TB is diagnosed by sputum microscopy and culture in liquid medium with subsequent drug-susceptibility testing. Nucleic acid

Table 15.17 Antitubercular therapy

Drug	Use	Main adverse effects
Ethambutol ^a	Initial therapy ^b	Ocular damage
Isoniazid	Initial therapy ^b	Peripheral neuropathy
	Continuation therapy ^c	Hepatotoxicity
Pyrazinamide	Initial therapy ^b	Hepatotoxicity
Rifampicin	Initial therapy ^b	Enhanced liver P450 drug-metabolizing enzymes
	Continuation therapy ^c	Red urine and saliva
		Bullous lesions
		Hepatotoxicity
		Nephrotoxicity
Streptomycin ^a	Initial therapy ^b	Vestibular nerve damage
		Circumoral paraesthesiae

^aIncreasing resistance.^bInitial therapy, usually = isoniazid + rifampicin + pyrazinamide or ethambutol for 2 months.^cContinuation therapy = isoniazid + rifampicin for 4 months.

amplification tests, imaging, and histopathological examination of biopsy samples help. IGRA and TSTs have no role in the diagnosis of active disease. A molecular diagnostic test now available in some high-income countries (Xpert MTB/RIF assay) detects *M. tuberculosis* complex within 2 hours, with a higher assay sensitivity than that of smear microscopy.

People who should be tested for TB include those who have symptoms, those who have had close day-to-day contact with active TB disease (family member, friend or co-worker), those who have HIV infection or AIDs, those with lowered immunity, those who are required to for employment or school, and those about to be treated with biological agents.

The top priority of TB control programmes is to identify and give complete treatment to all patients with active disease. TB is a notifiable disease and contact tracing is an important aspect of limiting spread. Treatment with antibiotics is indicated for people who are sick with TB, those infected but not sick, and those who are close contacts of infectious TB cases. Treatment for 'symptomatic sputum-positive' patients, which should be instituted as soon as possible, is combination chemotherapy, usually isoniazid plus rifampicin plus pyrazinamide or ethambutol for 2 months, with continuation of daily isoniazid and rifampicin for a further 4 months. Treatment for 'asymptomatic' patients who are believed to have been infected by contacts, but are not unwell, includes isoniazid for 6 months or isoniazid and rifampicin for 3 months. Rifapentine is a long-acting rifampicin used once weekly. Fluoroquinolones (moxifloxacin) may also act against TB. There may be resistance to one or more than one antibiotic.

Currently, given the potential risk of drug-resistant TB being present, treatment is usually started with isoniazid, rifampicin, pyrazinamide and ethambutol (or a quinolone such as gatifloxacin or moxifloxacin) for 2 months, then isoniazid and rifampicin for 4 months.

All antituberculous drugs (Table 15.17) have potentially serious adverse effects and require careful monitoring. If patient compliance is considered to be poor, directly observed therapy (DOT), where drugs are dispensed by and taken in the presence of a health-care professional, may be indicated. New drugs are on the horizon.

Immunization using BCG is advocated for schoolchildren, high-risk individuals and health-care professionals – although its efficacy has been questioned. New vaccines are in development.

Chemoprophylaxis with isoniazid and rifampicin is indicated in a number of situations (Box 15.4).

Box 15.4 Indications for tuberculosis (TB) chemoprophylaxis

- Previous inadequate treatment of TB
- Close contact with persons actively infected with TB
- Conversion of the tuberculin test within the past 2 years
- Biological therapy being considered
- A positive tuberculin test in the following groups:
 - Immunocompromised persons (diabetes, renal failure, cancer, HIV infection)
 - Persons under 35 years, or intravenous drug users
 - A foreign-born person who has migrated from a region of high prevalence within the previous 2 years

Drug-resistant TB (DR-TB)

TB can become resistant to the drugs used to treat it particularly when the drugs are misused or mismanaged. This may occur, for example, when:

- drugs are unavailable or of poor quality
- patients fail to complete the full treatment course
- health-care providers prescribe the wrong drugs, doses or length of treatment.

DR-TB is more common in people who:

- fail to take their TB drugs regularly or fail to take a complete course
- have recurrence of TB disease
- come from areas where DR-TB is common
- have spent time with someone who has DR-TB
- work in hospitals or health-care settings where DR-TB patients are seen.

More than 60% of DR-TB patients are in China, India, the Russian Federation, Pakistan and South Africa.

Multidrug-resistant TB (MDR-TB)

In some developing countries, approximately 10% of cases are multiple antibiotic-resistant; this is termed multidrug-resistant tuberculosis (MDR-TB); in the UK, only a small minority currently fall into this category but the number of cases is increasing. MDR-TB is defined as resistance to rifampicin and isoniazid; it may be atypical in presentation and the infection disseminates. More than 4% of people with TB worldwide have MDR-TB, and Eastern Europe has a high prevalence. MDR-TB is seen mainly in people with HIV/AIDS and in HIV/AIDS and in Africans. Bedaquiline, is a new anti-tubercular agent - the first active agent against tuberculosis to be registered since 1963.

Extensively drug-resistant TB (XDR-TB)

Extensively drug-resistant tuberculosis (XDR-TB) is a rare type of MDR-TB, not only resistant to isoniazid and rifampin, but also to any fluoroquinolone and at least one of three injectable second-line drugs (i.e. amikacin, kanamycin, or capreomycin). XDR-TB is of special concern for immunocompromised people (e.g. with HIV/AIDS), who are more likely to develop TB, and have a higher risk of death if they do develop it. XDR-TB is most often encountered in people from Eastern Europe, Russia and Africa. It has been transmitted in health-care facilities and is now seen worldwide. It is essentially untreatable, though capreomycin has been used effectively to treat MDR-TB in HIV-positive individuals.

Totally drug-resistant TB (TDR-TB or XXDR-TB)

Totally drug-resistant TB was reported initially in 2007–2009 in India, Iran and Italy; it is spreading, despite denials, and is most disquieting.

Fig. 15.7 Neck scarring from tuberculous lymphadenitis.

Dental aspects

Chronic ulcers, usually on the tongue dorsum, are the main oral manifestation of TB. They result from coughing of infected sputum from pulmonary TB, including in HIV-infected persons with TB, but are rare and such cases (usually middle-aged males) may result from neglect of symptoms or default from treatment. Occasionally, the diagnosis is made from biopsy of an ulcer after granulomas are seen microscopically. Acid-fast bacilli are rarely seen in oral biopsies, even with the help of special stains, so unfixed material should also be sent for culture if possible. Tuberculous cervical lymphadenopathy is the next most common form of the infection and is particularly common among those from South Asia. Most TB lymphadenitis is painless, with several enlarged, matted nodes, but systemic symptoms are present only in a minority and only about 15% have pulmonary manifestations on radiography (Fig. 15.7). Diagnosis relies on tuberculin testing, which can be positive in both tuberculous and non-tuberculous mycobacterial cervical lymphadenitis. Any person with lymphadenopathy and recent conversion from a negative to positive tuberculin test should be suspected of having mycobacterial infection, and this should prompt biopsy (e.g. fine-needle aspiration biopsy) for culture or histological confirmation. PCR will improve diagnosis, as culture must wait 4–8 weeks for a result. Oral complications of antitubercular therapy are rare, but rifabutin and rifampicin can cause red saliva.

Pulmonary TB is of high infectivity, as shown by cases of tuberculous infection of extraction sockets and cervical lymphadenitis in 15 patients treated by an infected member of staff at a dental clinic. Dental staff who themselves were HIV-positive, working in a dental clinic for HIV-infected persons in New York, have died from TB contracted occupationally. Transmission of MDR-TB between two dental workers may have occurred in an HIV dental clinic. Infection control is thus important, so staff with TB are usually precluded from their occupation until treated.

Management of a patient with TB depends upon the level of potential infectivity (Table 15.18). Patients with open pulmonary TB are contagious, and dental treatment is thus best deferred until the infection has been treated. Treatment with appropriate drugs for 2 weeks drastically reduces the infectivity of patients with pulmonary TB. If patients with open pulmonary TB must be given dental treatment, special precautions should be used to prevent the release of mycobacteria into the air, to remove any that are present and to stop their inhalation by other persons. Reduction of splatter and aerosols, by minimizing coughing and avoiding ultrasonic instruments, and use of a rubber dam, are important. Improved ventilation, ultraviolet germicidal light, new masks and personal respirators, and other personal protective devices,

Table 15.18 Dental management of patients with known or suspected tuberculosis (TB)

History of TB	Potential infectivity	Comment
Active sputum-positive TB	High	Urgent dental treatment only; use special infection control precautions.
Recent history of TB and sputum known to be positive for TB	High	Defer elective dental care until TB treatment complete
Past history of TB	Refer to physician; needs confirmation	Use special infection control precautions for emergency dental care
No history of TB but signs or symptoms suggestive		Defer elective dental care until medical advice received
No history of TB but positive tuberculin test		

Fig. 15.8 Respirator.

such as HEPA filters, are indicated (Fig. 15.8). Mycobacteria are very resistant to disinfectants, so that heat sterilization must be used.

LA is safe and satisfactory. Relative analgesia is contraindicated because of the risk of contamination of the apparatus. GA is also contraindicated for dental treatment because of the risk of contamination of the anaesthetic apparatus and because of impaired pulmonary function. Aminoglycosides, such as streptomycin, enhance the activity of some neuromuscular blocking drugs and in large doses may alone cause a myasthenic syndrome. Possible drug interactions are shown in Table 15.19.

Other factors, such as alcoholism or intravenous drug use (Ch. 34), hepatitis (Ch. 9) or HIV disease (Ch. 20), may also influence dental management.

ATYPICAL MYCOBACTERIA (NON-TUBERCULOUS MYCOBACTERIA, NTM; MYCOBACTERIA OTHER THAN TUBERCULOSIS; MOTT)

General aspects

Mycobacteria other than tuberculosis (MOTT) are widely distributed in water, soil, animals and humans, and rarely cause disease. Severe MOTT infections have been seen, however, in individuals predisposed because of defects in the interleukin-12 (IL-12) and interferon-gamma (IFN-gamma) pathways.

Mycobacterium abscessus, a bacterium found in water, soil and dust, has been known to contaminate medications and products, including

Table 15.19 Possible drug interactions in tuberculosis (TB)

Drug	May cause interactions with
Paracetamol (acetaminophen)	Isoniazid

Paracetamol (acetaminophen)	
Aspirin	Amikacin, capreomycin, kanamycin or streptomycin

Box 15.5 Mycobacteria other than tuberculosis

- *Mycobacterium abscessus*
- *M. avium*
- *M. chelonae*
- *M. fortuitum*
- *M. intracellulare* (*M. avium*–*intracellulare* complex; MAC)
- *M. kansasii*
- *M. marinum*
- *M. scrofulaceum*
- *M. ulcerans*
- *M. xenopi*

medical devices. Health-care-associated *M. abscessus* can cause a variety of infections, usually of the skin, but it can also cause lung infections in persons with various chronic lung diseases and is increasingly recognized as an opportunistic pathogen in *cystic fibrosis* (CF) patients

Person-to-person transmission of atypical mycobacteria is *not* important in acquisition of infection, except for skin infections. On rare occasions, MOTT skin infections have followed tattooing with contaminated tattoo inks. Many people become infected with and harbour MOTT in their respiratory secretions without any symptoms or evidence of disease. Individuals with respiratory disease from MOTT do *not* readily infect others and, therefore, do not need to be isolated. MOTT are generally not infectious to others.

Infection with *M. abscessus* is usually caused by injections of contaminated substances or by invasive medical procedures employing contaminated equipment or material. Infection can also occur after accidental injury where the wound is contaminated by soil. There is very little risk of transmission from person to person.

Clinical features

Atypical mycobacteria include *M. avium*, *M. intracellulare* (MAC) species and others (Box 15.5). *Mycobacterium avium* complex (comprising *M. avium* and *M. intracellulare*; MAC) can cause several different syndromes:

- In children, MAC most commonly cause cervical lymphadenitis.
- In non-immunocompromised adults, pulmonary disease is a result of infection with MAC.
- In immunocompromised adults, disseminated MAC infections may arise. An immune defect, underlying illness or tissue damage may result in disseminated MAC infection.

MAC complex, *M. scrofulaceum* and *M. kansasii* are possible causes of tuberculous cervical lymphadenitis. MAC may also infect the lungs (similar to TB), skin or lymph nodes. Lung disease is also caused occasionally by *M. kansasii*, mainly in middle-aged and older persons

with underlying chronic lung conditions. *M. fortuitum* and *M. chelonae* may cause skin and wound infections and abscesses, frequently associated with trauma or surgery. *M. marinum* may cause ‘swimming pool granuloma’, a nodular lesion that may ulcerate, usually on an extremity. *M. ulcerans* may produce chronic ulcerative skin lesions, usually of an extremity. *M. abscessus* skin infections present with swollen and/or painful areas that are usually red, warm and tender to the touch, and which can also develop into boils or pustules. Other features of *M. abscessus* infection are fever, chills, muscle aches and malaise.

General management and dental aspects

Cervical lymphadenitis due to MAC, *M. scrofulaceum* and *M. kansasii* may affect otherwise healthy young children, most commonly preschool females who have unilateral cervical lymphadenopathy, typically in the submandibular or jugulodigastric nodes, and they may form a ‘cold abscess’. MOTT is the usual cause in children under 12 years but TB is more common in older patients. Absence of fever or tuberculosis, a positive tuberculin test and failed response to conventional antimicrobials are highly suggestive of MOTT, but definitive diagnosis is by smear, culture or PCR of biopsy material obtained by fine-needle aspiration or removal of nodes.

Treatment is based on results of laboratory testing, which should identify the appropriate antibiotic. Preventive treatment of close contacts of persons with disease caused by MOTT is *not* needed. Most MOTT are resistant to standard antitubercular medication and, though it is possible that clarithromycin or clofazimine may have some effect, excision of affected nodes is the usual recommended therapy.

Water from dental units may contain MOTT species; mycobacterial proliferation in biofilms may explain the extent of this contamination (Ch. 31).

ASPIRATION SYNDROMES

Aspiration syndromes are conditions in which foreign substances are inhaled into the lungs and which can have consequences ranging from asphyxia to infection and lung abscess. Dental restorations or fragments of teeth, plaque, gastric contents and other materials may be aspirated, especially if material enters the pharynx, and particularly if the cough reflex is impaired for any reason.

Most commonly, aspiration syndromes involve oral or gastric contents associated with gastro-oesophageal reflux disease (GORD), swallowing dysfunction (Ch. 7), neurological disorders and structural abnormalities, such as a pharyngeal pouch. Cricopharyngeal dysfunction involves cricopharyngeal muscle spasm or achalasia of the superior oesophageal sphincter, and can be seen in infants who have a normal sucking reflex but have incoordination during swallowing, possibly secondary to delayed development or cerebral palsy. Anatomical disorders, such as cleft palate, pharyngeal pouch, oesophageal atresia, tracheo-oesophageal fistula, duodenal obstruction or malrotation, and motility disorders, such as achalasia, may have an aspiration risk. Infirm older patients are also at risk of aspiration, especially if they are bed-bound or have neurological disorders. Isolated superior laryngeal nerve damage, vocal cord paralysis, cerebral palsy, muscular dystrophy and Riley–Day syndrome (familial dysautonomia) are all associated with increased risk of aspiration.

VENTILATOR-ASSOCIATED PNEUMONIA (VAP)

Ventilator-associated pneumonia (VAP), as defined by the Centers for Disease Control and Prevention (CDC), is present when the

chest radiograph shows new or progressive infiltrate, consolidation, cavitation or pleural effusion in conjunction with either new onset of purulent sputum or change in character of sputum, and an organism isolated from blood, or the isolation of an aetiological agent from a specimen obtained via suction aspiration through an endotracheal or tracheostomy tube.

The major route for acquiring endemic VAP is oropharyngeal colonization by endogenous flora or by exogenously acquired pathogens from intensive care units. VAP is the most commonly reported health-care-acquired infection in patients receiving mechanical ventilation, with prevalence rates consistently in the 10–20% range. Mortality rates in VAP are at least double those in patients without VAP, ranging from 24% to 85% when the infection is caused by a multidrug-resistant Gram-negative pathogen.

The Healthcare Infection Control Practices Advisory Committee of the CDC has developed guidelines for the prevention of VAP. These include strategies aimed at preventing aspiration of contaminated oral or gastric material (e.g. raising the head of the bed and draining subglottic secretions), and interventions to alter bacterial colonization of stomach (e.g. stress ulcer prophylaxis and selective digestive decontamination) and mouth. Oral hygiene, suctioning and the provision of moisture to lips and oral mucosa, plus tooth-brushing, may be important in prevention of VAP. There are also strategies for managing ventilator circuits (e.g. replacement of ventilator circuits, use of closed rather than open suction, and use of heat moisture exchange as opposed to heated circuit technology).

LUNG ABSCESS

General aspects

Lung abscess is a localized infection leading to cavitation and necrosis. While some cases result from aspiration of foreign material, most develop from pneumonia caused by infection with *Staph. aureus* or *Klebsiella pneumoniae*. Bronchial obstruction by carcinoma is another important cause.

Clinical features

Symptoms resemble those of suppurative pneumonia. There is a risk of infection spreading locally or leading, via septicaemia, to a brain abscess.

General management

Diagnosis rests mainly on the chest radiograph, which may sometimes show cavitation or a fluid level. Antimicrobial chemotherapy, postural drainage and relief by bronchoscopy of any obstruction are indicated.

Dental aspects

A well-recognized cause of lung abscess is inhalation of a tooth or fragment, a restoration or rarely, an endodontic instrument. When undertaking endodontics or cementing restorations, such as inlays or crowns, a rubber dam or other protective device should always be used to avoid the danger of inhalation.

Lung abscesses may also result from aspiration of oral bacteria, particularly anaerobes, especially in infirm older patients or those who are intubated.

The other main dangers in dentistry are with GA, particularly if an inadequate throat pack has been used. Patients who inhale tooth fragments or dental instruments must have chest radiographs (lateral and postero-anterior) and, if necessary, bronchoscopy.

Table 15.20 *Sarcoidosis: possible clinical findings*

Type	Finding
Dermatological	Erythema nodosum, infiltrates around eyes and nose (lupus pernio)
Hepatic	Asymptomatic hepatomegaly, sarcoid liver disease
Lymph nodes	Lymphadenopathy (rarely lymphoma)
Musculoskeletal	Arthralgia, effusions, cyst-like radiolucent areas
Neurological	Cranial or peripheral neuropathies
Oral/para-oral	Salivary gland or gingival swelling
Ocular	Acute uveitis, cataracts, glaucoma
Pulmonary	Hilar lymphadenopathy; widespread infiltration
Renal	Nephrocalcinosis, renal calculi
Spleen	Splenomegaly
Systemic symptoms	Fever, weight loss, fatigue

LOEFFLER SYNDROME

Loeffler syndrome appears to be an allergic reaction, usually to the parasitic worm *Ascaris lumbricoides*, or drugs such as sulphonamides. It manifests with pulmonary infiltrates (and abnormal chest radiograph) and eosinophilia (eosinophilic pneumonia). The disease usually clears spontaneously.

SARCOIDOSIS

General aspects

Sarcoidosis, so named because skin lesions resembled a sarcoma, is a multisystem granulomatous disorder, seen most commonly in young adult females in northern Europe, especially in people of African heritage. The aetiology is unclear but *Propionibacterium acnes* and *P. granulorum* have been implicated and associations have been reported with exposure to inorganic particles, insecticides, moulds and occupations such as firefighting and metal-working. Serum samples contain antibodies directed against *Mycobacterium tuberculosis* antigens. Sarcoidosis is associated with HLA-DRB1 and DQB1, and a butyrophilin-like 2 (*BTNL2*) gene on chromosome 6. T-helper 1 (Th1) cells release IL-2 and IFN- γ , and augment macrophage tumour necrosis factor alpha (TNF- α) release. CD25 regulatory T cells cause a limited impairment of cell-mediated immune responses (partial anergy) but no obvious special susceptibility to infection.

Clinical features

Sarcoidosis affects the thorax in 90%, but has protean manifestations and can involve virtually any tissue (Table 15.20). Sarcoid most typically causes Löfgren syndrome (fever, bilateral hilar lymphadenopathy, arthralgia and erythema nodosum, especially around the ankles; Figs 15.9 and 15.10).

Other common presentations may include pulmonary infiltration and impaired respiratory efficiency, with cough and dyspnoea in severe cases, or acute uveitis, which can progress to blindness. Susceptibility to lymphomas has been suggested but not confirmed.

General management

Because of its vague and protean manifestations, sarcoidosis is under-diagnosed. In the presence of suggestive clinical features, helpful

Fig. 15.9 Sarcoid causing ankle swelling in Löfgren syndrome.

Fig. 15.10 Sarcoid lung image showing hilar adenopathy.

investigations include: chest radiography (enlarged hilar lymph nodes); raised serum angiotensin-converting enzyme (SACE; Table 15.21) in acute disease (this is insensitive, non-specific and a poor guide to therapy); positive gallium-67 citrate or gadolinium or positron emission tomography (PET) scans; labial salivary gland or transbronchial biopsy (for histological evidence of non-caseating epithelioid cell granulomas) – except in Löfgren syndrome, which is a classical clinical diagnosis. ^{18}F -deoxyglucose PET is helpful in identifying sites for biopsy.

Non-specific findings may include mild anaemia, leukopenia, eosinophilia, hypergammaglobulinaemia, raised ESR and low serum albumin. Hypercalcaemia is common because of extrarenal production of active vitamin D and can result in renal damage. Alkaline phosphatase, 5'-nucleotidase, lysozyme and adenosine deaminase levels are raised in hepatic sarcoidosis. Evidence of impaired delayed hypersensitivity reactions to some antigens may be useful. Kveim skin tests are not now used.

Table 15.21 Sarcoidosis: laboratory findings

Type	Finding
Histological	Non-caseating tubercle-like granulomas
Immunological	Anergy (partial)
	Negative response to tuberculin and some other common antigens on skin testing
	Lymphopenia; low numbers of T cells
	Raised serum levels of immunoglobulins
Biochemical	Hypercalcaemia
	Raised serum levels of lysozyme, serum angiotensin-converting enzyme (SACE) and adenosine deaminase

Half the patients with sarcoidosis remit within 3 years and about 66% remit by 10 years. Patients with only minor symptoms usually need no treatment but corticosteroids, sometimes with azathioprine, methotrexate, tetracyclines, hydroxychloroquine, infliximab or etanercept, are given if there is active organ disease (ocular disease, progressive lung disease, hypercalcaemia or cerebral involvement).

Dental aspects

Biopsy of the minor salivary glands frequently shows non-caseating granulomas and association with other features of sarcoidosis, particularly hilar lymphadenopathy. This is an important diagnostic finding that may obviate more invasive procedures. Sarcoidosis can involve any of the oral tissues but has a predilection for salivary glands. Asymptomatic swelling of the parotid glands or cervical nodes, and less frequently the lips, may accompany systemic disease. Superficial or deep-seated red submucosal nodules may develop intraorally and on the lips. Non-tender, well-circumscribed, brownish-red or violaceous nodules with superficial ulceration have also been reported. The oral and lip lesions may occasionally precede systemic involvement.

There is enlargement of the major salivary glands in about 6% of cases; some have xerostomia, and the association of salivary and lacrimal gland enlargement with fever and uveitis is known as uveoparotid fever (Heerfordt syndrome). Salivary swelling may also be seen without other features of Heerfordt syndrome. The salivary gland swellings usually resolve on treatment of sarcoidosis but this may take up to 3 years.

Facial palsy and other cranial neuropathies may be seen. There is also an association with Sjögren syndrome, when SS-A and SS-B serum autoantibodies are found. Rarely there is an association of thyroiditis with Addison disease, Sjögren syndrome and sarcoidosis (TASS syndrome). There is a group of patients who have histological features of sarcoid in one or more sites in the mouth, such as the gingivae, but no systemic manifestations. A few of these patients may ultimately develop other more or less systematized disease but the majority probably have isolated lesions. Such cases, where no exogenous cause for the granulomatous reaction can be found, are regarded as having 'sarcoid-like' reactions (orofacial granulomatosis) and treatment is unnecessary. However, patients should be kept under observation for as long as possible.

Management of patients with systemic sarcoidosis may include consideration of respiratory impairment, uveitis and visual impairment, renal disease, jaundice or corticosteroid treatment.

LA is safe and satisfactory. CS is contraindicated if there is any respiratory impairment. GA should only be given in hospital.

LUNG CANCER

General aspects

Lung cancer is the most common cancer in high-income countries in males and most frequently affects adult urban cigarette-smokers. Bronchogenic carcinoma accounts for 95% of all primary lung cancer and has also become increasingly common in women (because of increased tobacco use), to the extent that the mortality rate for the two sexes has become almost equal. Metastases from cancers elsewhere are also frequently found in the lungs.

Clinical features

Recurrent cough, haemoptysis, dyspnoea, chest pain and recurrent chest infections are the predominant features. Local infiltration may cause pleural effusion, lesions of the cervical sympathetic chain (Horner syndrome), brachial neuritis, recurrent laryngeal nerve palsy or obstruction of the superior vena cava with facial cyanosis and oedema (superior vena cava syndrome).

There are many non-metastatic extrapulmonary effects of bronchogenic (or other) carcinomas – for example, weight loss, anorexia, finger-clubbing, neuromyopathies, thromboses (thrombophlebitis migrans), muscle weakness, various skin manifestations and ectopic hormone production (of antidiuretic hormone, adrenocorticotrophic hormone, parathyroid hormone and thyroid-stimulating hormone).

Metastases from bronchogenic cancer are common and typically form in the brain (which may manifest with headache, epilepsy, hemiplegia or visual disturbances), liver (hepatomegaly, jaundice or ascites) or bone (pain, swelling or pathological fracture).

General management

The diagnosis is based on history and physical examination, supported by radiography, CT and magnetic resonance imaging (MRI), sputum cytology, bronchoscopy and biopsy. Spiral CT appears to detect tumours at an early stage.

The overall 5-year survival rate is only 8%. Radiotherapy is the most common treatment. Only some 25% of patients are suitable for surgery but, even then, the 5-year survival is only about 25%. Chemotherapy has been disappointing, except in small-cell carcinomas.

Dental aspects

Dental treatment under LA should be uncomplicated. CS should preferably be avoided. GA is a matter for specialist management in hospital, as patients often have impaired respiratory function, especially after lobectomy or pneumonectomy. This, along with any muscle weakness (myasthenic syndrome, Eaton–Lambert syndrome) that can make the patient unduly sensitive to the action of muscle relaxants, makes GA hazardous.

Oral cancer may be associated with lung cancer, and *vice versa*, or develop at a later stage (Ch. 22). Such synchronous or metachronous primary tumours must always be ruled out.

Metastases can occasionally affect the orofacial region and cause enlargement of the lower cervical lymph nodes, epulis-like soft-tissue swellings or labial hypoaesthesia or paraesthesia in the jaw. Soft palate pigmentation is a rare early oral manifestation.

Lung cancer is a fairly common cause of death in dental technicians, but it is unknown whether this is due to smoking alone or to dust inhalation.

CYSTIC FIBROSIS (CF; FIBROCYSTIC DISEASE; MUCOVISCIDOSIS)

General aspects

Cystic fibrosis (CF) is one of the most common fatal hereditary disorders. Inherited as an autosomal recessive trait, with an incidence of about 1 in 2000 births, it is the most common inherited error of metabolism and is seen mainly in people of European descent. The gene responsible is on chromosome 7q. CF is caused by defects in the cystic fibrosis transmembrane conductance regulator (CFTR), a protein that appears to be part of a cyclic adenosine monophosphate (cAMP)-regulated chloride channel, regulating Cl^- and Na^+ transport across epithelial membranes, and ion channels and intracellular fluid flow in sweat, digestive and mucus glands.

The basic defect in CF is abnormal chloride ion transport across the cell membrane of nearly all exocrine glands. The blockage of salt and water movement into and out of cells results in the cells that line the lungs, pancreas and other organs producing abnormally thick, sticky mucus that can obstruct the airways and various glands, especially in the respiratory tract and pancreas. Involved glands (lungs, pancreas, intestinal glands, intrahepatic bile ducts, gallbladder, submaxillary and sweat glands) may become obstructed by this viscid or solid eosinophilic material.

Clinical features

Recurrent respiratory infections result in a persistent productive cough and bronchiectasis, with the lungs becoming infected with a variety of organisms including *Staph. aureus*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Strep. pneumoniae*, *Burkholderia cepacia*, and sometimes mycoses or mycobacteria. *Mycobacterium abscessus* is a non-tuberculous mycobacterium increasingly recognized as an opportunistic pathogen in CF patients. Viral infections, such as measles, can have severe sequelae.

Pancreatic duct obstruction leads to pancreatic insufficiency, with malabsorption and bulky, frequent, foul-smelling, fatty stools. Gallstones, diabetes, cirrhosis and pancreatitis may result. Sinusitis is very common.

Growth is frequently stunted. The mutations can also cause congenital bilateral absence of the vas deferens, so fertility is impaired in most males with CF. In women, fertility may be impaired by viscid cervical secretions, but many women have carried pregnancies to term.

General management

Most patients have a high concentration of sodium in their sweat (also reflected in the saliva); a sweat test showing sodium and chloride values of more than 60 mmol/L is considered positive, between 40 and 60 mmol/L equivocal, and less than 40 mmol/L negative.

Physiotherapy and postural drainage are crucially important. Clearance of sputum is helped by water aerosols and bronchodilators (terbutaline or salbutamol), but mucolytics such as carbocisteine, methyl cysteine and dornase alfa are of questionable effectiveness. Treatment with ivacaftor, a CFTR potentiator, improves chloride transport through the ion channel.

Amoxicillin and flucloxacillin are effective prophylactic antimicrobials and may be given by aerosol. Vaccination against measles, whooping cough and influenza is important. A low fat intake, adequate vitamins and oral pancreatic enzyme replacement (pancreatin) are also necessary.

Double-lung or heart–lung transplantation may eventually become necessary.

Dental aspects

Sinusitis is very common; most CF patients have recurrent sinusitis and nasal polyps. The major salivary glands may enlarge and hyposalivation sometimes occurs. The low-fat, high-carbohydrate diet and dry mouth may predispose to caries. Enamel hypoplasia and black stain may be seen, and both dental development and eruption are delayed. Tetracycline staining of the teeth was common but should rarely be seen now. Pancreatin may cause oral ulceration if held in the mouth.

LA is satisfactory but CS is usually contraindicated because of poor respiratory function. GA is contraindicated if respiratory function is poor. Lung disease, such as bronchiectasis, liver disease and diabetes, may complicate treatment.

BRONCHIECTASIS

General aspects

Bronchiectasis is dilatation and distortion of the bronchi. Causes include:

- Congenital defects, which should be considered in all patients include cystic fibrosis, Kartagener syndrome, alpha-1-antitrypsin deficiency, collagen defects (e.g. Marfan syndrome)
- Immunodeficiencies
- Postinfection
- Gastric aspiration
- Bronchial obstruction
- Autoimmune diseases, e.g. Sjögren's syndrome
- Asthma
- Inflammatory bowel disease

There is no identifiable underlying cause in about 50% of adults and 25% of children.

The damaged and dilated bronchi lose their ciliated epithelium and therefore mucus tends to pool, causing recurrent LRTIs, typically with *Strep. pneumoniae*, *Haemophilus influenzae* or *Pseudomonas aeruginosa*.

Clinical features

Overproduction of sputum, which is purulent during exacerbations, a cough (especially during exercise or when lying down) and finger-clubbing are typical features, with recurrent episodes of bronchitis, pneumonia and pleurisy. Haemoptysis is not uncommon. In advanced bronchiectasis, chest pain, dyspnoea, cyanosis and respiratory failure may develop. Complications may include cerebral abscess and amyloid disease.

General management

Chest radiography and pulmonary function tests are required. High-resolution CT (HRCT) is useful. Postural drainage is important. Antimicrobials, such as amoxicillin, cephalosporins or ciprofloxacin, are given for acute exacerbations and for long-term maintenance treatment.

Dental aspects

GA should be avoided where possible and is contraindicated in acute phases.

OCCUPATIONAL LUNG DISEASE (PNEUMOCONIOSES)

General aspects

Workers exposed to airborne particles may develop pulmonary disease (pneumoconiosis), which ranges from benign (e.g. siderosis) to malignant, as in mesothelioma from asbestosis (see Appendix 15.1), but any pneumoconiosis can cause significant incapacity.

Dental aspects

GA may be contraindicated; the physician should be contacted before treatment.

Berylliosis may be a hazard in some dental technical laboratories, when lung cancer is more frequent.

POSTOPERATIVE RESPIRATORY COMPLICATIONS

Respiratory complications following surgical operations under GA include segmental or lobar pulmonary collapse and infection. They are more common after abdominal surgery or if there is pre-existent respiratory disease or smoking (see also Ch. 3), and can be significantly reduced by smoking cessation, preoperative physiotherapy and bronchodilators, such as salbutamol.

If postoperative pulmonary infection develops, sputum should be sent for culture, and physiotherapy and antibiotics should be given. The common microbial causes are *Strep. pneumoniae* and *Haemophilus influenzae*; in this case, suitable antibiotics include amoxicillin and erythromycin. Hospital infections may include other microorganisms, such as MRSA, *Klebsiella*, *Pseudomonas* and other Gram-negative bacteria.

Inhalation (aspiration) of gastric contents can cause pulmonary oedema and may be fatal (Mendelson syndrome); it is most likely if a GA is given to a patient who has a stomach that is not empty, has a hiatus hernia or is in the last trimester of pregnancy. Prevention is by ensuring the stomach is empty preoperatively; if it is not, an anaesthetist should pass an endotracheal tube. Antacids or an H₂-receptor blocker, such as cimetidine or ranitidine, may be given by mouth preoperatively to lower gastric acidity.

If gastric contents are aspirated, the pharynx and larynx must be carefully sucked out. Systemic corticosteroids have been recommended but probably do not reduce the mortality.

RESPIRATORY DISTRESS SYNDROMES

Respiratory distress in premature infants may be caused by immaturity of surfactant-producing cells, when the alveoli fail to expand fully; this necessitates endotracheal intubation for many weeks. It may, in turn, result in midface hypoplasia, palatal grooving or clefting, or defects in the primary dentition. The same oral effects may be seen with prolonged use of orogastric feeding tubes. The degree to which subsequent growth corrects these deformations is currently unknown, though the palatal grooves typically regress by the age of 2 years. Using soft endotracheal tubes does not obviate this problem and, at present, the best means of avoiding palatal grooving appears to be the use of an intraoral acrylic plate to stabilize the tube and protect the palate.

Acute respiratory distress syndrome (ARDS) is a sequel to several types of pulmonary injury and some infections, including those with oral viridans streptococci.

LUNG TRANSPLANTATION

General aspects

Patients with end-stage pulmonary disease are considered for potential transplantation, usually using a lung from a brain-dead organ donor. A combination of ciclosporin, azathioprine and glucocorticoids is usually given for lifelong immunosuppression to prevent a T-cell, alloimmune rejection response.

Inhaled nitric oxide modulates pulmonary vascular tone via smooth muscle relaxation and can improve ventilation/perfusion matching and oxygenation in diseased lungs. Early graft failure following lung transplantation has been described by various investigators as reimplantation oedema, reperfusion oedema, primary graft failure or allograft dysfunction. Pathologically, this entity is diffuse alveolar damage.

Dental aspects

See also Chapter 35.

A meticulous pre-surgery oral assessment is required and dental treatment must be undertaken with particular attention to establishing optimal oral hygiene and eradicating sources of potential infection. Dental treatment should be completed before surgery. For 6 months after surgery, elective dental care is best deferred. If surgical treatment is needed during that period, antibiotic prophylaxis is probably warranted.

HEART AND LUNG TRANSPLANTATION

General aspects

Cardiopulmonary transplantation (heart and lung transplantation) is the simultaneous surgical replacement of the heart and lungs in patients with end-stage cardiac and pulmonary disease, with organs from a cadaveric donor.

General management

All transplant recipients require lifelong immunosuppression to prevent a T-cell, alloimmune rejection response.

Dental aspects

See also Chapter 35.

A meticulous pre-surgery oral assessment is required and dental treatment must be undertaken with particular attention to establishing optimal oral hygiene and eradicating sources of potential infection. Dental treatment should be completed before surgery. For 6 months after surgery, elective dental care is best deferred. If surgical treatment is needed during that period, antibiotic prophylaxis is probably warranted.

APPENDIX 15.1 OCCUPATIONAL LUNG DISEASES

Disorder	Source of causal agent	Group at risk	Clinical significance of pneumoconiosis
Anthracosis	Soot, carbon smoke	Urban dwellers	Benign
Asbestosis	Asbestos, insulation, fertilizers, explosives	Asbestos workers	Pulmonary fibrosis (crocidolite) predisposes to cor pulmonale or amosite (bronchial carcinoma, mesothelioma)
Bagassosis	Mouldy sugar cane	Farmers	Acute pneumonia or fibre bronchiolitis
Barilosis	Barium	Barium miners	Benign
Berylliosis	Beryllium	Those using fluorescent lamps, various alloys	Chronic respiratory disease leading to cor pulmonale
Byssinosis	Cotton, flax or hemp	Cotton workers	Periodic bronchospasm leading to obstructive airways disease
Coal miner's lung	Coal dust	Coal miners	Largely asymptomatic but may cause fibrosis and emphysema
Kaolin	China clay	China-clay workers	Resembles silicosis (see below)
Siderosis	Iron dust	Welders, grinders	Benign
Silicosis	Silica (quartz) dust	Miners, sandblasters, potters	Pulmonary fibrosis leading to cor pulmonale, tuberculosis
Stannosis	Tin dust	Tin refiners	Benign

KEY POINTS

- Osteoarthritis is very common, especially in the hips, knees and spine, and with age
- Rheumatoid arthritis is an incapacitating, fairly common systemic condition
- Myasthenia gravis is an uncommon autoimmune myopathy

BONE

Bone morphogenetic proteins (BMPs) affect bone formation and are available as recombinant proteins, sometimes used in repair of periodontal defects, other bone defects and in implantology. Bone organic matrix consists largely of collagen produced by osteoblasts rich in alkaline phosphatase. Osteoblasts secrete osteoid, which mineralizes by deposition of calcium phosphate, largely as hydroxyapatite, together with smaller amounts of amorphous calcium phosphate, magnesium, sodium and other ions. Mineralization depends on the extracellular fluid calcium and phosphate levels.

Bone is a dynamic tissue, constantly remodelling, with deposition mediated by osteoblasts, and resorption mediated mainly by osteoclasts (also by prostaglandins and some cytokines). When osteoblastic activity rises, the serum level of alkaline phosphatase rises. When bone is resorbed, calcium and phosphate are removed and released into the extracellular fluid and serum. Osteoclasts are rich in acid phosphatase (particularly tartrate-resistant acid phosphatase), which may also be released into the serum when there is widespread osteolysis. Bone formation, metabolism and blood calcium levels are affected mainly by parathyroid hormone, vitamin D and calcitonin. Parathyroid hormone (PTH; parathormone) is regulated by blood calcium, vitamin D levels and phosphate levels. When PTH is secreted, intestinal transport of calcium and phosphate is promoted, and removal of calcium from bones accelerated.

Dietary vitamin D is fat-soluble and absorbed from the upper small intestine, promoting intestinal absorption of calcium and phosphate. Vitamin D is also synthesized in the skin from 7-dehydrocholesterol under the influence of sunlight, and converted by liver and then kidney to the most active metabolite, 1,25-dihydroxycholecalciferol (DHCC: calcitriol – the hormonal form of vitamin D), a process enhanced by PTH and low phosphate levels. The active metabolite (active vitamin D or DHCC) is a hormone that controls bone metabolism and enhances calcium absorption (Fig. 16.1). DHCC also, incidentally, affects the proliferation of various cells other than bone and enhances immunity. Vitamin D exerts its influence on many physiological processes, including the immune system; both the adaptive and innate immune systems are impacted by the active metabolite of vitamin D, 1,25(OH)(2)D, and individuals with vitamin D deficiency are prone to infectious diseases such as tuberculosis, as well as to autoimmune diseases such as type 1 diabetes mellitus, and to multiple sclerosis. Calcitonin opposes the action of PTH and lowers the blood calcium level, mainly by promoting deposition of calcium in the bones.

Bone growth varies throughout life; it is rapid in the fetus and infant, but slows somewhat during childhood until an adolescent growth

Fig. 16.1 Vitamin D: sources, metabolism and effects. 1,25-D3 acts as a hormone.

spurt. Several other hormones affect bone formation and metabolism to varying degrees, especially during the first two decades of life, including growth hormone, oestrogens in females and testosterone in males. Adult levels of bone mass are achieved by age 18 or so.

Lifestyle, especially physical activity and adequate nutrition, promotes the formation of bone, whereas smoking may impair it. Osteoblasts are also less efficient at laying down bone than are osteoclasts at removing it and, although the difference is slight, there is a gradual loss of bone mineral density (BMD) as a person ages (osteopenia). Anything that accelerates the rate of bone remodelling ultimately leads to a more rapid loss of bone mass and thus more fragile bones (osteoporosis).

BONE DISEASES

Acquired disorders of the skeleton are common. Genetic disorders are rare; the more important examples are discussed here and main features of others summarized in Appendix 16.1.

GENETIC DISORDERS

Osteogenesis imperfecta (fragilitas ossium; brittle bone syndrome)

General aspects

Osteogenesis imperfect (OI) is a rare, usually autosomal dominant, condition characterized by brittle bones that are susceptible to fracture. The underlying defect appears to be in type I collagen formation and, although osteoblasts are active, the amount of bone formed is

small and mostly woven in type. This disorder, with a frequency of 1 in 12 000 births, has several variants (Table 16.1). The gene for dentinogenesis imperfecta, one of the more common heritable defects of the teeth, is closely related – and some patients (OI types I and IV) have both conditions.

Clinical features

The long bones are normal in length, with epiphyses of normal width but slender shafts, giving a trumpet-shaped appearance. The bones are fragile and multiple fractures can follow minimal trauma; healing is rapid but usually with distortion, so the ultimate effect in severe cases is gross deformity and dwarfism. The frequency of fractures usually tends to diminish after puberty.

The parietal regions of the skull may bulge outwards, causing eversion of the upper part of the ear. Other features are blue sclerae, deafness, easy bruising, and weakness of tendons and ligaments, causing loose-jointedness and often hernias. Cardiac complications, such as mitral valve prolapse or aortic incompetence, may be present.

Dental aspects

It is important not to confuse children with OI with those who have been subjected to physical abuse (Ch. 24). The management problems relate to bone fragility and careful handling of the patient. Despite the brittleness of most of the skeleton, however, the jaws rarely fracture and therefore dental extractions can usually be carried out safely; care should obviously be taken to use minimal force, to support the jaws and to ensure haemostasis if there is any bleeding tendency (Ch. 8). GA is a risk if there are chest deformities or cardiac complications.

When dentinogenesis imperfecta is associated, the teeth may have the characteristic abnormal translucency, brown or purplish colour and tendency to wear readily. The enamel may adhere poorly to the dentine and be progressively shed under the stress of mastication. By adolescence, the teeth may be worn down to the gingival margins but obliteration of the pulp chamber by dentine usually prevents pulp

exposure. The soft dentine makes the fitting of post crowns impractical so that steel crowns on primary molars and crowns in the permanent dentition, or even extraction and replacement by dentures, may be needed in severe cases. Bisphosphonate treatment may have implications (see Osteonecrosis of the jaw).

Dentinogenesis imperfecta can appear as an isolated abnormality without OI.

Achondroplasia

The achondrodysplasias are heritable disorders of skeletal growth, presenting typically with dwarfism, high forehead, cleft palate and various ocular anomalies.

General and clinical aspects

There are defects in cartilaginous bone formation, often inherited as an autosomal dominant trait. The phenotypic appearance is of dwarfism with a head of normal size but appearing large, and short limbs, which has traditionally led to many achondroplastics becoming circus clowns. Nasal septal and base of skull growth is impaired so that the bridge is depressed and skull bossed. Lumbar lordosis can be severe and occasionally causes spinal cord compression. Many patients with achondroplasia are otherwise completely healthy but diabetes is occasionally associated.

Dental aspects

The only significant dental aspects are orthodontic in nature as a result of malocclusion, but short stature, diabetes and kyphosis may affect management. Surgery is usually required for the cleft palate and other deformities.

Cleidocranial dysplasia (cleidocranial dysostosis)

General aspects

Cleidocranial dysplasia is a rare defect, mainly of membrane bone formation, involving especially the skull and clavicle. It is an autosomal dominant trait related to chromosome 6 and a defect in the signal transduction SH3-binding protein. There are also sporadic cases.

Clinical features

The clavicles are either absent or defective, thus conferring the unusual and pathognomonic ability to approximate the shoulders anteriorly (Fig. 16.2). The head is large but brachycephalic, with persistent fontanelles, a persistent metopic (frontal) suture, numerous Wormian bones and bulging frontal, parietal and occipital bones. The middle facial third is hypoplastic, leading to a depressed nasal bridge and relative mandibular protrusion. The mandibular symphysis may close late. Cranial base abnormalities and clefts of the hard and soft palate have been recorded. Other skeletal defects may be associated, such as kyphoscoliosis or pelvic anomalies.

Dental aspects

Apart from the facial anomalies, there may be excess teeth (hyperdontia, supernumeraries; Fig. 16.3) with persistence of the deciduous dentition, multiple unerupted permanent teeth, twisted roots, malformed crowns and dentigerous cysts.

Table 16.1 Osteogenesis imperfecta: subtypes

Type	Inheritance	Bone disease	Stature	Extraskelletal involvement
I ^a	AD	Mild: fractures in childhood	Almost normal	Common. Blue sclerae; otosclerosis; thin aortic valves; hypermobile joints; ± dentinogenesis imperfecta
II	AR	Severe: skull virtually unossified; multiple fractures; lethal	Low	No dentinogenesis imperfecta
III	AR, some sporadic	Progressive: few can walk unaided	Low	Blue sclerae; no dentinogenesis imperfecta
IV	AD	Severe	Low	Sclerae not blue; dentinogenesis imperfecta common
V	Variable	Mild	Almost normal	Loose-jointedness prominent

AD/AR = autosomal dominant/recessive.

^aConstitutes 80% of all cases.

Osteopetrosis (Albers-Schönberg disease; marble-bone disease)

General aspects

Osteopetrosis is a rare genetic disorder of variable severity characterized by excessive bone density, probably as a result of a defect in osteoclastic activity and hence of bone remodelling. The bones, though dense, are weak and can fracture easily, but usually heal normally.

Clinical features

In mild osteopetrosis, there may be no symptoms and the diagnosis is made by chance by radiography. In severe osteopetrosis (malignant infantile osteopetrosis), patients may suffer bone pain, fractures or osteomyelitis; added complications can be cranial neuropathies leading, for example, to optic atrophy. Anaemia is common, as the medullary cavities are filled with bone, despite extramedullary haemopoiesis in liver, spleen and lymph nodes, and there is a susceptibility to infections, since macrophages and neutrophils are defective. Hydrocephalus, epilepsy and learning disability are less frequent.

Fig. 16.2 Cleidocranial dysplasia.

Fig. 16.3 Cleidocranial dysplasia (dysostosis).

General management

Serum levels of acid phosphatase are raised but calcium and phosphate levels are normal. Corticosteroid therapy may help but bone marrow transplantation (BMT) may be the best hope.

Dental aspects

The face may be broad, with hypertelorism, snub nose and frontal bossing. There may be retarded tooth eruption. Radiography shows excessive bone density and thickness, especially obvious in the skull. Trigeminal or facial neuropathies may complicate the disease.

Fracture of the jaw or osteomyelitis may complicate dental extractions. Eruption of posterior teeth may be complicated by osteomyelitis. Once established, infection is difficult to eradicate, so that surgery should be minimally traumatic; mucoperiosteal flaps should preferably not be raised and antibiotic cover should be given. Management problems may include anaemia (Ch. 8), corticosteroid therapy (Ch. 6) or complications of BMT (Ch. 35).

ACQUIRED DISORDERS

Rickets and osteomalacia

General aspects

Rickets is a disease of childhood characterized by inadequate skeletal mineralization. Osteomalacia has the same pathogenesis but affects adults, in whom there is failure of mineralization of replacement bone (osteoid) in the normal process of bone turnover. Both rickets and osteomalacia are largely related to a lack of vitamin D or calcium, due to the causes shown in Box 16.1. Rickets and osteomalacia are commonly results of a dietary deficiency in poorly nourished communities nowadays; South Asian immigrants living in northern Europe are particularly at risk. Contributory factors may be lack of sunshine exposure and eating chapattis made from wholemeal flour containing phytates, which impair calcium absorption.

Clinical features

In rickets, the bones are weak and readily deformed, fracturing easily but incompletely (greenstick or pseudofractures). Affected infants and young children are often also listless and irritable, with weak and hypotonic

Box 16.1 Risk factors for rickets and osteomalacia

- Dietary deficiency of vitamin D – abundant in fish liver oil and animal livers
- Failure of skin vitamin D synthesis from lack of sunlight exposure
- Vitamin D or calcium malabsorption – obstructive liver or biliary disease may lead to impaired absorption of vitamin D because of a lack of bile salts in the small intestine. The liver is also central to the conversion of vitamin D to its active forms. Phytates, in wholemeal flour, bind calcium and impair its absorption
- Excessive calcium demands in pregnancy and lactation
- Renal disease, with loss of calcium, loss of phosphate, acidosis and impaired synthesis of the active metabolite of vitamin D (1,25-dihydroxycholecalciferol)
- Vitamin D-dependent rickets – due to a defect of the enzyme required to form 1,25-dihydroxycholecalciferol
- Vitamin D-resistant rickets – an X-linked defect of renal reabsorption of phosphate (familial hypophosphataemia)
- Prolonged treatment with drugs that accelerate vitamin D metabolism – particularly phenytoin

muscles, and they suffer bone pains. Excess formation of osteoid matrix causes a 'rachitic rosary' (swellings at costochondral junctions).

General management

Plasma alkaline phosphatase levels are usually raised, calcium levels low (in 50%), and phosphate levels normal or low. The underlying cause should be rectified where possible. Vitamin D and calcium should be given.

Dental aspects

Dental defects are seen only in unusually severe cases but eruption may be retarded. The jaws may show abnormal radiolucency. Vitamin D deficiency is not a contributory cause of dental caries.

In malabsorption syndromes, there may be secondary hyperparathyroidism or vitamin K deficiency, with endocrine or bleeding disorders, respectively, and oral manifestations of malabsorption.

In vitamin D-resistant rickets (familial hypophosphataemia), the skull sutures are wide and there may be frontal bossing. Dental complaints frequently bring attention to the disease, since the teeth have large pulp chambers and abnormal dentine calcification, and are liable to pulpitis and multiple dental abscesses. Since even minimal caries or attrition can lead to pulpitis, preventive care and fissure sealing or prophylactic occlusal coverage are needed.

Osteoporosis

General aspects

Osteoporosis is a very common condition of diminished bone mass and low bone density, which leads to fragile bones, usually in the elderly. Factors that lead to limited formation of bone early in life or loss of bone structure later in life lead to osteoporosis. The same factors that encourage bone formation in youth affect the maintenance of bone mass during the adult years, particularly calcium intake, reproductive hormone status, normal parathyroid gland function and physical activity (Fig. 16.4). The difference between how much healthy bone is formed during the first 28 or so years of life and the rate at which it is remodelled and removed later determines how much osteoporosis or osteopenia (see later) results. From age 30 years, about 1% of bone is lost per year, rising to about 5% after the menopause. During the first 20 years of life, formation of bone is the most important factor preventing osteoporosis, but after that point it is prevention of bone loss that becomes most important. Risk factors for osteoporosis are shown in Box 16.2.

Clinical features

Mildly traumatic or non-traumatic injuries in osteoporosis can cause fractures. The chief complications are fractures of the femoral neck, distal radius or humerus, or of the vertebral bodies (causing gradual collapse of the spine – hence the shrinking size of some older women). Low back pain is common.

General management

Diagnosis of osteoporosis is mainly from bone densitometry – a radiographic technique that gives accurate and precise measurements of the amount of bone (not the *quality*), termed 'bone mineral density' (BMD). Dual X-ray energy absorptiometry (DXA or DEXA) or sometimes dual

Fig. 16.4 Osteoporosis.

Box 16.2 Risk factors for osteoporosis

- Advanced age – over the age of 60 years, nearly one-third of the population has osteoporosis – at least 1 in three women and 1 in 12 men
- Female gender and early menopause – the most common form of osteoporosis is post-menopausal and affects 50% of women over 70 years of age. It is due to loss of oestrogen production by the ovaries, which accelerates bone loss. In terms of bone remodelling, the lack of oestrogen promotes the ability of osteoclasts to absorb bone
- Positive family history
- Lifestyle factors
 - Lack of exercise – when the normal stresses placed upon bones by normal physical activity are removed, bones lose density, best illustrated in a significant loss of bone density in patients with spinal injuries. Athletes have stronger bones than normal sedentary adults
 - Diet low in calcium or vitamin D
 - Excess alcohol intake
 - Smoking
- Drugs and disease
 - Drugs such as corticosteroids, heparin, ciclosporin and anticonvulsants
 - Malignant disease
 - Chronic inflammatory states, such as rheumatoid arthritis or ulcerative colitis
 - Endocrine disorders (Cushing syndrome, hyperthyroidism, hypogonadism)

photon absorptiometry (DPA) is used. BMD values that fall well below the average for the 25-year-old female (stated statistically as 2.5 standard deviations below the average) are diagnosed as 'osteoporotic'. BMD values less than those in the normal 25-year-old female, but not 2.5 standard deviations below the average, are diagnosed as 'osteopenic'. Initial screening for osteoporosis should be performed according to National Osteoporosis Foundation recommendations. The optimal interval for repeating DXA scans is uncertain, but because changes in bone density over short intervals are often smaller than the measurement error of most DXA scanners, frequent testing (e.g. at less than 2-year intervals) is unnecessary in most patients. Even in high-risk patients receiving drug therapy for osteoporosis, DXA changes do not always correlate

Table 16.2 Recommended calcium intake

Age	Amount of daily calcium
Infants	
Birth to 6 months	400 mg
6 months to 1 year	600 mg
Children/young adults	
1–10 years	800–1200 mg
11–24 years	1200–1500 mg
Adult women	
Pregnant or lactating	1200–1500 mg
25–49 years (pre-menopausal)	1000 mg
50–64 years (post-menopausal taking oestrogen or similar hormone)	1000 mg
50–64 years (post-menopausal not taking oestrogen or similar hormone)	1500 mg
Over 65 years	1500 mg
Adult men	
25–64 years	1000 mg
Over 65 years	1500 mg

with probability of fracture. Therefore, DXAs should only be repeated if the result will influence clinical management or if rapid changes in bone density are expected. Recent evidence also suggests that healthy women aged 67 and older with normal bone mass may not need additional DXA testing for up to 10 years, provided that osteoporosis risk factors do not change significantly. Poor BMD, raised serum alkaline phosphatase and urinary loss of calcium and hydroxyproline are risk markers but there are often no biochemical abnormalities. Bone biopsy is not practical or necessary.

The best management is to avoid falls and injuries and to consider use of hip protectors. Exercise has a positive effect on BMD, particularly in adults who have been sedentary and begin to exercise. Weight-bearing exercises, such as walking, running, jogging and dancing, are recommended. Additional calcium and 1-alpha-hydroxyvitamin D may also be helpful. The main sources of calcium are dairy products and green vegetables; the main sources of vitamin D are sun exposure (15 minutes exposure daily from April to October in the northern hemisphere is sufficient), margarine, breakfast cereals, oily fish, eggs and meat. Table 16.2 shows the recommended calcium intake according to age, gender and hormone status.

Hormone replacement therapy (HRT) may be effective in post-menopausal women and may also help relieve other symptoms, such as flushing (Ch. 25), but oestrogens can cause vaginal bleeding and increased risk of breast cancer. Raloxifene, given post-menopausally, may help to maintain BMD and assist the kidneys in producing vitamin D. Raloxifene also behaves like natural oestrogen in the liver, where it raises production of 'good' cholesterol (high-density lipoprotein; HDL) and lowers 'bad' cholesterol (low-density lipoprotein; LDL). Raloxifene appears to have no effect on the uterine endometrial lining growth, so there is no need for progestogen and there is no periodic bleeding. Raloxifene may also lower the breast cancer risk. The role of androgens (testosterone) in males is less clear, but the loss of testosterone promotes osteoporosis.

Anti-resorption drugs, which lower the rate at which osteoclasts reabsorb bone, include calcitonin, bisphosphonates and denosumab:

- Calcitonin is a thyroid hormone – a powerful inhibitor of osteoclastic activity that produces modest improvements in bone mass. A disadvantage has been that calcitonin had to be injected but a nasal spray has been developed.

- Bisphosphonates are adsorbed on to hydroxyapatite and can prevent or significantly slow normal osteoclastic activity; they can lead to a 50% reduction in fractures (including hip and spine), compared with women taking calcium only.
- Denosumab, a monoclonal antibody against receptor activator of nuclear factor kappa-B ligand (RANKL), is another potent inhibitor of osteoclastic bone resorption.

Strontium ranelate may inhibit osteoporosis but can cause serious drug rashes with eosinophilia and systemic symptoms (DRESS).

Dental aspects

There seems to be a correlation between osteoporosis and excessive alveolar bone loss in the elderly. Jaw osteoporosis is particularly a problem in women. Systemic treatment of osteoporosis may improve jaw bone density.

Patients with osteoporosis may have any of the problems of older people (Ch. 25). They may be at risk during general anaesthesia (GA) if there has been vertebral collapse and chest deformities.

Osteonecrosis of the jaw (ONJ; osteoclast modifier-related osteonecrosis of the jaws, OMRONJ)

Bisphosphonate-related or induced ONJ (BRONJ; BIONJ), defined as the presence of exposed bone in the mouth that fails to heal after appropriate intervention over a period of 6–8 weeks, has been reported in about 5% of patients with cancer who are receiving high-dose intravenous bisphosphonates. Use of oral bisphosphonates, such as alendronate and risedronate, results in an incidence of ONJ of about 1 case per 1500 patients to 2 cases per 100 000 patient years.

Bisphosphonates, especially if used intravenously, may induce osteonecrosis of the jaws. These drugs are used to treat not only osteopenia/osteoporosis but also hypercalcaemia of malignancy, metabolic bone disease (hyperparathyroidism, Paget disease) and osteogenesis imperfecta, Gaucher disease and Langerhans histiocytosis. Bisphosphonates are pyrophosphate analogues that block the 3-hydroxy-3-methylglutaryl-coenzyme A (*HMG-CoA*) reductase pathway (mevalonate path) and inhibit osteoclasts, thereby decreasing bone resorption. However, bisphosphonates remain in bone for years and have an extremely long-lasting effect. Bisphosphonate potency varies enormously, from the lowest potency (etidronate, clodronate and tiludronate) to the highest nitrogenous bisphosphonates (risedronate, ibandronate and zoledronate). Intravenous bisphosphonates such as pamidronate and zoledronate, used in cancer patients, are a particularly high risk for producing BIONJ (ranging from 1 in 10 to 1 in 100 patients). However, in osteoporosis, in which the doses used are an order of magnitude lower, the prevalence appears to be very much lower. Oral bisphosphonates such as alendronate used for more than 3 years carry a risk between 1 in 10 000 to 1 in 100 000, the lowest risk being with the lower-potency agents etidronate and tiludronate.

ONJ has also been seen in patients treated with other drugs used in cancer patients, such as denosumab, bevacizumab and sunitinib.

Some 67% of ONJ cases are preceded by tooth extraction, whereas another factor, such as a denture pressure sore or a torus, is identified in 7%; no predisposing factor is found in 26% of patients. The mean time to development of ONJ in cancer patients treated with zoledronate is 1.8 years but ranges from 6 to 60 months.

Preventive dentistry prior to initiation of high-dose antiresorptive therapy is important in patients with cancer.

A working party from US National Institutes of Health and Canadian Institutes of Health Research recommendations (Khosla et al., 2007) defined a *confirmed case of BIONJ* as:

an area of exposed bone in the maxillofacial region that did not heal within 8 weeks after identification by a health care worker, in a patient who was receiving or had been exposed to a bisphosphonate and had not had radiation therapy to the craniofacial region

and a *suspected case* as:

an area of exposed bone in the maxillofacial region that had been identified by a health care provider and had been present for < 8 weeks in a patient who was receiving or had been exposed to a bisphosphonate and had not had radiation therapy to the craniofacial region.

Eighty per cent of cases present after surgery, as exposed necrotic bone, primarily mandibular alveolar bone (Fig. 16.5; Box 16.3). Lamina dura sclerosis or loss, and widening of the periodontal ligament space may well be early manifestations.

Prevention is by avoiding elective oral surgery; alternatively treatment should be carried out well before commencing bisphosphonates or after a drug holiday for 6 months. The patient must be counselled about risks and a risk assessment should be carried out. Risk factors include bisphosphonate type and dose (intravenous is worst), and dental co-morbidities (increase risk). Low bone turnover, as shown by low C-terminal cross-linking type 1 collagen telopeptides (CTX), increases risk. Recommendations for managing bisphosphonate patients are shown in Table 16.3.

If dental extractions become unavoidable in a patient taking bisphosphonates, the use of prophylactic antibiotics may be considered, but there are no controlled studies to support their use. The decision depends on the clinician's level of concern relative to the individual patient and their specific situation, including concomitant risk factors

Fig. 16.5 Bisphosphonate-related osteonecrosis of the jaw (BRONJ).

Box 16.3 Osteonecrosis of the jaws

- Exposed bone
- Loose teeth
- Foul discharge
- Pain ±
- Fistula

(e.g. prolonged use of oral bisphosphonates, intravenous bisphosphonates, older age and concomitant use of oestrogen or glucocorticoids). Therefore, whenever possible, dentists should avoid performing extractions and elective oral surgery in patients taking bisphosphonates. If surgery is essential, the dentist must counsel the patient about the risks of use of intravenous or oral bisphosphonates taken for more than 3 years. Teriparatide has recently been introduced for treatment of ONJ.

Osteoradionecrosis (ORN)

See Chapter 22.

Osteomyelitis

General aspects

Osteomyelitis literally means ‘inflammation of the bone marrow’, although sometimes the subperiosteal bone is mainly affected.

Haematogenous osteomyelitis is an infection caused by bacterial seeding from the blood, involves a single species of microorganism (typically a bacterium), occurs primarily in children, and is most common in the rapidly growing and highly vascular metaphysis of growing bones.

Direct or contiguous inoculation osteomyelitis is usually caused by trauma or surgery, and tends to involve multiple microorganisms.

Acute osteomyelitis of the jaws primarily affects the mandible, usually in adults, and is essentially an osteolytic destructive process, but an osteoblastic response is typical of sclerosing osteomyelitis. In children, proliferative periostitis may occur. Predisposing factors for osteomyelitis are sources from which bacteria can spread to bone, from:

- local odontogenic infections (commonest cause)
- other adjacent structures (e.g. otitis media, tonsillitis, suppurative sialadenitis)
- haematogenous spread of organisms (rare in relation to the jaws).

When osteomyelitis of the mandible does occur, it may be a sign of an underlying debilitating disease, such as diabetes mellitus, an immune defect, an autoinflammatory condition or alcoholism. Alternatively, it may be related to reduced vascularity, such as after irradiation, or in rare bone conditions such as Paget disease or osteopetrosis.

Table 16.3 Recommendations for bisphosphonate patients^a

	Patients with non-malignant disease on bisphosphonates > 3 y	Patients with malignancy, starting or already on bisphosphonates
Surgery	Conventional orthograde endodontics are recommended rather than extraction where possible	Conventional orthograde endodontics are recommended rather than extraction where possible
Periodontics	Periodontal surgery is appropriate if it reduces or eliminates disease	No periodontal surgery
Endodontics	No apical surgery	No apical surgery
Implants	Currently not contraindicated if taking bisphosphonates but prudent to gain informed consent, which should be documented (risk assessment)	Not recommended

^aFrom Khosla et al., 2007.

Staphylococcus aureus is the commonest organism causing jaw osteomyelitis, but streptococci (both α - and β -haemolytic) and anaerobic organisms (e.g. *Bacteroides* and *Peptostreptococcus* species) are occasionally implicated. In acute osteomyelitis, the organisms excite acute inflammation in the medullary bone and the consequent oedema and exudation cause pus to be forced under pressure through the medullary bone, resulting in intrabone blood vessel (i.e. inferior dental artery) thrombosis, reducing the vascular supply to bone, which then necroses. Eventually, pus bursts through the cortical plate to drain via sinuses in the skin or mucosa. Where pus penetrates the cortex, it may spread subperiosteally, stripping the periosteum and thus further reducing the blood supply. Necrotic pieces of bone become sequestra, surrounded by pus, which either spontaneously discharge or remain and perpetuate infection. The periosteum lays down new bone to form an involucrum encasing the infected and sequestered bone. The involucrum may prevent sequestra from being shed. Finally, if little new bone is formed, a pathological fracture may occur.

Clinical features

Jaw osteomyelitis presents with deep-seated, boring pain and swelling. Teeth in the affected area become mobile and tender to percussion, with pus oozing from the gingival crevices. The pain abates once pus penetrates the cortical plate, and discharges intraorally or extraorally, often through several sinuses. Labial anaesthesia is a characteristic feature because of pressure on the inferior alveolar nerve. The patient is often febrile and toxic with enlarged regional lymph nodes.

General management

Diagnosis is clinical, supported by imaging that, in established cases, shows marked bony destruction and sequestration. However, since radiographic changes are seen only after there has been significant decalcification of bone, early cases may not be detected; in these, isotope bone scanning using technetium diphosphonate may show increased uptake. Blood tests show a leukocytosis with neutrophilia and a raised erythrocyte sedimentation rate (ESR).

Treatment is with antibiotics and usually drainage. Penicillin was the drug of choice, but since many staphylococci are now penicillin-resistant, flucloxacillin or fusidic acid may be used. Lincomycin and clindamycin also give high bone levels but, because of a high incidence of pseudomembranous colitis, are now regarded as second-line drugs. Metronidazole gives good bone levels and is indicated for anaerobic infections. Drainage of pus follows the guidelines used for other infections. When dead bone is exposed in the mouth, it can often be left to sequestrate without surgical interference, but sequestrectomy should be undertaken if the separated dead bone fails to discharge; decortication of the mandible may be needed in order to allow this, along with drainage. Hyperbaric oxygen is an effective adjunct for recalcitrant osteomyelitis, especially where anaerobic organisms are involved.

Acute maxillary osteomyelitis is rare, and usually seen in infants, presumably because the lack of development of the antrum at this age means the maxilla is a dense bone.

Chronic osteomyelitis presents with intermittent pain and swelling, relieved by the discharge of pus through long-standing sinuses. Bone destruction is localized and often a single sequestrum may be the source of chronic infection. Removal of the sequestrum and curettage of the associated granulation tissue usually produces complete resolution.

Focal sclerosing osteomyelitis is usually asymptomatic and is revealed as an incidental radiographic finding. Most common in young adults, there is a dense, radio-opaque area of sclerotic bone caused by

formation of endosteal bone – usually related to the apical area of a mandibular molar. This appears to be a response to low-grade infection in a highly immune host. Following tooth extraction, the infection usually resolves (but the sclerotic bone often remains).

Diffuse sclerosing osteomyelitis is a sclerotic endosteal reaction, which, like focal sclerosing osteomyelitis, appears to be a response to low-grade infection. However, the area of bone involved is widespread and sometimes involves most of the mandible or occasionally the maxilla. Sometimes the infection arises in an abnormally osteosclerotic mandible, such as in Paget disease, osteopetrosis or fibrous dysplasia. Intermittent swelling, pain and discharge of pus may go on for years. Management is difficult because of the extensive nature of the disease process. Long-term antibiotics, curettage and limited sequestrectomy all have their place.

Proliferative periostitis (Garré osteomyelitis) is more common in children than adults. The cellular osteogenic periosteum of the child responds to low-grade infection, such as apical infection of a lower first molar tooth, by proliferation and deposition of subperiosteal new bone. The subperiosteal bone may be deposited in layers, producing an onion-skin appearance radiologically, which can simulate Ewing sarcoma. The endosteal bone, however, may appear to be completely normal, but in severe cases also appears moth-eaten radiologically. Removal of the infective source is usually followed by complete resolution, although subsequent bone remodelling can take a considerable time.

Tumoral calcinosis

This rare disease is characterized by ectopic, soft tissue calcifications but normocalcaemia. Early-onset periodontitis may be a feature.

Fibrous dysplasia

General aspects

Fibrous dysplasia consists of replacement of an area of bone by fibrous tissue, causing a localized swelling that may affect a single bone (monostotic) or, less commonly, several bones (polyostotic).

The aetiology of fibrous dysplasia is unknown. The process typically starts in childhood and, as the skeleton matures, the lesions ossify progressively; ultimately, when skeletal growth ceases, they usually become stabilized.

Cherubism shares some features in common with fibrous dysplasia but may cause bilateral lesions of the maxilla causing the eyes to 'up-turn towards heaven'.

Clinical features

Monostotic fibrous dysplasia is the most common type; it is more frequent in females and often involves the jaws, particularly the maxilla.

Polyostotic fibrous dysplasia may affect either sex and may involve over 50% of the skeleton, but is uncommon. The lesions may be unilateral and 50% have abnormal skin hyperpigmentation of a café-au-lait colour, especially over the dorsum of the trunk and limbs, usually on the same side as the bone lesions (Jaffe syndrome). Albright syndrome is polyostotic fibrous dysplasia with skin hyperpigmentation and precocious puberty in females; there are episodic rises in serum oestrogen and falls in gonadotropin levels.

General management

Radiography typically shows a ground-glass appearance with no defined margins. Serum calcium and phosphate levels are normal, often with raised serum alkaline phosphatase level and raised urinary hydroxyproline.

Fibrous dysplasia is typically self-limiting and usually ceases to progress after adolescence. Patients are sometimes managed with calcitonin. Bisphosphonate treatment may have implications (see Osteonecrosis of the jaw). Testolactone is effective for the precocious puberty of Albright syndrome. Surgery can be used to correct any residual cosmetic defect but the bone tends to bleed a great deal. Radiotherapy should be avoided because of the risk of inducing osteosarcomas.

Dental aspects

The facial bones are frequently involved in monostotic fibrous dysplasia and in 25% of cases of polyostotic disease. Monostotic fibrous dysplasia is not a medical problem but it is possible for the polyostotic type of the disease to be unrecognized when the facial lesions are the most obvious feature. Hyperthyroidism or diabetes mellitus may occasionally be associated with polyostotic fibrous dysplasia and therefore may, rarely, complicate treatment. Mucosal pigmentation may be seen but is rare in Albright syndrome. In the differential diagnosis, it may be confused with that of Addison disease, while the skin pigmentation may simulate that of neurofibromatosis.

PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)

General aspects

Paget disease is characterized by progressive deformity and enlargement of bones related to overactivity of osteoclasts and osteoblasts. There appears to be considerable geographical variation in the prevalence, disease being common in northern Europeans, and also in older age. Paget disease is rare in Africans, people from the Indian subcontinent, and other Asians.

The essential features are total disorganization of the normal orderly replacement of bone, and an anarchic alternation of bone resorption and apposition. In the earlier stages, resorption predominates (osteolytic phase) but later bone apposition takes over and, as disease activity declines, the affected bones become enlarged and dense (sclerotic stage).

There is a male predominance. The aetiology of Paget disease is unknown and a slow virus has been implicated. Inherited forms of Paget disease of bone, caused by mutations in genes such as *SOST* that affect osteoclast differentiation and function, are recognized.

Clinical features

Symptoms are absent in the early stages, which can only be detected by imaging. Bone pain is the most common feature in older patients; it is usually felt around the hips or knees but is non-specific. One or many bones may be affected. In the polyostotic type, the axial skeleton is mainly involved but hands and feet are usually spared (Fig. 16.6). Other possible complications of Paget disease are deformities, pathological fractures, and constriction of skull foraminae – sometimes compressing cranial nerves and leading to effects such as deafness or impairment of vision. Rarely, there is brainstem or spinal compression.

If Paget disease is widespread, hypervascularity of the bones can produce, in effect, an arteriovenous fistula and high-output cardiac failure. Development of osteosarcoma is a recognized but rare complication.

General management

The differential diagnosis includes hyperostosis frontalis interna (a benign condition characterized by frontal bone sclerosis), fibrous

Fig. 16.6 Paget disease of bone.

dysplasia, pustulotic arthrosteitis (sclerotic lesions of clavicle and ribs) and osteosclerotic metastases. Diagnosis is from radiographs of affected bones, which show predominantly radiolucencies due to osteolysis early on but mixed areas of lysis with sclerosis later. Affected bones become thicker. Radionuclide bone scanning showing increased uptake of technetium diphosphonate helps define disease extent. The serum total alkaline phosphatase level is grossly raised when many bones are affected, but usually there is little or no change in calcium or phosphate levels. More specific is a rise in bone-specific alkaline phosphatase, procollagen type I N-terminal propeptide and osteocalcin. There is also raised urinary hydroxyproline and pyridinoline excretion. Biopsy is rarely indicated.

Currently, the most effective treatment of Paget disease is with bisphosphonates. Vitamin D deficiency is a common accompaniment.

Dental aspects

When the skull is affected, a typical early feature is a large irregular area of relative radiolucency (osteoporosis circumscripta; Fig. 16.7). Later, there is radio-opacity, with loss of the normal landmarks and an irregular cotton-wool appearance. Basilar invagination may be seen. The maxilla is involved occasionally and the mandible rarely. Typically, maxillary enlargement causes symmetrical malar bulging (leontiasis ossea; Fig. 16.8). The intraoral features are gross symmetrical widening of the alveolar ridges, loss of lamina dura and hypercementosis, often forming enormous craggy masses that may become fused to the surrounding bone. Pulpal calcification may be seen. Serious complications follow efforts to extract severely hypercementosed teeth. Attempts using forceps may fail to move the tooth or cause fracture of the alveolar bone. Alternatively, the tooth may be mobilized but retained, as if in a ball-and-socket joint. If hypercementosis is severe, a surgical approach with adequate exposure should be used for extractions.

Fig. 16.7 Paget disease affecting the skull.

Fig. 16.8 Leontiasis ossea in Paget disease.

In the early stages of the disease, the highly vascular bone may bleed freely; later, the poor blood supply to the bone makes it susceptible to chronic suppurative osteomyelitis. Bisphosphonate treatment may have implications (see Osteonecrosis of the jaw). Prophylactic antibiotics, such as penicillin (immediately before and for 3 or 4 days after the operation), may help prevent postoperative infection. Dentures have to be replaced as the alveolar ridge enlarges. Benign giant cell tumours may be seen.

Patients with Paget disease involving facial or maxillo-mandibular parts of the skeleton have a higher prevalence of heart disease and of deteriorating hearing, sight and smell. Osteosarcoma is rare in the jaws. If the patient is in heart failure, the usual precautions have to be taken but, since GA may be needed for extractions, this aspect of the disease needs to be kept in mind. Chest deformity may also complicate GA.

Hyperparathyroidism

See Chapter 6.

THERAPEUTIC PROCEDURES

Guided bone regeneration (GBR)

Guided bone regeneration (GBR) is a surgical procedure that uses barrier membranes to direct new bone growth to sites having insufficient volumes or dimensions for function or prosthesis placement. Barrier membranes have been derived from a variety of sources, both natural and synthetic, and are marketed under various trade names. Membranes used in GBR may be of two principal varieties: non-resorbable (expanded polytetrafluoroethylene) and resorbable (collagen from various sources, ox caecum cargile membrane, polylactic acid, polyacetic acid, polyglycolic acid, polyglactin 910 (Vicryl), synthetic skin (Biobrane) and freeze-dried dura mater). A range of materials – from demineralized bone matrix formulations and bone morphogenic proteins to synthetic ceramic materials – are now being used. Animal studies have even enabled a hybrid tooth–bone construct to be developed.

Distraction osteogenesis

Distraction osteogenesis is a surgical process involving the gradual, controlled displacement of surgically created fractures, which permits simultaneous expansion of bone and soft tissue, in order to reconstruct combined deficiencies in bone and soft tissue. This is effective in orofacial skeletal reconstruction, including cleft palate reconstruction and alveolar ridge augmentation for placement of osseointegrated implants. Disadvantages are the expense, technical difficulty and the long training required. The most frequent complications are infection, and loosening and breaking of the introduced pins, with osteomyelitis and fracture of the newly generated bone.

JOINTS

A joint is the location at which two or more bones make contact. Joints can be:

- fibrous – joined by dense irregular connective tissue that is rich in collagen fibres
- cartilaginous – joined by cartilage
- synovial – not directly joined; the bones have a synovial cavity and are united by the dense irregular connective tissue that forms the articular capsule that is normally associated with accessory ligaments (e.g. temporomandibular joint; TMJ).

JOINT DISEASES

A joint disorder is termed an arthropathy; when it involves inflammation, it is called arthritis. Joints are considerably more frequently affected by disease than are bones or muscles. The jaws and TMJ are, however, rarely involved in systemic disease. Acquired disorders are the most common.

GENETIC DISORDERS

Marfan syndrome

The Marfan syndrome is most common genetic connective tissue disorder and has skeletal, cardiovascular, dermatological and ocular manifestations. It is an autosomal dominant condition involving the *FBN1* gene, which encodes connective tissue protein fibrillin-1 and is

also a binding protein for transforming growth factor beta (TGF- β), which has a damaging effect on vascular smooth muscle development. Prevalence is 2–3 per 10000 and disease affects both sexes equally. There is usually great variation in the phenotype within families whose members share the same genetic condition. The diagnosis of Marfan syndrome is usually clinical but may be difficult (Table 16.4). A Marfanoid body build may also be a feature of the benign joint hypermobility syndrome or multiple endocrine adenoma syndrome (MEA III; Ch. 6). The Marfan syndrome also shares the features of loose-jointedness, cardiac valvular defects and ocular lesions with various of the subtypes of Ehlers–Danlos syndrome; there can also be confusion with other rare disorders, particularly homocystinuria and congenital contractural arachnodactyly (long, spider-like fingers). However, the most obvious distinguishing feature of the Marfan syndrome is the long, thin body habitus and long slender fingers.

Clinical features

The condition can be asymptomatic, although patients are usually longer and thinner than average (Fig. 16.9). Fingers and toes are also usually long and thin. The following organs are affected:

- Skin – striae
- Cardiovascular system – abnormalities affect 90% of patients and aortic dissection can be life-threatening. There is often severe aortic and mild mitral incompetence. Death in the fifth decade is common. Mitral valve prolapse can lead to arrhythmias, embolism or sudden death; if it causes a systolic murmur, it can

predispose to infective endocarditis, particularly in older persons. Thoracic aortic dilatation/rupture/dissection, aortic mitral valve/prolapse, mitral regurgitation, abdominal aortic aneurysm and cardiac arrhythmia may occur.

- Eyes – visual impairment is common due to lens subluxation or dislocation in 80%, glaucoma or myopia.
- Joints – arthralgia, lax ligaments are common, predisposing to joint hyperextensibility, subluxation or dislocation, and hernias.
- Skeleton – misshapen chest and excessive length of tubular bones so that patients are tall with a wide arm span (often exceeds the patient’s height by a ratio of more than 1.03) and arachnodactyly.
- Lungs – function can be impaired by cysts, which lead to spontaneous pneumothorax and kyphoscoliosis.

Survival has been greatly improved with aortic graft surgery and the use of beta-blockers.

Dental aspects

Maxillary/mandibular retrognathia and long face are the main features. The palatal vault is high and TMJ dysfunction or recurrent subluxation may be troublesome. Bite problems may arise from malocclusion. Management may be complicated by chest deformities and cardiovascular abnormalities, which may be contraindications to GA, and by the risk of infective endocarditis (Ch. 5).

Ehlers–Danlos syndrome

General aspects

Ehlers–Danlos syndrome (EDS) is a group of rare disorders of collagen formation, characterized by hyperextensible skin, bleeding tendency and propensity to bruising and loose-jointedness. The most common forms are inherited as autosomal dominant traits, while the remainder are recessive.

Clinical features and general management

There is wide variation in the clinical features of the different EDS types (Table 16.5). Hypermobility of joints is the best-known manifestation of EDS and may be extreme (India-rubber man). Recurrent, semi-spontaneous dislocation may result. It may be possible to hyperextend the fingers until they are at right angles to the back of the hand, and the diagnosis is often made by the unusual ability of the patient to pull their thumb back to the forearm (Fig. 16.10).

The skin is typically soft, abnormally extensible, fine and thin, and may appear lax; even when it appears normal, it may be possible to pull the skin out for 2.5–5 cm (Fig. 16.11). Other, incidental oddities that may be seen in EDS include the ability to touch the nose with the tip of the tongue (Gorlin’s sign). Wounds tend to gape or to split after slight trauma, while healing is slow and may leave fragile scars with a tissue-paper texture.

Easy (‘spontaneous’) bruising, though of vascular origin, may mimic purpura caused by haematological diseases but, unlike any of the latter, there is a combination of subcutaneous, submucosal and deep bleeding. Although platelet defects have occasionally been reported, haemostatic function is often normal, except in type IV. Weakness of the connective tissue component may cause lesions in the gastrointestinal tract, urinary tract and respiratory system. In the vascular type (type IV), spontaneous rupture of major arteries (dissecting aneurysm) can cause fatal haemorrhage and internal bleeding.

Table 16.4 Marfan syndrome

Skeletal defects	Cardiovascular defects	Neuro-ocular defects
Disproportionately long limbs	Dilatation of ascending aorta	Ectopia lentis
Arachnodactyly (spider fingers)	Dissecting aneurysm	Blue sclerae in some
Loose joints	Aortic regurgitation	Learning impairment (sometimes)
Pectus excavatum	Mitral valve prolapse	
Temporomandibular joint subluxation		

Fig. 16.9 Arachnodactyly in Marfan syndrome.

Table 16.5 Ehlers–Danlos syndrome: subtypes

Types	Inheritance	Hyper-extensibility	Skin fragility and bruising	Joint hypermobility	Special features
I (gravis)	AD	++	++	++	Parrot face. Frequent musculoskeletal disorders. Mitral valve prolapse
Classical type					
II (mitis)	AD	+	+	+ Hands and feet only	Mitral valve prolapse. Bruising common
Classical type					
III (benign hypermobility)	AD	±	+	++	Dislocations, haemarthrosis, early-onset arthritis. Mitral valve prolapse
Hypermobility type					
IV	AR	±	+++	± Digits only	Bleeding from major arteries
Vascular type					
V (sex-linked)	X-linked	++	+	±	Frequent musculoskeletal disorders. Males only
VI (ocular or hydroxylysine-deficient)	AR	++	±	++	Fragile cornea and sclera. Multiple ocular defects, deafness, often early loss of sight
VII (multiple congenital dislocation or arthrochalasis multiplex congenita)	AR	+	±	++	Early onset of multiple dislocations. Some laxity of ligaments, short stature
VIII (periodontal)	AD	±	±	±	Severe early-onset periodontitis and loss of teeth. Blue sclerae
IX (skeletal and urinary tract dysplasia) ^a	AR	–	±	±	Occipital exostoses, low copper levels
X (fibronectin deficiency)	AR	±	±	±	Bleeding tendency

AD/AR = autosomal dominant/recessive.

^aNo longer classified as Ehlers–Danlos syndrome.

Fig. 16.10 Ehlers–Danlos syndrome. A typical party trick.

Fig. 16.11 Extensible skin in Ehlers–Danlos syndrome.

Mitral valve prolapse (floppy valve syndrome) is seen in many types of EDS, particularly type III, and may confer susceptibility to infective endocarditis or lead to rapid development of mitral insufficiency and heart failure. Cardiac conduction defects may be present.

Dental aspects

In EDS, the teeth may be small, with short or abnormally shaped roots and many pulp stones. The deciduous dentition shows abnormal morphology of the molars, obliteration of the tooth pulp and severe enamel attrition. The permanent dentition shows agenesis and microdontia of several teeth. Tooth discolouration, dysplastic roots and tooth pulp obliteration are present in a restricted number of permanent teeth:

- In types I, VI and VII EDS, joint hypermobility is severe and TMJ subluxation and dislocation is a possibility.
- In type III EDS, local anaesthetics may have less effect, though there is no satisfactory explanation.
- In type IV EDS (vascular type), post-extraction bleeding is likely to be most severe, with semi-spontaneous purpura, extensive ecchymoses and also weakness of arterial walls. Severe bleeding from the gingivae, especially after tooth-brushing or from extraction sockets, may sometimes be the main complaint.
- In type VII EDS, there may be micrognathia, an anterior open bite and gingival hyperplasia with varying degrees of hyperkeratosis.
- In type VIII EDS and possibly type IV, there is early onset of periodontal disease, with early loss of teeth.

Patients with mitral valve prolapse may develop heart failure with attendant risks during GA (Ch. 5).

Recurrent temporomandibular joint dislocation

Chronic recurrent TMJ dislocation is defined as the complete loss of articular relationships, during mouth wide-opening, between the temporal articular fossa and the condyle–disc complex. This may be seen in patients with EDS, those with internal derangements and those with other conditions. The classic treatment was the Dautrey operation (eminectomy), which modifies the bony obstacle, preventing condylar locking, but it does not have a therapeutic effect on TMJ ligament and capsular laxity or masticatory muscle incoordination, which seem to be the real causes of TMJ dislocation in most cases. Plication of the joint capsule may help.

ACQUIRED DISORDERS

ARTHRITIS

Osteoarthritis (osteoarthrosis)

General aspects

Osteoarthritis (OA) is the most common form of arthritis and is most frequently found in adults over the age of 45 years. It is especially painful in frequently used, weight-bearing or traumatized joints. OA is characterized by degeneration of articular cartilage with compensatory thickening of the exposed underlying bone and development of peri-articular cysts. Collapse of these peri-articular cysts, together with continued peripheral bone proliferation, causes progressive joint deformity. Risk factors for OA are shown in [Box 16.4](#).

OA may affect any joint, but especially frequently used, weight-bearing or traumatized joints, such as those in the fingers, hips, knees, lower back and feet. Initially, it tends to strike only one joint but, if the fingers are affected, multiple hand joints may become arthritic, sometimes painlessly. The essential change in OA is degeneration of articular cartilage with compensatory thickening of the underlying bone, which becomes exposed and is at first smooth and shiny but later becomes roughened. Cystic spaces form beneath and bone proliferates at the joint margins. Exposure and collapse of the cystic cavities, together with continued peripheral proliferation, cause progressive deformity.

Clinical features

In OA there are no systemic symptoms, no obvious inflammation of affected joints or serological changes ([Table 16.6](#)) (in contrast to rheumatoid arthritis). Features of OA may include: pain with stiffness, progressively diminished function and deformity, particularly of larger joints, such as the hips or knees; pain, swelling and stiffness in a joint during or after use, or pain before or during a change in the weather; loss of joint flexibility; bony lumps on the fingers, on the middle (Bouchard nodes) or

Table 16.6 Comparison of osteoarthritis and rheumatoid arthritis

Feature	Osteoarthritis	Rheumatoid arthritis
Age of onset	Late middle age or old age	Middle age
Pain and disability	+	++
Main joints affected	Weight-bearing or frequently used joints (hip, spine, knee, fingers)	Bilateral, interphalangeal
Clinical inflammation over joints	–	+
Joint deformities	Heberden or Bouchard nodes	Swelling and deviations
Morning stiffness	Some	Pronounced
Systemic problems, malaise, fatigue	–	+
Erythrocyte sedimentation rate	Normal	Raised
Rheumatoid factor	–	+ Usually

Fig. 16.12 Heberden nodes in osteoarthritis.

end joints (Heberden nodes; [Fig. 16.12](#)), or the first metacarpophalangeal joint at the thumb base ([Fig. 16.13](#)).

General management

The diagnosis is usually made on clinical grounds, supported by imaging. The characteristic radiographic features include narrowing of the joint space, marginal osteophyte formation (lipping), subchondral bone sclerosis, bone ‘cysts’ (rounded areas of radiolucency just beneath the joint surface) and deformity.

Physical methods of treatment are important and include a number of factors shown in [Box 16.5](#). Medical methods of treatment are less important but include: topical pain relievers (counterirritant medications, such as trolamine salicylate, methyl salicylate, menthol and capsaicin), which may relieve pain in joints close to the skin surface, such as fingers, knees and elbows; anti-inflammatory drugs (non-steroidal anti-inflammatory drugs; NSAIDs); licofelone or cyclooxygenase 2 (COX-2) inhibitors, such as celecoxib; glucosamine as a food supplement – said to provide moderate pain relief comparable to that from NSAIDs; antidepressants, which, independent of their antidepressant properties, can help lessen chronic pain; and intra-articular injections with a corticosteroid or hyaluronate, which can give pain relief for a time.

Surgical methods of treatment include joint replacement surgery – the most important surgical treatment for arthritis. The damaged joint is removed and replaced with a plastic or metal prosthesis. The hip

Box 16.4 Risk factors for osteoarthritis

- Age: most in people > 45 y
- Gender: females more commonly affected
- Genetic predisposition
- Obesity
- Malformed joints (hereditary or acquired)
- Occupation (athletes)
- Haemochromatosis
- Paget disease
- Gout

Fig. 16.13 Osteoarthritis.

Box 16.5 Physical aids to osteoarthritis

- Regular exercise – to help maintain joint mobility
- Weight control – to minimize stress on joints
- Appropriate footwear – if there is arthritis in weight-bearing joints or back
- A walking stick – to ease the load on a damaged joint
- Heat application – to ease pain, relax tense, painful muscles, and increase the regional flow of blood
- Cold application – for occasional flare-ups

joint is most commonly replaced, but implants are available for knee, shoulder, elbow, finger or ankle joints. Completely normal function is usually restored. Arthroscopy can be used to remove loose fragments of bone or cartilage that may cause pain or mechanical symptoms, such as 'locking', but there is rarely significant improvement in pain relief or function 2 years afterwards. Surgery can also reposition bones to help correct deformities and can permanently fuse bones in a joint to improve stability and reduce pain.

Dental aspects

OA affects the TMJ in some older patients but is typically painless. Those with OA of other joints also do not appear to have significantly more TMJ involvement than controls. The radiographic severity of TMJ OA does not correlate with symptoms. Since TMJ OA is rarely clinically significant, patients should not be made unnecessarily anxious. A syndrome of dry mouth and OA has been described (sialoadenitis, osteoarthritis, xerostomia – SOX) but whether this is a true entity rather than simple coincidence needs confirmation.

Age and immobility may influence access to dental care. Patients with OA may also experience restricted manual dexterity, which may compromise their ability to maintain adequate oral hygiene. These patients may need toothbrushes with specially adapted handles (such as a handle with a ball added to help the patient grip) or may benefit from using electric toothbrushes. Since joint stiffness tends to improve during the day, short appointments in the late morning or in the early afternoon are recommended for patients with arthritis. Supine positioning may be uncomfortable for them and they may need neck and leg supports.

Dentists should consider a patient's tendency to bleed and any need for corticosteroid supplementation or antibiotic coverage before performing any invasive procedures. There is no reliable evidence of a need for antibiotic prophylaxis before dental treatment in most patients with prosthetic joints, and the risks from adverse reactions to antibiotics probably exceed any benefit. Infections of prosthetic joints are usually due to non-oral organisms such as staphylococci and are only caused by oral bacteria exceptionally rarely. Even where viridans streptococci have been found in infected joints, they could have come from non-oral sources, or simply from a bacteraemia associated with chewing. The same arguments as to the risk:benefit of antimicrobial prophylaxis in OA apply as for endocarditis (Ch. 5). Antibiotic prophylaxis is therefore not indicated for dental surgery on most patients with bone pins, plates and screws or with total joint replacements. The overall infection risk in hip replacement is less than 1% and in knee replacement less than 2%. Only rarely are these infections caused by oral streptococci and only a few have been attributed to recent dental procedures. Since the degree of the bacteraemia is reduced by good oral hygiene, best practice should incorporate dental screening to eliminate current dental disease before the replacement procedure, with advice on good oral hygiene maintenance following surgery.

Since the administration of antibiotic prophylaxis is likely to be ineffective, it should not be given routinely. The possible adverse effects and the risks of creating antibiotic resistance must also be considered. Gastrointestinal upsets and rashes are relatively common (1–10%). Anaphylaxis is rare but associated with a significant mortality rate of approximately 10%, and would result in more deaths than might occur as a consequence of infected replacements. There is a risk of developing *Clostridium difficile* infection, which is associated with significant morbidity and mortality, especially in people over 65 years, who are the ones most likely to need prostheses.

In 2012, the American Academy of Orthopedic Surgeons and American Dental Association (AAOS/ADA) released the first co-developed evidence-based guidelines on the prevention of orthopaedic implant infection in patients undergoing dental procedures (Appendix 16.2). Of note, that review found *no* direct evidence that dental procedures cause orthopaedic implant infections and concluded that antibiotic prophylaxis does not reduce the risk of subsequent implant infection. Three recommendations were drawn up:

1. The practitioner *might* consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joints undergoing dental procedures (strength of recommendation: limited).
2. The work group was unable to recommend for or against the use of topical oral antimicrobials in patients with prosthetic joint implants or other orthopaedic implants undergoing dental procedures (strength of recommendation: inconclusive).
3. In the absence of reliable evidence linking poor oral health to prosthetic joint infection, it was the opinion of the work group that patients with prosthetic joint implants or other orthopaedic implants maintain appropriate oral hygiene.

Another publication, a 'Shared decision-making tool' (<http://ebd.ada.org/contentdocs/DentalSDMTool.pdf>; accessed 30 September 2013), has been released as an aid to the AAOS/ADA *Prevention of orthopaedic implant infection in patients undergoing dental procedures* clinical practice guideline. It states:

- Patients who have compromised immune systems (diabetes mellitus, rheumatoid arthritis, cancer, chemotherapy, chronic steroid use) might be at greater risk for implant infections.
- Patients who are immune-compromised might wish to consider antibiotics before dental procedures because of their greater risk for infection.
- Thus, if there is any doubt on the management of such patients, the patient's orthopaedic surgeon should be consulted.
- Ideally, patients who are to undergo a total joint arthroplasty/ replacement should undergo dental evaluation and any oral disease present should be eliminated before the scheduled surgery.
- Patients with prosthetic joint implants should be encouraged to practise effective daily oral hygiene procedures and seek regular professional dental care.
- Patients who develop oral infections should be treated aggressively with antibiotics, incision and drainage, endodontics and extractions.

Thus, although the evidence may be controversial, medico-legal and other considerations suggest that dental professionals should err on the side of caution and fully inform and have discussions with the patient; take medical advice in any case of doubt; and give antibiotic prophylaxis only for at-risk procedures in patients at high risk for infection. Antibiotic prophylaxis 1–1.5 hours before dental treatment likely to initiate a bacteraemia (Box 16.6) may be considered where

dental at-risk procedures are to be carried out in patients who have recent new joints (within 2 years), or in haemophiliacs, or where the joint has previously been infected, or where patients are immunocompromised, such as those with diabetes or rheumatoid disease. Antibiotic regimens are shown in Box 16.6; cephradine 1 g orally or intravenously is a further choice.

Dental management may also be complicated by a bleeding tendency if the patient is anticoagulated or takes high doses of aspirin (Ch. 8).

Rheumatoid arthritis

Rheumatoid arthritis (RA) affects about 2% of the population in the West, and women approximately three times as frequently as men, typically between the ages of 30 and 40 years. RA is a multisystem, immunologically mediated disease seen in genetically predisposed individuals (HLA-DR4 genotype). It is characterized by an autoantibody directed against IgG (rheumatoid factor, RF), which is usually IgM; it forms immune complexes and leads to activation of complement, synovial inflammation and destructive joint disease.

Clinical features

RA often has an insidious onset, with increasing stiffness of the hands or feet; it is worse in the morning. In the acute stage, there is aching, swelling, redness, tenderness and limitation of movement of small joints of the wrists, hands and feet, which are typically affected first. The metacarpophalangeal and interphalangeal joints typically become spindle-shaped as a result of joint swelling with muscle wasting on either side (Fig. 16.14). Ulnar deviation of the fingers may develop later. Eventually, the wrists, elbows, ankles and knees also may be involved and the patient becomes disabled (Fig. 16.15). The cervical spine is involved in 30% and there may be atlanto-axial subluxation (Fig. 16.16). Other common manifestations are tenosynovitis or subcutaneous nodules, but clinically apparent effects on other systems are less common (Table 16.7).

Box 16.6 Prophylactic antibiotics in patients with prosthetic joints^a

Dental at-risk procedure

- Tooth removal
- Oral or periodontal surgery or raising of mucogingival flaps for any other purpose (including implants)
- Subgingival procedures, including probing, scaling, root planing, subgingival fibre placement or any form of periodontal surgery
- Intraligamentary injections
- Reimplantation of avulsed teeth
- Endodontic manipulation beyond the root apex
- Orthodontic banding

Joint at risk

- Joint placed within previous 2 years
- History of previous infection
- Patient with haemophilia
- Patient with type 1 diabetes
- Patient with rheumatoid arthritis
- Patient on immunosuppressive therapy

Antibiotic prophylaxis regimens

- Cefalexin 2 g or
- Clindamycin 600 mg or
- Azithromycin 500 mg or
- Clarithromycin 500 mg or
- Amoxicillin 2 g

^aModified from American Association of Orthopedic Surgeons and American Dental Association guidelines (2012).

Fig. 16.14 Rheumatoid arthritis.

Fig. 16.15 Patient wheelchair-bound by severe rheumatoid disease.

Fig. 16.16 Rheumatoid arthritis.

General management

RA is diagnosed if at least four of the features shown in Box 16.7 are present and is confirmed by finding a raised ESR and other inflammatory markers, and positive RF (present in about 70%; sensitive but not specific). The autoantibodies may occasionally be IgG and therefore not detected by the routine agglutination tests (latex and sheep-cell agglutination test; SCAT); in this case, the term ‘seronegative’ is used. However, radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) detect either class of RF.

Antiperinuclear factor (APF) and antikeratin antibodies (AKA), identified by immunofluorescence, have a specificity of close to 90% for RA and react with the same antigen, a citrullinated form of filaggrin (citrulline is an unusual amino acid formed by post-translational modification of arginine residues by the enzyme peptidyl arginine deaminase). Recombinant filaggrin fragments, after enzymatic deamination *in vitro*, react with autoantibodies in RA sera. Synthetic cyclic

Table 16.7 Rheumatoid arthritis: features and complications

System	Features/complications
Cardiovascular	Cardiac conduction defects Myocarditis Pericarditis Valvulitis Vasculitis
Dermal, oral and para-oral	Oral drug lesions Palmar erythema Sjögren syndrome Subcutaneous rheumatoid nodules Temporomandibular arthritis Vasculitis and various rashes
Haematological	Anaemia Leukopenia Thrombocytopenia
Hepatic	Abnormal liver function
Joints	Arthritis Laxity of ligaments Spinal nerve root compression Subluxation Tenosynovitis

Table 16.8 *Laboratory findings in rheumatoid arthritis*

Test	Typical findings
Full blood count	Normocytic anaemia Mild leukocytosis (or leukopenia) Mild thrombocytopenia
Erythrocyte sedimentation rate*	Raised
Protein electrophoresis	Hypergammaglobulinaemia
Rheumatoid factor – latex agglutination	Positive usually
Antinuclear antibodies	Positive in 20–60%

* = or CRP

citrullinated peptide (CCP) variants also react with anti-filaggrin autoantibodies and serve as the substrate for detecting anti-CCP antibodies serologically. Most studies of anti-CCP antibodies demonstrated that these autoantibodies have much improved specificity for RA compared to RF. Anticyclic citrullinated peptide (anti-CCP) antibody can also help determine which patients may benefit from treatments such as anti-tumour necrosis factor alpha (TNF α) monoclonal antibodies; can be predictive of the progression of patients, indicating more erosive disease or increased joint involvement; and is more predictive of erosive arthritis measures, such as matrix metalloproteinases-3, ESR, and C-reactive protein (CRP). Antinuclear antibodies (ANA) are also often found but are usually in low titre (Table 16.8).

The Simplified Disease Activity Index DAS28) uses 28 tender and swollen joint counts, physician's and patient's global assessments, and CRP.

Radiographic features include widening of the joint space (in early disease); joint erosion, destruction and deformity; and peri-articular osteoporosis. Later, there is narrowing of the joint spaces, cyst-like spaces in the bone and subluxation. Ultimately, there may be severe bone destruction and deformity, but ankylosis is rare. Factors associated with a poor prognosis in RA include positive RF, extra-articular disease, HLA-DR4, early erosions and severe disability at presentation.

The main aspects of treatment include rest in the acute phases, but between these episodes maintenance of mobility of affected joints is important. Drugs used include symptom-modifying drugs, such as simple analgesics or NSAIDs, and disease-modifying antirheumatic drugs (DMARDs), which may relieve painful swollen joints and slow joint damage; the most commonly used are methotrexate, sulfasalazine and leflunomide (others include gold, penicillamine, minocycline, anti-malarials, corticosteroids, azathioprine, ciclosporin and cyclophosphamide). A Proserba column, a blood-filtering technique used weekly to remove autoantibodies, is sometimes available.

Biological response modifiers may include anakinra (a direct and selective blocker of interleukin-1 [IL-1] receptor – now rarely used) and TNF inhibitors – both first-generation (etanercept, infliximab and adalimumab) and second-generation agents (certolizumab and golimumab). Other drugs include tocilizumab (anti-IL-6); abatacept (a T-cell co-stimulator blocker) and rituximab (a monoclonal antibody

against cluster of differentiation [CD]20 antigen on B lymphocytes). Biological therapies may be effective and given for severe active disease, as they are costly and can cause severe toxic effects.

Management of RA also includes general supportive measures, such as splints and appliances to facilitate mobility, reduce pain and preserve function. Surgery may be indicated for replacement of severely damaged joints.

Dental aspects

Sjögren syndrome is the most common oral complication. RA has a predilection for small joints, including the TMJ, but though there may be limitation of opening or stiffness, these are often painless. Radiographic changes are common in the TMJ and consist of erosions, flattening of the joint surfaces and marginal proliferation. Even when disease is severe, pain from the TMJ appears to trouble only a minority. Occasionally, an anterior open bite or even sleep apnoea may result.

Intubation for GA can be difficult. In some patients, dislocation of the atlanto-axial joint or fracture of the odontoid peg can readily follow sudden jerking extension of the neck, as a result of weakness of the ligaments. Disastrous accidents of this sort have been known to follow adjustment of the headrest on older types of dental chair, or sudden extension of the neck during the induction of GA.

Patients with RA may experience restricted manual dexterity, which may compromise their ability to maintain adequate oral hygiene. These individuals may need toothbrushes with specially adapted handles (such as a handle with a ball added to help the patient grip) or may benefit from using electric toothbrushes. Since joint stiffness tends to improve during the day, short appointments in the late morning or in the early afternoon are recommended for patients with arthritis. Supine positioning may be uncomfortable for them, and they may need neck and leg supports. Dentists should consider a patient's tendency to bleed and any need for corticosteroid supplementation or antibiotic coverage before performing any invasive procedures. There is no reliable evidence of a need for antibiotic prophylaxis before dental treatment in most patients with prosthetic joints, and the risks from adverse reactions to antibiotics probably exceed any benefit.

Patients with joint prostheses because of RA may possibly require antibiotic cover before surgical procedures since they are regarded as mildly immunocompromised. A few cases are treated with corticosteroids. Some treatments induce neutropenia, thrombocytopenia or a bleeding tendency.

The drugs used in RA can be a cause of oral side-effects, such as ulcers and lichenoid reactions (Table 16.9). NSAIDs, gold and low-dose methotrexate may cause ulceration.

Felty syndrome

Felty syndrome comprises RA, splenomegaly and lymphadenopathy, and is managed as RA. These patients are at risk from infections because of leukopenia. Management can also be complicated by anaemia and mild thrombocytopenia. Orofacial manifestations may include severe ulceration or oropharyngeal infections, including chronic sinusitis.

Juvenile rheumatoid arthritis**General aspects**

There are many types of juvenile arthritis, one of which resembles adult RA; another has features in common with ankylosing spondylitis. Juvenile rheumatoid arthritis (JRA) is uncommon compared with adult RA, but can be considerably more severe.

Table 16.9 Drugs in rheumatoid arthritis: oral adverse effects

Drugs	Adverse effects
Antimalarials	Lichenoid reactions Hyperpigmentation
Anti-tumour necrosis factor (TNF) agents	Candidosis Other infections Erythema multiforme Ulceration Cancer?
Corticosteroids	Candidosis
Gold	Lichenoid reactions Ulceration
Leflunomide	Candidosis Salivary swelling Taste disturbance
Methotrexate	Ulceration
Non-steroidal anti-inflammatory drugs (NSAIDs)	Lichenoid reactions Ulceration
Pencillamine	Lichenoid reactions Loss of taste Severe ulceration

Clinical features

One important form of JRA predominantly affects girls in late childhood, involves virtually any joint and is associated with rheumatoid nodules, mild fever, anaemia and malaise. Over 50% develop severe arthritis and deformity.

General management

RF is positive in most cases and ANA are present in 75%. Management is as for RA.

Dental aspects

Damage to the TMJ of various types has occasionally been described. Complete bony ankylosis has been reported and micrognathia may develop in 4–25%. Chronic use of aspirin may occasionally cause tooth erosion.

Psoriatic arthritis

Psoriatic arthritis can affect the lower spine and sacroiliac joints in particular. Joint disease can closely resemble RA but is usually milder. There are no characteristic serological abnormalities. General management is with NSAIDs or methotrexate. Anti-TNF agents are available for use in psoriatic arthritis.

Psoriatic arthritis of the TMJ is rare. Oral mucosal lesions, histologically verified as oral psoriasis, are occasionally seen. Methotrexate or anti-TNF agents may cause oral ulcers.

Temporomandibular pain–dysfunction syndrome

See Chapter 13.

Gout

In gout, deposits of sodium urate monohydrate crystals in the joints result in the release of lysosomal enzymes from polymorphonuclear

leukocytes, causing acute inflammation. Gout may be primary or secondary.

Primary gout is an inborn error of metabolism causing raised plasma urate levels (hyperuricaemia). It mainly affects adult men; food or drink rich in purines (e.g. fish roe) can precipitate an attack in those with the underlying metabolic disorder. Ethanol favours conversion of pyruvate to lactate, which impairs renal excretion of urate, so an alcoholic 'binge' (especially with beer) can precipitate an attack. Some forms of primary gout are inherited in an autosomal dominant manner, while in others there is evidence of polygenic inheritance.

Secondary gout is usually caused by cell breakdown from drug treatment or radiotherapy for myeloproliferative diseases, which releases large amounts of purines into the blood. Hyperuricaemia is common but usually symptomless.

Gout of either type is aggravated or can be caused by diuretics (thiazides and loop diuretics), which impair renal excretion of uric acid. Women are not significantly at risk from gout until after the menopause.

Lesch–Nyhan syndrome, deficiency of hypoxanthine–guanine phosphoribosyltransferase (HGPRT), is a rare cause of gout, associated with learning impairment, choreoathetosis and compulsive self-mutilation. The lips are chewed and self-inflicted injuries, especially to the face and head, despite the pain it obviously causes, are typical.

Clinical features

Many gouty patients are obese, and there is a high incidence of hyperlipidaemia, hypertension, diabetes and atherosclerosis. An acute attack of gout causes sudden and intensely severe joint pain, usually in the large toe, associated with fever, leukocytosis and raised serum uric acid. Gouty tophi are masses of urate crystals, which, in joints, interfere mechanically with function and also destroy bone and cartilage to cause a severe deforming arthritis. Extra-articular tophi typically form in the helix of the ear as conspicuous, almost white, hard, subcutaneous nodules. Chronic tophaceous gout is often associated with renal disease (gouty nephropathy), which, unless treated, leads to fatal renal failure in up to 25%.

General management

Blood chemistry shows raised uric acid levels. Secondary gout should be investigated to establish the underlying disorder.

Colchicine, etoricoxib, naproxen and indometacin relieve an acute attack but can cause severe adverse effects. Anti-inflammatory analgesics are therefore used but aspirin, which interferes with uricosuric agents, should not be given. Allopurinol reduces the frequency of acute gouty attacks by inhibiting xanthine oxidase, conversion of xanthine to uric acid, and purine synthesis. In severe cases, uricosuric agents, such as probenecid or sulfinpyrazone, can be used in addition to increase urate excretion. In very few patients (less than 1%) with diminished HGPRT activity, allopurinol does not work and the drug can, rarely, cause xanthine renal stones to form. Activation of 6-mercaptopurine and azathioprine, both purine antimetabolites, depends on HGPRT; consequently, these drugs are not effective in Lesch–Nyhan syndrome.

Dental aspects

Gout affects the TMJ only rarely. Drugs used for the treatment of gout, particularly allopurinol, can occasionally cause oral ulceration.

Hypertension, ischaemic heart disease, cerebrovascular disease, diabetes and renal disease may affect dental management. Aspirin is contraindicated, as it interferes with uricosuric drugs. The incidence

Fig. 16.17 Ankylosing spondylitis in this patient did not permit him to place his neck on the headrest.

of rashes with ampicillin, but not other penicillin allergies, is greater in patients on allopurinol.

Calcium pyrophosphate deposition disease involves deposition of calcium pyrophosphate in and around joints in conditions of high plasma calcium, low phosphate or low magnesium. It manifests similarly to gout and is treated with NSAIDs and by correction of the metabolic disturbance.

Ankylosing spondylitis

General aspects

Ankylosing spondylitis is a seronegative spondyloarthropathy (predominantly affecting the spine), seen mainly in young males. The inflammation involves the insertions of ligaments and tendons, and is followed by ossification, forming bony bridges that fuse adjacent vertebral bodies or other joints. Ankylosing spondylitis is genetically determined in part; the family history may be positive and in Caucasians over 90% are positive for HLA-B27.

Clinical features

Ankylosing spondylitis onset is usually insidious, with low back pain (spondylitis) and stiffness, followed by worsening pain and tenderness in the sacroiliac region due to sacroiliitis. Hip joints may also be involved. Over the course of years, the back becomes fixed (**Fig. 16.17**), usually in extreme flexion, and chest expansion becomes limited and respiration impaired. About 25% develop eye lesions (acute uveitis or iridocyclitis) and about 10% develop cardiac disease (aortic incompetence or conduction defects; **Fig. 16.18**).

General management

ESR is raised, HLA-B27 is often positive and there is a mild anaemia, but no other significant laboratory findings – and no autoantibodies. Radiography shows progressive squaring-off of vertebrae (which become

Fig. 16.18 Ankylosing spondylitis.

Box 16.8 Aetiology of reactive arthritis

- Sexually transmitted infections with *Chlamydia trachomatis* (urogenital reactive arthritis)
- Gut infections, such as with *Shigella flexneri*, *Salmonella typhimurium*, *Yersinia* or *Campylobacter* (enteric or gastrointestinal reactive arthritis)
- Respiratory infections with *Chlamydia pneumoniae*

rectangular), intervertebral ossification ('bamboo spine'), calcification of tendon/ligament insertions and obliteration of the sacroiliac joints.

Treatment consists of: physiotherapy and exercises; anti-inflammatory analgesics to control pain and allow the back to be kept as mobile as possible (indometacin may be used); and anti-TNF agents. Radiotherapy to the spine is occasionally given but carries the risk of leukaemia.

Dental aspects

Ankylosing spondylitis can affect the TMJ in about 10%, especially those aged over 40 with widespread disease, but symptoms are usually mild. GA can be hazardous because of severely restricted opening of the mouth, impaired respiratory exchange associated with severe spinal deformity or cardiac disease (aortic insufficiency).

Reactive arthritis or seronegative spondyloarthropathy (Reiter disease)

This comprises arthritis, urethritis and conjunctivitis, but there are numerous other effects and it is more appropriate to speak of reactive arthritis or seronegative spondyloarthropathy. It may follow a range on infections (**Box 16.8**).

Reactive arthritis typically begins about 1–3 weeks after infection; it is itself not contagious but the causative bacteria can be passed from person to person or affect many individuals who acquire it from the same source. It most often targets males between 20 and 40 years of age, about 80% of whom are HLA-B27-positive.

Clinical features

Seronegative spondyloarthropathy often affects and causes symptoms in the urogenital tract, particularly the prostate or urethra in men, and the urethra or, rarely, the uterus or vagina in women. Joint symptoms typically include pain and swelling in the knees, ankles and feet. Approximately 50% have low back and buttock pain. Eye involvement usually takes the form of conjunctivitis and uveitis, with eye redness, pain and irritation, and blurred vision. Characteristic skin lesions are small, hard nodules of hyperkeratotic thickening, which can be gross, and affect the palms and soles (keratoderma blenorrhagica). The penis may show painless circinate lesions (circinate balanitis), and similar lesions may be seen in the mouth. The symptoms usually last 3–12 months, although they can return or develop into long-term disease in a few.

General management

There is no specific diagnostic test for seronegative spondyloarthropathy, which is usually diagnosed by the exclusion of other arthritides, the finding of a raised ESR and leukocytosis, and the demonstration of causal microorganisms or antibodies to them.

Treatment may include antibiotics for up to 3 months to eliminate the triggering of bacterial infection. Anti-inflammatory analgesics help control the acute phase. Corticosteroid injections are used if NSAIDs are unsuccessful. Other immunosuppressives, TNF inhibitors, sulfasalazine, methotrexate, etanercept or infliximab may be effective if other treatments fail.

Dental aspects

The most characteristic lesion is a pattern of painless scalloped white lines surrounding reddish areas and closely resembling one variant of migratory glossitis (geographic tongue), but affecting any part of the mouth. Oral ulcers or other lesions may be frequent but are transient and often unnoticed.

Infective arthritides

Infective (pyogenic) arthritides are rare but may follow penetrating wounds, extension from adjacent septic areas or extension by blood-stream spread. Possible causal agents include *Neisseria gonorrhoeae*, *Haemophilus influenzae*, *Staphylococcus aureus*, *Mycobacterium tuberculosis*, *Salmonella* or *Borrelia* (Lyme disease). Oral microorganisms are only rarely implicated.

Pain, limitation of movement, swelling and erythema may be evident (Fig. 16.19). Ankylosis can be a complication.

Infective arthritides are an emergency; joint fluid should be sent for microbiological examination and culture, and antibiotics given. Empirical treatment, given until the causal agent is known, is flucloxacillin intravenously plus fusidic acid or, in penicillin-allergic patients, clindamycin. Gentamicin is added if the patient is immunocompromised.

Lyme disease

General aspects

Lyme disease is caused by the spirochaete *Borrelia burgdorferi*, transmitted mainly by insects (*Ixodes* ticks from deer mainly). It is

Fig. 16.19 Infective arthritis.

considerably more common in the USA (first described in Lyme, Connecticut) than in other countries, but cases are seen in most parts of the world and it is spreading in most areas, possibly as global warming increases the range of habitats of the vectors.

The risk of Lyme disease is mainly to those who live or work in or close to areas surrounded by tick-infested woods or overgrown brush. Lyme disease is not transmitted between humans.

Clinical features

The first sign is usually a red 'bull's-eye' rash (erythema migrans) that spreads outwards from the site of the insect bite. Tiredness, fever, headache, stiff neck and muscle aches are common. Arthritis may develop in the acute phase and be transient, or later persistent, most typically affecting the knees severely. Chronic arthritis can be a late complication. Neurological involvement may result in facial palsy. Cardiac disease, such as atrioventricular block, myopericarditis or cardiomegaly, is uncommon.

General management

Antibiotic treatment for 3–4 weeks with doxycycline or amoxicillin is generally effective in early disease but early treatment does not necessarily prevent development of chronic arthritis.

Cefuroxime axetil or erythromycin can be used for persons allergic to penicillin or who cannot take tetracyclines.

Dental aspects

Facial palsy and lymphadenitis may be seen. TMJ involvement is rare, even in endemic areas.

MUSCLE

Muscle fibres contain specialized structures for excitation–contraction coupling to ensure that a contractile stimulus (received at the synapse) is quickly and evenly communicated to the whole fibre. Force production occurs in the *myofibrils*, which are chains of sarcomeres running from one end of the fibre to the other. Contractile forces are closely linked to the myosin heavy chain isoform expressed by the fibre responsible for force generation. Myosin is a protein composed of a globular head with adenosine triphosphate (ATP) and actin binding

sites, and a long tail involved in its polymerization into myosin filaments. Actin is the other major protein in force production. Troponin is the major regulator of force production. Titin maintains the neatly ordered striation pattern of skeletal (striped) muscles by anchoring myosin to actin. Nebulin acts as a molecular ruler, regulating the length of actin filaments.

ATP is the immediate source of energy for muscle contraction. Energy for contraction comes from the metabolism of fatty acids and sugars. Fatty acids are the major source of energy during normal activities and are derived from fats broken down to acetyl coenzyme A, which is then oxidized by the same citric acid cycle involved in the metabolism of glucose. Blood glucose diffuses into the muscle cytoplasm and is locked there by phosphorylation. A glucose molecule is then rearranged slightly to fructose and phosphorylated again to fructose diphosphate. Glucose is metabolized anaerobically in the cytoplasm but this is only moderately efficient. Aerobic metabolism is more efficient, but requires oxygen and takes place in the mitochondria. Creatine phosphate is one of the other important energy stores, a source for high-energy phosphate groups with which to replenish ATP, particularly in fast-twitch glycolytic fibres.

Anabolic steroids work by increasing synthesis of muscle proteins. Muscle cells are embedded in a basal lamina of collagen and large glycoproteins, between which are satellite cells important in the growth and repair of the fibres.

MUSCLE DISEASES

When weakness is limited to one side of the body, a stroke may be responsible (Ch. 13); weakness that affects the body below a certain level may be caused by a spinal cord disorder (Ch. 13).

Weakness that affects muscles of the upper arms and legs more than the hands and feet may indicate a disorder that affects all muscles (myopathy). Myopathies tend to affect the largest muscles first; the person may have difficulty combing hair or climbing stairs. When the

hands and feet are weaker than the upper arms and legs, the problem is often a polyneuropathy, which tends to affect the longest nerves first (those in the hands and feet). The affected person may thus have the most trouble with fine finger movements. Strength that decreases with repetitive activity suggests myasthenia gravis.

Muscle diseases (myopathies) are uncommon and rarely cause oral manifestations or affect dental management. The genetic myopathies, which comprise the muscular dystrophies and the myotonic disorders, have the most significance but are uncommon. Acquired myopathies are rare but significant; metabolic myopathies are tabulated in Appendix 16.3.

GENETIC MYOPATHIES

Muscular dystrophies

General and clinical aspects

Muscular dystrophies, the main crippling diseases of childhood, are a group of uncommon genetically determined diseases characterized by degeneration of muscle leading to progressive weakness (Table 16.10).

Duchenne muscular dystrophy – a recessive sex-linked disorder that results from lack of a specific muscle protein, dystrophin – is the most common. Complications include loss of ability to walk, deterioration of lung and cardiac function, and, often, early death. The pelvic girdle is affected first and the disease becomes evident as the infant begins to walk with a waddling gait and severe lumbar lordosis. The child has difficulty in standing and, after lying down, typically has to climb up his legs in order to stand (Gower sign). The shoulder girdle is also weak and winging of the scapulae is characteristic. Weakness spreads to all other muscles but tends to spare those of the head, neck and hands.

The affected muscles enlarge (pseudohypertrophy) but the child is crippled and, before puberty, becomes confined to a wheelchair. Cardiac disease (cardiomyopathy), respiratory impairment and intellectual deterioration appear at an early stage, and patients usually die in their twenties.

Table 16.10 Muscular dystrophies

Type	Inheritance	Muscles affected	Pseudo-hypertrophy	Onset	Progress	Other features
Duchenne	X-linked	All	Usual	Early childhood	Rapid	Cardiomyopathy Death in early adulthood
Becker	X-linked	All	Usual	Late childhood	Variable	More benign than Duchenne type
Childhood	AR	All	Usual	Late childhood	Variable	More benign than Duchenne type
Limb girdle	AR	Pelvic and shoulder girdles	Occasional	Adolescence	Variable	Severely disabling May be cardiomyopathy
Facioscapulohumeral	AD	Starts in face and shoulder	Rare	Adolescence	Slow	Most benign type Normal life expectancy Pouting of lips with facial weakness Cardiac conduction defects
Scapuloperoneal	AD or X-linked	Scapular Peroneal All	Occasional	Adolescence	Slow	Relatively benign
Congenital muscular	AR	All	Rare	Birth	Variable	Possible joint deformities
Distal myopathy	AD	Distal	Rare	Any age	Slow	–
Oculopharyngeal	AD	Facial and sternomastoid	Rare	Adult	Slow	Dysphagia may be prominent Weakness of masticatory muscles and tongue

AD/AR = autosomal dominant/recessive.

Dental aspects

In those muscular dystrophies where there is facial myopathy (classically in the facioscapulohumeral type), there is lack of facial expression and, often, inability to whistle. Malocclusions, especially expansion of the arches, may be seen, but there is no abnormal susceptibility to dental disease. Cardiomyopathies and respiratory disease are contraindications to GA. Muscular dystrophy may also predispose to malignant hyperthermia (Ch. 23).

Myotonic disorders

Myotonic disorders are characterized by abnormally slow relaxation after muscle contraction. *Dystrophia myotonica* – the most disabling myotonic disorder – can lead to ptosis (Fig. 16.20), progressive facial weakness, cataracts, testicular atrophy and frontal baldness. The onset is typically in the third decade. Complications include cardiac conduction defects, respiratory impairment, mild endocrinopathies, intellectual deterioration and personality changes.

Myotonia congenita (Becker type) appears late in childhood and is characterized by muscle hypertrophy.

Myotonia congenita (Thomsen disease), a generalized myotonia without weakness, starting in infancy.

Paramyotonia congenita causes myotonia and weakness after exposure to cold.

Dental aspects

In dystrophia myotonica, there is atrophy of the temporalis, masseter and sternomastoid muscles (producing a swan-neck appearance), and sometimes distal limb weakness and wasting. Myotonia in the tongue causes difficulty in speaking (dysarthria) and there may also be problems with masticating food. Atrophy of the masticatory muscles leads

Fig. 16.20 Ptosis in dystrophia myotonica.

to an open mouth posture. There may also be dysphagia, dysarthria and dental caries.

GA may be a risk because of cardiac conduction defects, suxamethonium sensitivity, respiratory impairment, behavioural problems or malignant hyperthermia. Patients may have dental management problems resulting from treatment with corticosteroids or phenytoin.

ACQUIRED MYOPATHIES

Polymyalgia rheumatica

General aspects

Polymyalgia rheumatica is an uncommon disorder characterized by muscle pain and stiffness, which is sometimes accompanied by cranial arteritis (Ch. 13). Women are predominantly affected, usually after the age of 55.

Clinical features

There is pain, stiffness and weakness across the shoulders, in the upper arms and in the pelvic region, radiating into the thighs.

General management

The ESR is typically raised and electromyography (EMG) normal. Biopsy may be helpful. Small doses of corticosteroids usually give rapid relief but in most cases the disease is ultimately self-limiting after 1–2 years or longer.

Dental aspects

Orofacial manifestations are present if cranial arteritis is associated.

LA is safe. CS can be given if required. Corticosteroid treatment may be associated with its usual problems (Ch. 6).

Myasthenia gravis

General aspects

Myasthenia gravis (MG) is a chronic autoimmune disorder that causes weakness and rapid fatigue of voluntary muscles, and usually affects women between 20 and 30. Circulating autoantibodies to the nicotinic acetylcholine (ACh) receptor proteins on the post-synaptic membrane of the neuromuscular junction, detected in 85%, damage the receptor so that the response of the muscle to ACh is weak. These autoantibodies in 75% of cases suggest thymic hyperplasia and, in the remainder, a thymoma.

Occasional cases of MG are associated with carcinoma (Eaton–Lambert syndrome), drugs (penicillamine can also result in anti-ACh receptor antibodies) or other diseases.

Clinical features

Typically, the extraocular muscles and the muscles of face, tongue, neck and extremities are severely affected. Ptosis and diplopia are common early features. Disability is worsened by fatigue of the muscles, particularly towards the end of the day, but improves with rest. Other factors that can make MG worse include illnesses such as a cold, stress and overexertion.

MG can cause difficulties with speech, chewing and swallowing, as well as weakness of limbs. Speech may have a nasal quality. Problems

Fig. 16.21 Myasthenia gravis.

with swallowing, with nasal regurgitation of food and drink, may also develop (Fig. 16.21). The muscle weakness can lead to a variety of symptoms, including difficulties in:

- swallowing or mastication, causing frequent gagging, drooling or choking
- climbing stairs, lifting objects or rising from a seated position
- talking
- holding the head up
- maintaining a steady gaze
- breathing.

The Myasthenia Gravis Foundation of America Clinical Classification is as follows:

- Class I: Any eye muscle weakness, possible ptosis, no other evidence of muscle weakness elsewhere
- Class II: Eye muscle weakness of any severity, mild weakness of other muscles
 - Class IIa: Predominantly limb or axial muscles
 - Class IIb: Predominantly bulbar and/or respiratory muscles
- Class III: Eye muscle weakness of any severity, moderate weakness of other muscles
 - Class IIIa: Predominantly limb or axial muscles
 - Class IIIb: Predominantly bulbar and/or respiratory muscles
- Class IV: Eye muscle weakness of any severity, severe weakness of other muscles
 - Class IVa: Predominantly limb or axial muscles
 - Class IVb: Predominantly bulbar and/or respiratory muscles (can also include feeding tube without intubation)
- Class V: Intubation needed to maintain airway.

There is a potentially fatal complication of MG respiratory muscle involvement, particularly in the older patients: respiratory insufficiency may result from either the disease (myasthenic crisis) or treatment (cholinergic crisis).

Thymic disease is common and can also depress immunological responses; 10–25% have thymoma. There is also an uncommon syndrome of thymoma, myasthenia gravis, depressed cell-mediated immunity, chronic mucocutaneous candidosis and haematological disease (Good syndrome; Ch. 20).

General management

Examination may show muscle weakness – eye muscles are usually affected first – with normal reflexes and sensation. The diagnosis is made from the clinical features and confirmed by an edrophonium (anticholinesterase) test, sometimes supported by electrodiagnostic tests and detection of serum antibodies to ACh receptors. Other investigations that may be helpful include:

- antibodies against MUSK (muscle-specific kinase); these patients do not have evidence of thymus pathology
- HLA-B8 and DR3, with DR1 more specific for ocular myasthenia
- EMG and nerve conduction studies
- chest imaging: thymic disease should be excluded by mediastinal CT or MRI.

Myasthenia gravis very occasionally remits spontaneously but in those with thymoma the prognosis is poor. The following may be recommended:

- Scheduling of rest periods
- An eye patch (if diplopia is bothersome)
- Avoidance of stress and heat exposure (which can aggravate symptoms)
- Neostigmine or pyridostigmine
- Corticosteroids and other immunosuppressants
- Plasmapheresis
- Thymectomy.

Dental aspects

The most obvious features are facial muscle weakness, diplopia, ptosis and voice changes. Facial weakness may cause a snarling appearance as the patient attempts to smile. Weakness of the masticatory muscles may cause the mouth to hang open (hanging or lantern jaw sign) and patients typically tend to support the jaw with their hand. Occasionally, there is also furrowing, atrophy or paresis of the tongue or uvula palsy.

Occasionally, Sjögren syndrome or other autoimmune disorders, particularly pemphigus, may be associated. If there is a thymoma, there may be chronic candidosis. Salivation is increased if an anticholinesterase is being taken.

Dental treatment is best carried out during a remission, preferably early in the day, within 1–2 hours of routine medication with anticholinesterases, and with short appointments, since weakness increases during the day and fatigue or emotional stress may precipitate a myasthenic crisis.

LA is preferred but minimal doses should be given: lidocaine, prilocaine or mepivacaine can safely be used. A small oral dose of a benzodiazepine may be given if the patient is anxious, but intravenous sedation must not be given in the dental surgery since bulbar or

respiratory involvement impairs respiration. GA is an issue. Many drugs used in GA, such as opioids, barbiturates, suxamethonium, curare or anaesthetic agents, are potentiated by or aggravate the myasthenic state. Postoperative respiratory infection can result and may also cause myasthenia to worsen.

Drugs that can also worsen myasthenia and should be avoided include beta-blockers, lithium, phenytoin and some antimicrobials (aminoglycosides, clindamycin, lincomycin, quinolones, sulphonamides, tetracyclines). Penicillin or erythromycin can be used safely unless there are other issues. Occasionally, aspirin has caused a cholinergic crisis in those on anticholinesterases; paracetamol (acetaminophen) and codeine do not have this potential disadvantage.

Corticosteroids, other immunosuppressants or emotional lability may also complicate dental treatment.

Myositis ossificans

Myositis ossificans is a rare condition in which there is ossification in muscles (muscles turn to bone). Two types are recognized.

Myositis ossificans is an autosomal dominant genetic disorder with overexpression of bone morphogenetic protein 4 (BMP4) mapped to chromosome 14. The most common sites affected are the sternomastoid, paraspinal, masticatory, shoulder and pelvic girdle muscles. The abdominal muscles, extraocular muscles and gastrointestinal tract and tongue muscles are spared. ECG findings may be abnormal, while spirometry may demonstrate a restrictive pattern.

Myositis ossificans circumscripta develops in response to soft tissue injury (blunt trauma, stab wound, fracture/dislocation or surgical incision) or without known injury. Non-documented trauma, repeated small mechanical injuries and non-mechanical injuries caused by ischaemia or inflammation may also be implicated. Most ossifications (80%) arise in the thigh or arm but intercostals, erector spinae, pectoralis and gluteal muscles may be affected.

In both types of myositis ossificans the diagnosis is made by serial radiography. There is no definitive treatment; immediate immobilization with a regime of gradually increased exercise should be arranged. Analgesics, corticosteroids and adrenocorticotropin may be indicated. Genetic counselling is indicated.

Albers-Schönberg syndrome	Ch. 37
Albright syndrome	Ch. 37
Apert syndrome	Craniostenosis; syndactyly
Cheney syndrome	Osteoporosis; early loss of teeth
Cherubism	Familial symmetrical self-limiting soft-tissue jaw lesions
Cleidocranial dysplasia	See main text
Congenital hyperphosphatasia	Thickened calvarium; early loss of teeth; visual or hearing defects; blue sclerae
Crouzon syndrome	Hypoplastic mid-face; proptosis; craniostenosis; hearing defects
Ellis-van Creveld syndrome	Atrial septal defect; dwarfism; polydactyly
Gardner syndrome	Ch. 37
Gaucher disease	Ch. 37
Goldenhar syndrome	Same as Treacher Collins syndrome plus epibulbar dermoids
Gorlin syndrome	Ch. 37
Hallermann-Streiff syndrome	Cataracts; mandibular retrognathism; scanty hair
Holt-Oram syndrome	Abnormalities of thumb, wrist and clavicle; atrial septal defect
Hypophosphataemia	Vitamin D-resistant rickets; dental anomalies leading to early pulp involvement in caries
Klippel-Feil deformity	Ch. 37
Maffucci syndrome	Ch. 37
Mucopolysaccharidoses	Ch. 23
Noonan syndrome	Ch. 37
Odontomatosis	Multiple odontomas; cirrhosis; oesophageal stenosis
Ollier disease	Multiple enchondromas
Orofacial digital syndromes	Facial anomalies; fraenal hyperplasia; tongue hamartomas; digital anomalies
Osteogenesis imperfecta	See main text
Pierre Robin syndrome	Micrognathia; cleft palate; glossoptosis
Rubinstein-Taybi syndrome	Broad thumbs and toes; maxillary hypoplasia; patent ductus arteriosus
TAR syndrome	Thrombocytopenia, absent radius; atrial septal defect or tetralogy of Fallot
Treacher Collins syndrome	Hypoplastic malars and mandible; palpebral fissures slope down and out; colobomas; hearing defects
van Buchem syndrome	Generalized cortical hyperostosis; facial palsy; optic atrophy; hearing defects

APPENDIX 16.2 AMERICAN ACADEMY OF ORTHOPEDIC SURGEONS AND AMERICAN DENTAL ASSOCIATION (AAOS/ADA) CLINICAL PRACTICE GUIDELINE, 2012

The full guideline is available at: http://www.aaos.org/research/guidelines/PUDP/PUDP_guideline.pdf (accessed 30 September 2013)

SUMMARY OF RECOMMENDATIONS

The following is a summary of the recommendations of the AAOS-ADA clinical practice guideline, Prevention of orthopaedic

implant infection in patients undergoing dental procedures. This summary does not contain rationales that explain how and why these recommendations were developed; nor does it contain the evidence supporting these recommendations. All readers of this summary are strongly urged to consult the full guideline and evidence report for this information. We are confident that those who read the full guideline and evidence report will see that the recommendations were developed using systematic evidence-based processes designed to combat bias, enhance transparency, and promote reproducibility.

This summary of recommendations is not intended to stand alone. Treatment decisions should be made in light of all circumstances presented by the patient. Treatments and procedures applicable to the individual patient rely on mutual communication between patient, physician, dentist and other healthcare practitioners.

1. *The practitioner might consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures.*

Grade of recommendation: *Limited*

Definition: *A Limited recommendation means the quality of the supporting evidence that exists is unconvincing, or that well-conducted studies show little clear advantage to one approach versus another.*

Evidence from two or more "Low" strength studies with consistent findings, or evidence from a single Moderate quality study recommending for or against the intervention or diagnostic.

Implications: *Practitioners should be cautious in deciding whether to follow a recommendation classified as Limited, and should exercise judgment and be alert to emerging publications that report evidence. Patient preference should have a substantial influencing role.*

2. *We are unable to recommend for or against the use of topical oral antimicrobials in patients with prosthetic joint implants or other orthopaedic implants undergoing dental procedures.*

Grade of recommendation: *Inconclusive*

Definition: *An Inconclusive recommendation means that there is a lack of compelling evidence resulting in an unclear balance between benefits and potential harm. Evidence from a single low quality study or conflicting findings that do not allow a recommendation for or against the intervention.*

Implications: *Practitioners should feel little constraint in deciding whether to follow a recommendation labelled as Inconclusive and should exercise judgment and be alert to future publications that clarify existing evidence for determining balance of benefits versus potential harm. Patient preference should have a substantial influencing role.*

3. *In the absence of reliable evidence linking poor oral health to prosthetic joint infection, it is the opinion of the work group that patients with prosthetic joint implants or other orthopaedic implants maintain appropriate oral hygiene.*

Grade of recommendation: *Consensus*

Definition: *A Consensus recommendation means that expert opinion supports the guideline recommendation even though there is no available empirical evidence that meets the inclusion criteria.*

(Continued)

The supporting evidence is lacking and requires the work group to make a recommendation based on expert opinion by considering the known potential harm and benefits associated with the treatment.

Implications: *Practitioners should be flexible in deciding whether to follow a recommendation classified as Consensus, although they may set boundaries on alternatives. Patient preference should have a substantial influencing role.*

APPENDIX 16.3 METABOLIC MYOPATHIES

- Endocrine
 - Acromegaly
 - Diabetes mellitus
 - Hyperthyroidism

- Hypothyroidism
- Cushing syndrome and steroid therapy
- Hyperaldosteronism
- Bone disease
 - Hyperparathyroidism
 - Osteomalacia
 - Chronic renal failure
- Drugs
 - Alcohol
 - Diuretics
 - Carbenoxolone
 - Vincristine
 - Cimetidine
 - Tryptophan
- Malignant hyperthermia
- Neuromuscular disorders
 - Peroneal muscular atrophy (Charcot–Marie–Tooth disease)
 - Hypertrophic polyneuritis (Dejerine–Sottas disease)
 - Glycogen storage diseases
 - Mitochondrial myopathies

KEY POINTS

- Allergic reactions are common and increasing; some are potentially fatal
- Latex allergy is increasingly common
- Allergies may underlie asthma – and many other diseases
- Local anaesthetic allergies are rare

Allergy is an abnormal immune response (usually a type I or type IV hypersensitivity response) to an antigen – a protein or allergen. Many allergies have a hereditary component but the prevalence of allergies appears to be increasing. People who suffer allergies to one type of substance are more likely to suffer allergies to others.

Hypersensitivity responses are summarized in Table 17.1 and common allergens are shown in Table 17.2. Allergies to dental materials are discussed in Chapter 29.

Common allergens are pollen, dust mites, mould, pet dander, milk and egg proteins but, in many cases, the allergen cannot be reliably identified. The most common types of allergic type I hypersensitivity reactions include allergic rhinitis (hay fever), some asthma, eczema and urticaria – so-called ‘atopic reactions’, which affect about 10% of the population, have a strong genetic basis (and family history), and are related to antibody of immunoglobulin E (IgE) class. The first time an allergy-prone person is exposed to the allergen, T-helper

(Th2) lymphocytes produce interleukin-4 (IL-4) and interact with B cells, stimulating them to produce large amounts of IgE antibody. This attaches to receptors on basophils (in the circulation) and mast cells (in the lungs, skin, tongue and linings of the nose and intestinal tract; Fig. 17.1). When the specific allergen is encountered again, the IgE antibody–antigen reaction on basophils and/or mast cells signals them to synthesize chemical mediators (prostaglandins and leukotrienes) and to release others (histamine and heparin, as well as substances that activate platelets and later on attract eosinophils and neutrophils). This produces a rapid type I hypersensitivity response within minutes, which may be anaphylactic and cause bronchospasm and hypotension (Fig. 17.2).

Type IV (delayed) hypersensitivity, seen mainly in contact allergies, arises more slowly and less dramatically, often more than 24 hours after exposure to the allergen; it is mediated by sensitized T lymphocytes, which release cytokines that attract macrophages to the site of exposure. Table 17.3 shows common contact allergens.

Type IV reactions also appear to be involved in the pathogenesis of some chronic diseases that result in granulomas (e.g. tuberculosis, leprosy, sarcoidosis, orofacial granulomatosis and Crohn disease) characterized by foci of chronic inflammatory cells, especially macrophages, that may fuse to produce giant cells, which arise in response to certain antigens (sometimes of an unidentified nature; Box 17.1).

Why allergies appear to be increasing is unclear, but alterations in exposure to microorganisms may be an explanation. Children who live in crowded households, or who attend day care, have fewer allergies, a fact that has been attributed to microbial exposure somehow protecting against allergies. Exposure to bacterial endotoxins reduces release of inflammatory cytokines such as tumour necrosis factor alpha (TNF- α), interferon gamma (IFN- γ), IL-10 and IL-12. Toll-like receptors (TLR), which respond to microorganisms, may also be involved.

Table 17.1 Hypersensitivity reactions

Type	Alternative nomenclature	Mechanisms	Examples
I	Immediate (anaphylactic)	IgE-mediated via mast cell degranulation	Atopic disorders Anaphylaxis
II	Cytotoxic	Antibody against membrane-bound surface antigens	Pemphigus Idiopathic thrombocytopenic purpura Blood transfusion reactions
III	Immune complex	Immune complexes deposited in tissues	Systemic lupus erythematosus Rheumatoid arthritis
IV	Cell-mediated	T-lymphocyte-mediated	Contact allergies Graft rejection

Table 17.2 Common allergens

Source of allergen	Hypersensitivity	Examples
Food products	I	Milk, nuts, egg, shellfish
Drugs	I, III	Aspirin, penicillins, sulphonamides
Environmental	I, IV	Animal hair, dust mite, pollen
Latex	IV, I (rare)	Condoms, dressings, elastic bands, gloves
Dental materials	IV	Amalgam alloy, gold, mercury, resin-based materials

CLINICAL FEATURES OF ALLERGIES

Clinical manifestations of an allergic reaction are dependent upon the nature of the response, the antigenic challenge and the individual's allergic predisposition. Early symptoms and signs of a type I (immediate) hypersensitivity reaction include wheezing, breathlessness, sneezing, runny eyes, itching and urticaria, which typically occur within a few minutes to an hour. As the reaction progresses, bronchospasm, acute hypotension and angioedema of the face and laryngopharynx may result in life-threatening anaphylactic shock (Table 17.4).

Contact allergy (type IV delayed hypersensitivity), being a T-cell-mediated process, is characterized by local inflammation at the allergen contact site (skin or mucous membrane), and is usually slower and less profound. Metals, disinfectants, rubber, detergents and bonding agents can cause allergic contact (and irritant contact) dermatitis. Rashes are seen in many allergies (Fig. 17.3).

GENERAL MANAGEMENT OF ALLERGIES

Physical factors (thermal stimuli, sunlight, water, pressure) and drugs may also release histamine in susceptible individuals and cause features

Fig. 17.1 Immunopathogenesis of allergic reactions. IL = interleukin.

Fig. 17.2 Mast cell involvement in allergies. IgE = immunoglobulin E.

similar to allergies. For example, morphine can directly trigger mast cell histamine release and occasionally causes anaphylactoid reactions.

Diagnosis of an allergy is based on clinical history and presentation, including a family history of allergy; skinprick or patch testing to identify contact allergens using a battery of test allergens (*European Standard Contact Dermatitis Testing Series*; Table 17.5); or an elimination diet to identify food allergens. Patch testing is usually carried out with Finn chambers on Scanpor, a non-woven adhesive skin-friendly tape that contains no colophony. Assays of serum IgE levels (PRIST: paper radio-immunosorbent test) and serum specific IgE antibodies (RAST: radioallergosorbent test) can help. In the RAST, purified extracts of a range of allergens are coupled to cellulose or paper discs to which the patient's serum is applied. Its ability to react with one or more of these allergens is tested by adding rabbit anti-IgE labelled with radioactive iodine. The level of radioactivity then indicates the levels of specific IgE antibodies.

The *British Standard Series* of 12 allergens, used in addition to those already in the European Standard Series, includes carba mix,

Table 17.3 Common contact allergens	
Allergens	Sources
Balsam of Peru	Cosmetics, perfumes
Chromate	Bleaches, cement, dental alloys, leather, matches, tattoos
Cobalt	Dental alloys, dental and other prostheses, jewellery, polish stripper
Colophony	Polish, solder flux, sticking plaster, varnishes
Epoxy resins	Glues, resins, PVC products, surface coatings
Ethylenediamine	Antifreeze, creams, paints, rubber
Formaldehyde	Clothing, cosmetics, deodorant, newsprint, shampoo
Mercaptobenzothiazole	Catheters, glues, rubber boots and gloves
Nickel	Clothing clasps, coins, dental alloys, earrings, jewellery, spectacles
Parabens	Cosmetics, skin creams
Paraphenylenediamine	Clothing colour, hair dyes, henna, rubber
Plant allergens	Blister bush (<i>Diplophium burchanaii</i>), dahlia, garlic, onion, poison ivy, primula, sesquiterpene lactones (artichoke, boneset, burdock, chamomile, chrysanthemum, cocklebur, gaillardin, lettuce, marsh elder, mugwort, parthenium, poverty weed, pyrethrum, ragweed, sagebrush, sneezeweed, spinach, sunflower, wormwood), tulip bulbs
Plant phototoxins	Celery, fennel, orange, parsley, parsnip
Thiurams	Clothing dyes, fungicides, hair dye, rubber, stockings
Topical medications	Antihistamines (antazoline), benzocaine, chloramphenicol, neomycin, quinoline
Wool alcohols	Cosmetics, skin creams, emollients, lanolin

ethylenediamine, cetearyl alcohol, 2-bromo-2-nitropane-1,3-diol, diazolidinyl urea, chlorocresol, fusidic acid, imidazolidinyl urea and chloroxylenol.

The *Dental Series* typically includes amalgam, amalgam alloying metals, ammoniated mercury, ammonium tetrachloroplatinate,

Box 17.1 Granulomatous disorders

- Infections
 - Tuberculosis and non-tuberculous mycobacterial infections
 - Leprosy
 - Syphilis
 - Deep mycoses
 - Cat-scratch disease
 - Toxoplasmosis
- Foreign body reactions
 - To zirconium, beryllium, silicone or others
- Disorders of uncertain aetiology
 - Crohn disease
 - Orofacial granulomatosis, cheilitis granulomatosa and Melkersson–Rosenthal syndrome
 - Sarcoidosis
 - Granulomatosis with polyangiitis (formerly called Wegener granulomatosis)
- Some malignant diseases

Table 17.4 Common clinical features of allergy

Affected organ	Features
Nose	Sneezing, congested or runny nose and rhinorrhoea (allergic rhinitis)
Sinuses	Post-nasal drip and pain (allergic sinusitis)
Airways	Coughing, wheezing and dyspnoea (asthma or angioedema)
Eyes	Red, itchy, runny eyes (allergic conjunctivitis)
Ears	Discomfort and impaired hearing, due to blocked Eustachian tube (allergic rhinitis)
Skin	Eczema and hives (urticaria)
Gastrointestinal	Abdominal pain, bloating, vomiting, diarrhoea (food allergies)

**Fig. 17.3** Rash from penicillin allergy.

benzoyl peroxide, bisphenol A (Bis-GMA), diurethane dimethacrylate, ethylene glycol dimethacrylate, eugenol, 2-hydroxyethyl methacrylate (2-HEMA), hydroquinone, menthol, methyl methacrylate, palladium chloride peppermint oil, potassium dicyanoaurate, *N,N*-dimethyl-*p*-toluidine, sodium thiosulfatoaurate and triethylene glycol dimethacrylate.

Table 17.5 The European Standard Contact Dermatitis Testing Series: some allergens and their sources

Allergen	Source
Benzocaine	Benzocaine (local anaesthetic)
Cl + Me-isothiazolinone	Isothiazolinone (preservative)
Clioquinol	Clioquinol (antibacterial)
Cobalt chloride	Cobalt (metal)
Colophonium	Rosin and colophony (adhesive)
Epoxy resin	Epoxy resin (adhesive)
Formaldehyde	Formaldehyde and formalin (in clothing, cosmetics, household products)
Fragrance mix	Fragrance and perfume
Lanolin alcohol	Wool fat
Mercaptobenzothiazole	Rubber
Mercapto mix	Rubber
Methyldibromo-glutaronitrile	Preservative
<i>Myroxylon pereirae</i> resin	Balsam of Peru (fragrance)
Neomycin sulfate	Neomycin (topical antibiotic)
Nickel sulfate	Nickel (metal, coins, jewellery)
<i>N</i> -isopropyl- <i>N</i> -phenyl-4-phenylenediamine	Rubber
Parabens mix	Parabens (preservative)
4-Phenylenediamine base	Hair dye
Potassium dichromate	Chrome (cement, shoes, metal)
Primin	<i>Primula obconica</i> (plant)
Quaternium-15 (Dowicil 200)	Quaternium-15 (preservative)
Sesquiterpene lactone mix	Plant dermatitis (daisies)
4-tert-butylphenol formaldehyde resin	Para-tertiary butylphenol formaldehyde resin (adhesive)
Thiuram mix	Rubber
Budesonide	Topical corticosteroid
Tixocortol pivalate	Topical corticosteroid

No tests, however, can *reliably* predict the possibility of allergic or anaphylactic reactions. Many cases of ‘local anaesthesia (LA) allergy’ represent untoward events, such as the unintended intravenous injection of the drug, while many cases of ‘food allergy’ are of food intolerance or occasionally food poisoning only. Supposed phenomena such as systemic ‘allergy’ to amalgam restorations, ‘candida syndrome’ and ‘total allergy syndrome’ are myths.

Medications such as antihistamines or antidepressants that interfere with allergy tests must be stopped from 2 days to 6 weeks or more before testing. Resuscitation facilities must be available during allergy testing, since anaphylactic reactions can occasionally follow intradermal skin test doses, particularly of penicillin. The test procedure includes a positive control (usually histamine), a negative control – a solution without allergens, and then the test – the various suspect allergens. If the test substance provokes an allergic reaction, a raised, red, itchy wheal may develop within about 20 minutes; in general, the larger the reaction, the more sensitive is the patient. A negative skin test means that the patient is not allergic to that particular allergen. A complication of skin testing is that it can induce sensitivity to the test compound.

To avoid future allergic reactions, known allergens should be avoided, which is easier said than done, since sensitive individuals may react to minute traces and allergens can be present in the most unexpected places (more likely in commercially prepared foods and drinks than in natural products).

Table 17.6 Management of allergies

Allergen	Avoidance	Other measures
Any	Warning wristbands or bracelets detailing an individual's allergies. Avoid allergens	Patients at risk of anaphylaxis should carry adrenaline (epinephrine) in an EpiPen, Anapen or Twinject for immediate self-administration
Drugs	Accurate documentation of drug allergies in medical notes	Antileukotrienes (leukotriene receptor antagonists), such as montelukast or zafirlukast
Food products	Systematic elimination diets	Corticosteroids
House dust mite	Mite-proof bed linen and wooden floors	Cromoglicate to prevent mediator release
Pets	Avoid or exclude	Antihistamines to relieve itching and oedema
Pollens	Windows should be kept shut and grassy spaces avoided	Bronchodilators for the management of bronchospasm

Individuals with a complex history of allergy should be referred to a specialist allergy clinic for careful assessment and management. Treatments include drugs to block allergic mediators, or the activation of cells and degranulation (Table 17.6). These include antihistamines, corticosteroids and cromoglicate. Antileukotrienes (leukotriene receptor antagonists, e.g. montelukast or zafirlukast) are also effective. Intravenous injection of monoclonal anti-IgE antibodies (omalizumab), which bind to free and B-cell-associated IgE, causes their destruction. Immunotherapy by desensitization or hyposensitization is a treatment in which the patient is gradually vaccinated with progressively larger doses of the responsible allergen for at least a year – but this is potentially hazardous, as it can induce anaphylaxis.

Patients who have had serious allergic reactions are also usually advised *always* to carry adrenaline (epinephrine) with them, for subcutaneous self-administration in the event of a reaction (e.g. EpiPen; see below).

There is no reliable evidence that supports the use of alternative medicine in the control of allergies.

ANAPHYLAXIS

General aspects

Anaphylaxis is a severe life-threatening type I hypersensitivity reaction, which may affect up to 15% of the population. Hyper-IgE syndromes predispose to anaphylaxis and it is caused mainly by food, drugs, latex and insect stings (Table 17.7).

Clinical features

Bronchospasm, acute hypotension and angioedema of the face and laryngopharynx are the critical features, but there may also be flushing, dizziness and urticaria. The condition may progress to arrhythmias or cardiac arrest. The time to onset is usually indicative of the severity of the reaction (i.e. the more rapid the onset, the more severe the reaction). Most reactions occur within seconds to 30 minutes of exposure to the responsible precipitant.

General management

People at risk *must* avoid the allergens responsible and carry adrenaline (epinephrine) for immediate use to inject into the outer thigh

Table 17.7 Main precipitants of anaphylaxis^a

Latex	Drugs	Foods	Hymenoptera stings
–	Radiocontrast media	Eggs	Ants
	Chemotherapeutic agents	Fish	Bumble bees
	Asparaginase	Milk	Honey bees
	Ciclosporin	Peanuts	Hornets
	Fluorouracil	Shellfish	Wasps
	Methotrexate	Soy	
	Vinca	Tree nuts	
	Antimicrobials	Wheat

muscle. Patients should carry 2 EpiPens[®] with them because >35% of patients may require more than one adrenaline dose and up to 20% of patients will go on to develop a biphasic anaphylactic response sometimes hours later (Fig. 17.4).

ALLERGIC RHINITIS (HAY FEVER)

General aspects

There is often a positive family history. The common specific allergens are inhaled and include pollen, mould, dust mites and pet dander. Pollen from trees such as birch, alder, cedar, hazel, hornbeam, horse chestnut, willow, poplar, plane, linden/lime and olive can be responsible; in northern latitudes, birch is the most important. Grasses, especially ryegrass and timothy, may be responsible, as may various weeds.

Clinical features

Features typically include: itchy eyes, nose, roof of mouth or throat; frequent sneezing, nasal congestion and discharge; lacrimation; and

cough. Nasal polyps often develop. In the northern hemisphere, symptoms are particularly prevalent from late May to the end of June.

General management

The best management is to avoid the allergens, if possible, but this can be difficult. Medications include: topical cromoglicate (which inhibits mast-cell release of chemicals) as prophylaxis to nose and eyes or lungs; corticosteroids, such as beclometasone (which suppress the response but take 3–10 days to provide maximum relief); leukotriene receptor antagonists; or antihistamines (which suppress the symptoms but many cause sedation). Non-sedating preparations include fexofenadine, loratadine and terfenadine.

Dental aspects

Patients with allergic rhinitis may be mouth-breathers and develop mild gingival hyperplasia. No oral diseases are known to have any significant direct association with atopic disease, although aphthae and geographic tongue may possibly be more frequent. Antihistamines can cause a dry mouth. Cromoglicate was once used in an attempt to control aphthae. Corticosteroids occasionally induce candidosis.

Azole antifungals, macrolide antibiotics such as erythromycin, human immunodeficiency virus (HIV) protease inhibitors and grapefruit juice can impair metabolism of the antihistamine terfenadine and can lead to arrhythmias (torsades de pointes).

ASTHMA

See Chapter 15.

ECZEMA

See Chapter 11.

ANGIOEDEMA

Causes of angioedema include:

- allergic angioedema:
 - ◆ food (fish, shellfish, tree nuts, groundnuts [peanuts])
 - ◆ hymenoptera (sawflies, wasps, bees and ants) stings
 - ◆ latex
 - ◆ medications
- non-allergic angioedema(chronic, recurrent forms):
 - ◆ hereditary angioedema (HAE; HANE)
 - ◆ idiopathic angioedema
 - ◆ medication-acquired angioedema (angiotensin-converting enzyme inhibitors [ACEIs], non-steroidal anti-inflammatory drugs [NSAIDs]).

General aspects

Acute urticaria ('nettle rash') and angioedema are potentially dangerous reactions, which can be triggered when mast cells release histamine and other chemicals into the bloodstream, causing increased blood vessel dilatation and permeability. About 1 in 5 people will experience one of these at one time or another. The risk of urticaria and angioedema is greater if there is a history of urticaria and angioedema, other allergies or a positive family history of allergies.

Angioedema can be life-threatening if swelling blocks the airway.

Fig. 17.5 Angioedema.

Table 17.8 Laboratory findings differentiating the various forms of angioedema

Type	C4 level	C1-esterase level	C1-esterase function	C1q level
Hereditary angioedema type 1	Raised	Raised	Raised	Normal
Hereditary angioedema type 2	Raised	Normal	Raised	Normal
Acquired angioedema	Raised	Raised	Raised	Raised
Other forms of angioedema	Normal	Normal	Normal	Normal

Allergens that precipitate acute angioedema and urticaria can be: latex; foods (shellfish, peanuts, eggs and milk); drugs (e.g. penicillin, aspirin, ibuprofen, ACEIs and opioids); and animal allergens (mainly pollen, animal dander and insect stings). Physical factors that can release histamine in susceptible individuals (heat, cold, sunlight, water, pressure on the skin, emotional stress and exercise) and immune factors (e.g. blood transfusions, immune disorders, such as lupus or cancer, thyroid disorders and infections, such as hepatitis A or B) are occasionally responsible.

Clinical features

Allergic angioedema typically occurs within several minutes of exposure to an identifiable allergic trigger, including food, medications and insect stings often with acute swelling of the lips, face and tongue. Depending on the severity of the reaction, urticaria, diarrhoea, cough, wheeze, conjunctivitis and rhinitis may also be present. Characteristically, neither ACEI-induced angioedema nor HAE is associated with urticaria, but patients with HAE may have a prodromal seriginous rash, known as erythema marginatum. Features of urticaria include raised, red, often itchy skin wheals that appear and disappear most commonly where clothes rub the skin. Features of angioedema include non-pitting, asymmetric swelling of the face, lips, tongue, larynx, genitalia and extremities, especially near the eyes and lips, but also inside the throat (Fig. 17.5). Complications can include dyspnoea and anaphylaxis – bronchospasm and hypotension, sometimes causing loss of consciousness or death.

General management

Allergy tests should be made to determine the cause. Blood assays of C4 and C1inh may be indicated (Table 17.8). The standard treatment of allergic angioedema is with antihistamines such as loratadine or

cetirazine. H₂-receptor antagonists such as cimetidine and ranitidine may help control symptoms. Occasionally, for severe urticaria, systemic corticosteroids of adrenaline given subcutaneously or intramuscularly may be indicated. Montelukast or omalizumab (anti-IgE) are increasingly used.

Dental aspects

Angioedema is characterized by rapid development of oedematous swelling, particularly of the head and neck region. It is the only type of allergy that can involve the oral tissues by causing swelling, particularly the lips or the floor of the mouth. When oedema affects the neck and extends to the larynx, it can cause rapidly fatal respiratory obstruction.

There is possibly a greater risk of sensitization or of acute allergic reactions to drugs used in dentistry. Dental materials (such as mercury), which accidentally come into contact with the patient's skin, can very occasionally provoke contact dermatitis but do *not* affect the oral mucosa.

There are anaesthetic hazards in asthma, and severe asthma or anaphylaxis can occur in the dental surgery (Ch. 15). Problems may be caused by drugs, particularly corticosteroids. Beclometasone dipropionate and betamethasone valerate inhalers can cause oropharyngeal thrush in a minority. Corticosteroids absorbed from ointments used for eczema can cause adrenal suppression. Dry mouth and drowsiness affect patients taking antihistamines.

Although there may be a slightly greater prevalence of allergic diseases associated with aphthous stomatitis, there is little evidence for an allergic mechanism (Ch. 11), though in a very few patients ulceration appears to be precipitated by foods – especially walnuts, chocolate or citrus fruits.

FOOD ALLERGY AND INTOLERANCE

True food allergy, primarily mediated by IgE antibodies to food proteins, is present in 3–4% of adults and the incidence appears to be increasing. There may be a positive family history but the cause is otherwise unclear. There is evidence that breast-feeding for at least 4 months prevents or delays the occurrence of cows' milk allergy, as well as childhood atopic dermatitis and wheezing. Symptoms range from mild mouth-itching ('oral allergy syndrome') to anaphylaxis. Peanut and shellfish allergies, in particular, can be dangerous or even fatal. However, many cases of suspected 'food allergy' are actually due to food intolerance or occasionally food poisoning.

General aspects

Food allergy is an abnormal immune response to a food but is comparatively rare. There may be a positive family history of atopic disease. The most common food allergens are eggs, milk and peanuts in children; and shellfish, fish, nuts and eggs in adults (Table 17.9). Gluten intolerance is discussed in Chapter 7.

Food allergens are proteins that usually are not broken down by the heat of cooking or by gastric acid or digestive enzymes; as a result, they enter the bloodstream, to reach target organs.

Other reactions include allergic eosinophilic reactions that present with oesophagitis, gastritis or gastroenteritis; reactions such as food protein-induced enteropathy (e.g. coeliac disease; Ch. 7), proctocolitis or enterocolitis syndrome (FPIES); milk soy protein intolerance (MSPI); and Heiner syndrome – a lung disease resulting from formation of milk protein/IgG antibody immune complexes.

Table 17.9 Important allergens in foods

Food	Main types implicated
Eggs	Hens'
Fish	Cod
Fruit	Apple, cherry, peach, nectarine
Gluten	Wheat, barley, rye
Milk	Cows'
Moulds	–
Mustard	–
Nuts	Peanuts and tree nuts (e.g. walnuts, brazil nuts, almonds, hazelnut)
Sesame	–
Shellfish	Crab, crayfish, lobster, mussels, prawns, shrimp, squid
Soya	–
Sulphites	–
Vegetables	Carrot, celery, potato

Clinical features

The symptoms may begin as itching in the mouth as the person starts to eat the food responsible, followed by abdominal symptoms (vomiting, diarrhoea or pain). Then, as the food allergens enter the bloodstream, hypotension, urticaria or eczema and bronchospasm can appear.

General management

A detailed patient history and diet diary or an elimination diet, together with skin tests, PRIST and RAST, are needed but confirmation is by double-blind food challenge. Food allergy is treated by dietary avoidance, which is possible if labels are read carefully and care is taken in choosing restaurant-prepared foods. However, many allergy-inducing foods, such as peanuts, eggs and milk, can appear and be unsuspected in prepared dishes.

Symptoms can be relieved by antihistamines and bronchodilators, but patients with severe food allergies can react to minute traces of the allergen. Such patients must always avoid the allergen and should wear medical alert bracelets or necklaces stating that they have a food allergy. If subject to severe reactions, they should always carry a syringe of adrenaline (epinephrine) to self-administer and be prepared to treat an inadvertent exposure instantly.

ORAL ALLERGY SYNDROME

General aspects

Oral allergy syndrome (pollen food allergy syndrome) is an uncommon variant of the reactions described above, usually preceded by hay fever typically associated with birch-pollen allergies, but it can also affect people with allergies to the pollens of grass, mugwort (more common in Europe) and ragweed (more common in North America; Table 17.10).

The precipitating antigens are commonly Proline Rich Polypeptides (PRPs). It can arise as a cross-reaction to proteins in a variety of fresh fruits or their juices (mainly apple, orange, grape and strawberry), vegetables (particularly tomato) and nuts. Cooking often destroys the allergens (except with celery and nuts, which may cause reactions even after being cooked).

Oral allergy syndrome occasionally causes urticaria or anaphylaxis; beans, celery, cumin, hazelnut, kiwi fruit, parsley and white potato are then typically responsible.

Table 17.10 Causes of oral allergy syndrome

Pollens	Foods that may trigger an allergic reaction
Birch	Fruits: apple, apricot, cherry, kiwi, nectarine, peach, pear, plum, prune Nuts: almond, hazelnut, walnut Seeds: sunflower Vegetables: anise, beans, caraway, carrot, celery, coriander, cumin, dill, fennel, green pepper, lentils, parsnips, parsley, peas, peanuts, potato, tomato
Grass	Fruits: kiwi, melon, orange, tomato, watermelon
Mugwort	Fruits: apple, melon, watermelon Vegetables: celery, carrot
Ragweed	Fruits: banana, cantaloupe, honeydew, watermelon Vegetables: cucumber, courgettes

Box 17.2 Dental materials and health-care products that may cause allergic reactions

- Denture fixatives
- Essential oils
- Iodides
- Latex
- Metals (amalgam, gold and other alloys, nickel, wires)
- Methylmethacrylate
- Oral health-care products – mouthwashes (including chlorhexidine), toothpastes
- Periodontal dressings
- Resins (colophony, composite and epoxy)
- Rubber base materials

Clinical features

Symptoms usually develop within minutes but occasionally more than an hour later. Irritation, pruritus and swelling of the lips, tongue, palate and throat are sometimes associated with other allergic features, such as rhinoconjunctivitis, asthma, urticaria–angioedema and anaphylactic shock.

Some individuals, after peeling or touching the offending foods, may develop a rash, itching or swelling where the juice touches the skin.

General management

Individuals hypersensitive to the foods in Table 17.10 usually find that they can eat them provided that they are well cooked, tinned or microwaved. People who develop symptoms when touching or peeling these foods may prevent them by wearing gloves. Consultation with an allergologist is recommended.

FOOD INTOLERANCE

Food intolerance symptoms can resemble food allergy but enzyme defects, chemicals, additives, toxins or infections are implicated rather than the immune system.

Lactase (a gut enzyme that degrades milk lactose) deficiency is the most common; it is almost universal in people of Chinese origin and common in people of southern European or African descent, affecting at least 1 out of 10 other people. In lactase deficiency, lactose cannot be digested and remains in the gut to be used by bacteria, which produce gas, causing bloating, pain and sometimes diarrhoea.

Histamine (often along with tyramine) is a chemical present in foods such as some cheese, wines and fish (particularly tuna and mackerel); it can provoke a reaction mimicking food allergy.

Additives that may cause reactions that can be confused with food allergy include mainly caffeine, yellow dye number E5, benzoates, salicylates, tartrazine, monosodium glutamate (MSG) and sulphites.

Toxins found in some foods, such as mushrooms and potatoes, and from bacteria in putrefying meat and fish, can cause similar symptoms.

Infections are discussed in Chapter 21.

HYPERSENSITIVITY TO DRUGS AND MATERIALS

Latex allergy has become a significant clinical problem, along with iodine, Elastoplast and drug allergies (hence the acronym LIED). The drugs causing the most severe and potentially fatal reactions are

Box 17.3 People at high risk of latex allergy

- People with regular occupational exposure: health-care workers, car mechanics, caterers and electronics tradespeople
- People with atopy or dermatitis/eczema (can facilitate the transfer of antigens across the skin)
- Patients frequently exposed to latex: pre-term infants; patients who have undergone multiple surgical procedures; those with spina bifida (up to 60% may be allergic), urogenital anomalies, imperforate anus, tracheo-oesophageal fistula, ventriculo-peritoneal shunts, paraplegia, learning impairment and cerebral palsy
- People allergic to foods with known latex cross-reactivity (see Box 17.4)

penicillins and intravenous anaesthetic agents. Allergies to other drugs and materials are uncommon.

Patients may be more likely to develop hypersensitivities if they are from an affected family, have atopic disease, have HIV disease or have Sjögren syndrome.

Of the dental materials that can induce reactions (Box 17.2), latex is particularly important. Thus many clinicians have switched to using non-latex (nitrile) gloves and latex-free equipment.

Adverse reactions to other materials and drugs are discussed in Chapter 29.

LATEX ALLERGY

See also Appendices 17.1 and 17.2.

Natural rubber latex (NRL) is manufactured from the sap (latex) of *Hevea brasiliensis*, which is found in Africa and South-East Asia; it is allergenic, as are some of the chemicals added during production. NRL products that are dipped or stretchy (e.g. athletic shoes, babies’ bottles, rubber toys, balloons, condoms, gloves, teats and dummies, rubber bands, underwear, waistbands) more frequently cause allergic reactions than do dry rubber products (e.g. tubing, tyres) but by far the most common sensitizer is the rubber in the soles of shoes. Synthetic rubber is made from chemicals and does not trigger allergic reactions in people who are allergic to NRL products. Latex products are common in the home and workplace, including clinics, wards and operating theatres, where allergy is an important occupational problem, especially with abrasive hand-washing, which increases the risk of sensitization.

Allergic reactions have become increasingly common since the widespread use of protective medical/dental gloves following the advent of HIV/AIDS. Latex allergies are also now common in patients who have been frequently exposed to rubber gloves or long-term indwelling urinary catheters (Box 17.3). Latex allergy affects approximately 1%

Box 17.4 *Foods that sometimes cross-react with latex*

- Apricots
- Avocados
- Bananas
- Celery
- Cherries
- Chestnuts
- Figs
- Grapes
- Kiwi fruit
- Melons
- Nectarines
- Papaya
- Passion fruit
- Peaches
- Pineapples
- Pistachios
- Plums
- Potatoes
- Strawberries
- Tomatoes

of the general population and up to 15% of health-care workers, and is usually due to a contact allergy (type IV delayed hypersensitivity) and only rarely to a type I immediate hypersensitivity reaction. Latex exposure may occur via the skin, mucous membranes or bronchial tree with inhalation of latex glove powder (NRL allergens may attach to lubricating powder and become aerosolized, causing sensitization or, in those allergic, respiratory, ocular or nasal symptoms).

Patients with food allergies to avocado, banana, chestnut, kiwi, papaya, tomato and others (Box 17.4) may show allergen cross-reactivity to latex.

Clinical features

Usually, latex allergy develops after several previous exposures. Symptoms begin within minutes of exposure to latex and may include itching, redness and swelling of skin that touched the item. Anaphylaxis and severe asthmatic reactions have been caused by inhaling latex proteins arising from powder in the latex glove. Latex causes immediate allergic reactions ranging from pruritus to urticaria and, rarely, anaphylaxis (type I) or, more commonly, slower contact dermatitis reactions (type IV), which appear after 24–48 hours and are eczematous. 'Allergic contact dermatitis', caused by chemicals such as thiurams and carbamates used in the manufacture of rubber gloves, manifests with eczema and blisters on the hands starting 1–3 days after wearing the gloves.

General management and dental aspects

Persons with symptoms of type I latex hypersensitivity should be regarded as truly allergic, since testing for latex allergy is problematic; intradermal injection carries the risk of inducing anaphylactic shock and false positives are not uncommon in patients with RAST. Individuals with type IV reactions can have patch testing, but this is difficult to standardize because of variations in latex preparations. Skinprick tests or RAST assays can also be used.

Anything containing, or contaminated by, latex should be avoided; a latex-free clinic and environment is ideal. Latex is found in many items

Box 17.5 *Latex in medical items*

- Equipment previously handled with latex gloves
- Anaesthetic masks, props, intubation tubes, airways and other equipment
- Catheters and cannulae
- Tourniquets
- Rubber gloves
- Rubber surgical drains
- Sphygmomanometer cuffs
- Stethoscopes

Box 17.6 *Latex in dental items*

- Equipment and laboratory work previously handled with latex gloves
- Adhesive dressings and their packaging
- Amalgam carrier tips
- Bandages and tapes
- Chip syringes
- Dappens pot
- Endodontic stops
- Gloves
- Gutta percha and gutta balata
- Headgear and head positioners
- Induction masks
- Latex ties on face masks
- Local anaesthetic cartridges^a
- Mixing bowls
- Needle guards
- Orthodontic elastics
- Prophylaxis cups and polishing wheels and points
- Protective eyewear
- Rubber dam
- Rubber gloves
- Rubber sleeves on props and bite blocks
- Spatula
- Suction tips
- Surgical face masks and other protective items of clothing (e.g. gowns, overshoes)
- Tourniquets and blood pressure cuffs
- Wedges

^aLatex is present in some rubber dental LA cartridges, stoppers or plungers – either where the harpoon penetrates or where the flat piston end of a self-aspirating syringe rests. At the other end of the cartridge is the diaphragm, which the needle penetrates. Any of these components may contain latex. Although there are no documented reports of allergy due to the latex component of cartridges of dental LA, the UK preparation of prilocaine (Citanest) contains no latex.

used in hospital clinics, wards and operating theatres (Box 17.5), and even equipment and laboratory work previously handled with latex gloves may elicit an allergic response.

Many items used in dental practice can contain latex (Box 17.6).

Patients with latex type I hypersensitivity (category A)

Latex antigens must particularly be avoided for type I hypersensitivity patients. People with severe allergy reactions should:

- warn clinicians
- wear medical alert identification

Table 17.11 *Treatment of latex-sensitive patients*

History of latex allergy	Drug prophylaxis	Drug regimen
Previous anaphylaxis	Methylprednisolone	1 mg/kg 6-hourly i.v. Max. dose 50 mg
	Chlorphenamine	1 month–1 year 250 mcg/kg 1–5 years 2.5–5 mg 6–12 years 5–10 mg
Previous allergy with no anaphylaxis (e.g. urticaria, central dermatitis, facial swelling, bronchospasm)	Methylprednisolone	1–mg/kg 6-hourly i.v. Max. dose 50 mg
	Chlorphenamine	1 month–1 year 250 mcg/kg 1–5 years 2.5–5 mg 6–12 years 5–10 mg

- carry an adrenaline (epinephrine) auto-injector for emergency treatment.

They should be treated by latex avoidance and in an environment where staff are confident in their ability to manage such problems, particularly anaphylaxis. NRL-free gloves and equipment *must* be used, which may mean specialist management in a hospital latex-free environment; affected persons should contact only latex-free vinyl (polyvinyl chloride), nitrile (acrylonitrile butadiene), vitrile (a blend of vinyl and nitrile), polychloroprene (Neolon), polystyrene–poly(ethylene–butylene)–polystyrene (Tactylon), styrene butadiene, polyurethane or other polymer gloves, medical or dental products. Treatment should be scheduled for the first case of the day, when airborne latex particles should be at the lowest level. Minimum staff should be present.

If there is any possibility of contact with traces of latex, pre-medication prophylaxis with corticosteroids and/or antihistamines may be indicated (Table 17.11).

Patients with unproven latex hypersensitivity (category B)

If the history of latex allergy is dubious, treatment is best carried out as above but without pre-medication. In the absence of a latex-free clinic, care is best offered at the beginning of the day, before environmental levels of latex allergens rise as activity in the surgery continues.

APPENDIX 17.1 LATEX ALLERGY

(Adapted from: <http://www.hse.gov.uk/latex/dental.htm>)

Natural rubber latex products may impact on dental health-care workers (i.e. dentists, nurses, hygienists) because:

1. they are at greater risk of developing NRL allergy through the frequent use of NRL gloves
2. they may need to manage NRL-sensitive patients, which may be either known in advance or previously undiagnosed
3. they have a statutory responsibility to reduce risk of sensitization in themselves, their colleagues and their patients.

Ensure you have and are familiar with:

- a written *policy* – on action to protect staff from developing NRL allergy; on safe accommodation of NRL-sensitive members of staff; for the safe dental management of patients with known or suspected NRL allergy
- an *education programme* to inform new and existing staff
- *posters* for patient and staff information, clearly displayed and on file
- an *occupational health* surveillance programme, which includes pre-employment screening
- a named *responsible person* for managing health and safety.

PREVENTION OF NRL ALLERGIES

It is important that you protect yourself against breaches of the skin barrier that can result from frequent use of skin cleansers and occlusive glove-wear, especially if you have an atopic background (asthma, hay fever or flexural eczema) where damage to the skin from irritants is more common. A compromised skin barrier will increase your chances of developing type IV rubber chemical or type I NRL allergy. Hand-disinfectant agents and protective gloves need to be selected with great care and it is also important to use a suitable aqueous-based emollient at the end of the session and also at other times if your skin has any tendency to dry out.

The British Dental Association (BDA) offers the following tips on hand care:

- Don't wear jewellery (e.g. rings).
- Wash and disinfect hands at the beginning and end of each session, as well as between each glove change.
- Use cool/tepid water when washing, to keep hand temperature down.
- Use hand-wash agents sparingly.
- Rinse thoroughly to remove all traces of hand wash.
- Pat skin dry rather than rubbing it.
- Use soft towels (disposable).
- Ensure hands are dry before putting on gloves.
- Use non-powdered gloves with low levels of NRL proteins and residual chemicals.
- Choose the right size of gloves.
- Minimize contact with other potential irritants/allergens in the surgery (e.g. acrylic powders/antimicrobial solutions).
- Outside work, don't forget to protect hands when gardening/doing household chores, etc.

The Faculty of General Dental Practice UK is presently developing NRL guidelines.

If you or your patients are not NRL-sensitive and you choose to wear NRL gloves to protect yourself from blood-borne pathogens, choose powder-free and low-protein (<50 mcg/g) gloves only.

Ensure that gloves comply with national and international standards of performance (British and European Standard BSEN 455, 1993). These should carry the 'CE' mark.

(See Hand dermatitis and latex allergy, BDA Fact File, May 2008; https://www.bda.org/Images/hand_dermatitis_factfile.pdf; accessed 30 September 2013.)

MANAGEMENT OF SENSITIZED WORKERS

If you suspect that you may be allergic to NRL, it is best to seek a referral to a dermatologist or immunologist via your general practitioner or occupational health physician so that this can be appropriately investigated as soon as signs and symptoms develop.

If you are found to be NRL-sensitive, then it is essential that your work environment is adapted as soon as possible to avoid unnecessary exposure to NRL, which would increase your sensitivity and put you at risk of more severe reactions.

Type I NRL allergy

If you are diagnosed with type I allergy, it may be possible for you to continue to work in the clinical environment, although this depends on the severity of reactions you experience (see earlier).

It is important that you learn to avoid NRL proteins in consumer and medical products both at home and at work. As gloves are the main cause of allergic reactions to NRL, it is essential that you replace NRL gloves with suitable *NRL-free gloves* for yourself and ensure that you are not working in powdered NRL environments (i.e. from the use of powdered NRL gloves worn by colleagues).

A minority of allergic workers can only work symptom free in a strict NRL-free glove environment so it may become necessary for colleagues to switch to using NRL-free gloves too or other modifications to the work environment may be required.

It is recommended that you wear a Medic-Alert® bracelet.

If you have been advised to carry adrenaline (epinephrine) for self-administration (e.g. EpiPen® or Anapen®), colleagues should be instructed on how to use it.

Type IV allergy

If you are diagnosed with type IV allergy to a rubber chemical, then you need to find a glove that does not contain the chemical to which you are allergic. The dermatologist who has diagnosed this should be able to help you with appropriate glove selection.

MANAGEMENT OF A PATIENT WITH TYPE I NRL ALLERGY

(See Field EA, et al. 1998.)

Establish a *patient history* to identify whether your patient needs to be treated in an NRL-safe environment. Questions include the following:

- Has the patient ever experienced an adverse reaction (itch or swelling) to balloons, condoms or household gloves, or associated with surgery, internal examination or dental treatment?

- Does the patient have an allergy to foods cross-reacting with NRL (e.g. banana, kiwi, avocado, chestnut)?
- Has the patient experienced hives, asthma or hay-fever symptoms as a result of their work, where latex gloves are used?

Contact with natural rubber latex in dental equipment and products (including medicines) must be avoided in patients with diagnosed or suspected type 1 NRL allergy, and NRL-free alternatives used instead.

Treatment at the beginning of the working day is preferred, before environmental levels of NRL allergens rise with increased activity in the surgery.

Patients with NRL allergy have often been treated in a general dental practice without significant problems when adjustments have been made by the dental team to manage the patient's allergy. However, if the dentist is in doubt or lacks confidence (e.g. managing a highly reactive patient), the patient may need to be referred for appropriate management, possibly in a Community and Primary Dental Services or hospital setting.

All forward planning and documentation should inform future carers of the patient's sensitization by effective recording in notes and the use of *labels for patient notes*.

Possible sources of NRL in dental practice include the following:

- General:
 - Gloves
 - Rubber dam and some wedges
 - Local anaesthetic cartridges
 - Prophylaxis polishing cups
 - Orthodontic elastics
 - General anaesthesia/sedation equipment, including tubing, face masks, props
 - Endodontic stops
 - Amalgam carrier tips
 - Adhesives and dressings and their packaging
 - Equipment and laboratory work previously handled with latex gloves
- Emergency equipment:
 - Oral and nasal airways
 - Oxygen masks and nasal cannulae
 - Self-inflating bag
 - Blood pressure monitor
 - Emergency medication

For the more reactive patient or member of staff, other items should be checked for their latex content (e.g. mixing bowls, spatula, chip syringes, needle guards, dappens pot).

MANAGEMENT OF ALLERGIC REACTIONS DURING DENTAL TREATMENT

Ensure that NRL-free emergency equipment and medicines are readily available to treat any allergic reaction from mild (e.g. urticaria and asthma) to severe (i.e. laryngeal oedema/bronchospasm/cardiovascular collapse from anaphylaxis) and that staff are fully trained in resuscitation techniques.

APPENDIX 17.2 LATEX AND LOCAL ANAESTHESIA (LA)

Type	Composition	Dosage
<u>Latex-free LA</u>		
<u>Articaine</u>		
Artikent	Articaine 4% with adrenaline (epinephrine) 1:100 000	2.2 mL cartridge
Bartineest	Articaine 4% with adrenaline 1:100 000	2.2 mL cartridge
Espestesin	Articaine 4% with adrenaline 1:100 000	1.8 mL cartridge
	Articaine 4% with adrenaline 1:200 000	1.8 mL cartridge
Isonest	Articaine 4% with adrenaline 1:100 000	2.2 mL cartridge
Septanest	Articaine 4% with adrenaline 1:100 000	2.2 mL cartridge
	Articaine 4% with adrenaline 1:200 000	2.2 mL cartridge
<u>Lidocaine</u>		
Eurocaine	Lidocaine 2% with adrenaline 1:80 000	2.2 mL cartridge
Lignokent	Lidocaine 2% with adrenaline 1:80 000	2.2 mL cartridge
Lignospan Special	Lidocaine 2% with adrenaline 1:80 000	1.8 and 2.2 mL cartridge
Rexocaine	Lidocaine 2% with adrenaline 1:80 000	2.2 mL cartridge
Utilycaine	Lidocaine 2% with adrenaline 1:80 000	2.2 mL cartridge
Oraqix periodontal gel	Lidocaine 2.5% and prilocaine	2.5% 25 g tube
Xylonor gel	Lidocaine 5% 15 g tube	
Xylonor spray	Lidocaine 10% spray	36 g bottle
<u>Mepivacaine</u>		
Scandonest	Special mepivacaine 2% and adrenaline 1:100 000	2.2 mL cartridge
Scandonest	Plain mepivacaine 3%	2.2 mL cartridge
<u>Prilocaine</u>		
Citanest with Octapressin	Prilocaine 3% and felypressin 0.03 units/mL	2.2 mL standard and 2.2 mL self-aspirating cartridge
<u>Latex-containing LA</u>		
<u>Lidocaine</u>		
Xylocaine	Lidocaine 2% with adrenaline 1:80 000	2.2 mL standard and 2.2 mL self-aspirating cartridge
<u>LA that possibly contains latex</u>		
Emla cream	Lidocaine 2.5% (with or without prilocaine 2.5%)	5 g tube
Xylocaine spray	Lidocaine 10% spray	50 mL bottle
Ametop gel	Tetracaine 4%	1.5 g tube

KEY POINTS

- Autoimmune conditions are seen mainly in women and with increasing age
- Autoimmune diseases are often associated one with another, and with Raynaud disease and Sjögren syndrome

The normal immune response and tests are summarized in Chapter 19.

Many diseases are immunologically mediated and this is especially notable in allergies and autoimmunity. A genetically determined susceptibility to immunologically mediated diseases is often suggested by a positive family history, and by significant associations with certain major histocompatibility complex (MHC) histocompatibility (human lymphocyte antigen, or HLA) antigens. The genes for histocompatibility antigens are identified by a letter (A–D) and a number (e.g. HLA-D2). This chapter discusses autoimmune disorders – mainly those that affect multiple tissues; organ-specific disorders are discussed in the appropriate chapters (Table 18.1). Autoimmunity is an immune response that destroys normal body tissues. There are more than 80 different autoimmune disorders and they may result in: destruction of body tissue; abnormal growth of or changes in organ function.

The causes of autoimmune disease are unclear but heredity appears to play a role; several polymorphic genes (i.e. *HLA-DRB1*, tumour necrosis factor [*TNF*] and *PTPN22* [protein tyrosine phosphatase non-receptor 22]) influence the susceptibility to different autoimmune diseases. Regulatory T cells (Treg) fail in their function. Many organ-specific autoimmune diseases are associated with HLA-B8 and DR3, but the association is not sufficiently strong to help in the diagnosis. Rheumatoid arthritis, by contrast, is associated with HLA-DR4.

General aspects

Autoimmune diseases are caused by antibodies and T cells directed against self, produced when immune system recognition fails or

malfunctions. Autoimmune diseases may be initiated by viruses, drugs, chemicals or other factors, and affect the immune system at several levels. In patients with systemic lupus erythematosus, for instance, B cells are hyperactive while suppressor cells are underactive; it is not clear which defect comes first. Moreover, production of interleukin-2 (IL-2) is low, while levels of interferon-gamma (IFN- γ) are high. Patients with rheumatoid arthritis, who have defective suppressor T cells, continue to make antibodies to common viruses, a response that would normally cease after about 14 days. Some autoantibodies are directed against specific antigens and cause localized disease (e.g. autoantibodies to desmoglein in epithelial intercellular cement, which cause pemphigus; autoantibodies to red blood cells, which cause anaemia; autoantibodies to pancreatic islet cells, which contribute to juvenile diabetes; and autoantibodies to acetylcholine receptors, which are present in myasthenia gravis). Polyglandular autoimmune diseases are examples of autoimmune attack on many organs.

Where autoantibodies are directed against several types of cell and cellular components, including nuclear components such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA) or proteins, then generalized disease, such as systemic lupus erythematosus, may result (see Table 18.1).

Clinical features

Autoimmune diseases share common features (Table 18.2).

General management

The blood picture may show results of autoantibodies against haematological factors (e.g. haemolytic anaemia, thrombocytopenia or leukopenia). Alternatively, there may be leukocytosis associated with inflammatory processes. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often raised. Serum protein levels are also typically increased because of immunoglobulin overproduction. Specific tests for autoimmune disease include assays for serum autoantibodies (see Ch. 2 and Table 18.3). Specific autoantibodies

Table 18.1 Types of autoimmune disease

Non-organ-specific autoantibodies: the connective tissue diseases ^a	Organ or cell-specific autoantibodies ^b
Raynaud disease	Autoimmune haemolytic anaemia
Lupus erythematosus	Chronic atrophic gastritis (pernicious anaemia) ^c
Rheumatoid arthritis	Hashimoto thyroiditis
Sjögren syndrome	Idiopathic Addison disease
Scleroderma	Idiopathic hypoparathyroidism
Dermatomyositis	Idiopathic thrombocytopenic purpura
Mixed connective tissue disease	Myasthenia gravis
Antiphospholipid syndrome	Pemphigoid
	Pemphigus vulgaris

^a Probably mediated by immune complex reactions: discussed in this chapter.

^b Discussed elsewhere in this book (Section B).

^c Not all chronic atrophic gastritis.

Table 18.2 Typical features of autoimmune diseases

Clinical features	Laboratory features
Female predisposition	Hypergammaglobulinaemia
Family history often positive	Autoantibodies specific to tissue under attack sometimes present in the circulation. Circulating autoantibodies often detectable in apparently unaffected relatives. Multiple autoantibodies often detectable but frequently without clinical effect
Response to immunosuppressive treatment in many	Immunoglobulin and complement deposits sometimes detectable by immunofluorescence microscopy at sites of tissue damage (e.g. damaged blood vessels)
Patients especially liable to develop further autoimmune diseases	Associations with HLA-B8 and DR3 in some

Table 18.3 Significance of the more common antinuclear antibodies related to connective tissue diseases^a

Autoantibodies	Main associations
Anti-Jo 1 (GAD65; histidine tRNA ligase)	Polymyositis, dermatomyositis, anti-synthetase syndrome
Anti-Ku	Polymyositis/scleroderma (PM/Scl) overlap syndrome
Anti- double-stranded (anti-ds) DNA	Antibody with the highest specificity for systemic lupus erythematosus (SLE) and found in most patients
Anti-extractable nuclear antigen (anti-ENA antibodies)	SLE
Anti-5m antibody (snRNP)	
Anti-extractable nuclear antigen (anti-ENA antibodies) directed against RNP	Sjögren syndrome
Anti-Ro (Robair) = SS-A	
Anti-extractable nuclear antigen (anti-ENA antibodies) directed against RNP	Sjögren syndrome
Anti-La (Lattimer) = SS-B	
Anti-extractable nuclear antigen (anti-ENA antibodies)	Mixed connective tissue disease (MCTD), SLE
Anti-snRNP70	
Anti-PM/Scl (anti-exosome)	PM/Scl overlap syndrome
Anti-histone	Drug-induced lupus, SLE
Anti-Scl 70	
Anti-topoisomerase	Scleroderma
Anti-centromere	CREST syndrome (calcium deposits; Raynaud phenomenon; oesophageal dysfunction; sclerodactyly; and telangiectasias)

^aSee Appendix 2.6.

can be identified by special tests but often an autoantibody profile is carried out (this includes the most common abnormalities – namely, rheumatoid and antinuclear factors and thyroid microsomal, gastric parietal cell, mitochondrial, smooth muscle and reticulin antibodies). Serum complement levels may show the complement consumed when the cascade is activated by antigen/antibody reactions or other triggering factors, with complement levels (CH50) often depressed. Biopsy and tissue immunostaining may show immunoglobulin or complement deposits. Vasculitis with deposits of immunoglobulins and complement in the damaged vessel walls strongly suggests immune complex injury.

Treatments for autoimmune diseases include mainly anti-inflammatory and immunosuppressive drugs (including biologics) or plasmapheresis (removal of the antibodies).

THE CONNECTIVE TISSUE DISEASES

The connective tissue diseases (collagen diseases) are autoimmune diseases that share, to a variable degree, common features, such as: multiple autoantibodies, often against nuclear components (antinuclear antibodies [ANAs]; see Table 18.3); immune complex reactions; associations with Raynaud phenomenon and Sjögren syndrome; responsiveness to immunosuppressives; and malignancy as a possible late complication.

Antinuclear antibodies

ANAs are found in a number of different autoimmune diseases (such as systemic lupus erythematosus, Sjögren syndrome, rheumatoid

arthritis, polymyositis, scleroderma, juvenile diabetes mellitus, Addison disease, vitiligo, pernicious anaemia, glomerulonephritis); infections (viral or bacterial, mainly); lung diseases (primary pulmonary fibrosis, pulmonary hypertension); gastrointestinal diseases (ulcerative colitis, Crohn disease, primary biliary cirrhosis, alcoholic liver disease); hormonal diseases (Hashimoto autoimmune thyroiditis, Graves disease); blood diseases (idiopathic thrombocytopenic purpura, haemolytic anaemia), cancers (melanoma, breast, lung, kidney, ovarian and others); and skin diseases (psoriasis, pemphigus). They are also found in those people with a family history of rheumatic diseases and in older patients, and in association with some drugs, including procainamide, hydralazine and phenytoin. Since ANAs appear in several types of disease, they have a low specificity.

ANAs can present different ‘patterns’ on histology, depending on the staining of the cell nucleus in the laboratory – homogeneous or diffuse; speckled; nucleolar; and peripheral or rim – but these patterns are not specific for any particular illness, though (for example) the nucleolar pattern is more commonly seen in scleroderma. ANAs can be found in approximately 5% of the normal population, usually in low titres; these people rarely have disease. ANA titres of 1:40 or below are considered negative. Titres lower than 1:80 are unlikely to be significant. Higher titres may be indicative of disease, but even these levels are often insignificant in patients over 60 years of age. Nevertheless, the sensitivity and simplicity of an ANA test makes it popular as a screen for lupus in particular, since most affected people (more than 95%) test positive, and thus a negative ANA test can be helpful in excluding lupus. Only about 11–13% of people with a positive ANA test do have lupus and up to 15% of completely healthy people have a positive ANA test. Thus a positive ANA test does not necessarily mean a diagnosis of lupus or, indeed, any autoimmune disease. Tests for ANA sub-serologies (including antibodies to double-stranded DNA, Smith, RNP, SSA, SSB, Scl-70 and centromere) are usually negative if ANA is negative. Exceptions include anti-Jo1, which can be positive in some forms of myositis, or occasionally anti-SSA, in the setting of lupus or Sjögren syndrome. Broad testing of autoantibodies should be avoided; instead, the choice of autoantibodies should be guided by the specific disease under consideration.

RAYNAUD DISEASE AND RAYNAUD PHENOMENON

Raynaud phenomenon manifests as recurrent vasospasm of the fingers and toes – usually in response to stress or cold exposure. Raynaud phenomenon is characterized by skin arteries that over-respond to cold, contracting briefly and limiting blood flow (vasospasm), so that the skin first turns white, then blue and finally red, as the arteries relax and blood flows again. Women are mainly affected.

Primary Raynaud disease (idiopathic Raynaud disease) is characterized by vasospasm alone and has no obvious cause, but 10–30% eventually progress to secondary Raynaud disease. Older patients and males often have vasospastic symptoms that predate systemic disease by as many as 20 years. Young female patients who have had Raynaud phenomenon alone for more than 2 years and have not developed any additional manifestations are, however, at low risk for developing autoimmune disease.

Secondary Raynaud disease is a term used when vasospasm is associated with another condition – most commonly an autoimmune disease, and usually progressive systemic sclerosis and mixed connective-tissue disease. Raynaud phenomenon has also been described with disorders such as cryoglobulins, vibration injury, polyvinyl chloride (PVC) exposure and drugs (e.g. some cardiovascular drugs and ergotamine). In older patients with recent-onset Raynaud phenomenon and no obvious underlying cause, malignancy must also be excluded.

Fig. 18.1 Raynaud syndrome. Patients often wear gloves.

Fig 18.2 Loss of digit and atrophy of distal phalanges in severe Raynaud syndrome.

Clinical features

Symptoms include changes in skin colour (white to blue to red) and coldness (Fig. 18.1). Both hands and feet are usually affected. Raynaud phenomenon can sometimes attack other areas too, such as the nose and ears. It is common for the affected area to feel numb or prickly. Primary Raynaud disease usually affects both hands and both feet, while secondary Raynaud phenomenon may affect either both hands or both feet only.

The condition tends to be slowly progressive, with more frequent and prolonged episodes of spasm. Ischaemia can cause atrophy of the fat pads or ulceration at the tips of the fingers or toes, sometimes with the loss of more tissue (Fig. 18.2).

General management

Diagnosis is made from the fact that the attacks are triggered by exposure to cold and/or stress, symmetric bilateral involvement, an absence of necrosis, no detectable underlying cause, normal capillaroscopy findings, normal laboratory findings for inflammation, and an absence of antinuclear factors.

People suffering from Raynaud phenomenon should stop smoking (nicotine is vasoconstricting), protect themselves from cold, keep all their body warm – not just their extremities – and guard against cuts, bruises and other injuries to affected areas.

Primary Raynaud disease

Pharmacological therapy may include:

- angiotensin-receptor antagonists (losartan)
- calcium-channel blockers (e.g. nifedipine)
- fluoxetine
- iloprost (prostacyclin analogue)
- inositol nicotinate
- naftidrofuryl
- nitroglycerin (topically)
- prostaglandins (intravenously)
- reserpine.

Secondary Raynaud disease

Therapy should be tailored to the underlying disorder:

- Hyperviscosity syndromes and cryoglobulinaemia improve with treatments that decrease blood viscosity (e.g. plasmapheresis).
- Hepatitis B, hepatitis C and *Mycoplasma* infections need treating.

Pharmacological therapy is as for primary Raynaud disease.

Dental aspects

The dental environment should be kept at a comfortable temperature and humidity. Nifedipine may cause gingival swelling. Sjögren syndrome may be present.

LUPUS ERYTHEMATOSUS

Lupus can be categorized as systemic lupus erythematosus (SLE), drug-induced SLE or discoid lupus erythematosus (DLE).

Systemic lupus erythematosus

General aspects

SLE is a potentially fatal disease characterized by autoantibodies to DNA (anti-dsDNA [double strand DNA] antibody is peculiar to SLE). The immune complex reactions, in particular vasculitis, result in multisystem disease. Lupus susceptibility relates to several genes, including *HLA-DR3* and *B8*, *HLA-DR2*, complement *C4* genes and a polymorphism of the T-cell receptor that has been associated with Ro (SS-A) antibodies.

Clinical features

SLE can cause a variety of clinical manifestations, which differ greatly in severity, ranging from mild to significant and potentially fatal lesions. The onset may be acute, resembling an infection, or there may be vague symptoms that may progress over many years (Table 18.4). The acronym SOAPBRAIN may serve as an *aide-mémoire* (serositis; oral ulcers; arthritis; pericarditis; blood problems; renal; ANA; immune; neurological).

The classic picture of SLE is that of a young woman with fever, malaise, anaemia, joint pains, Raynaud phenomenon and a rash variable in character but erythematous, often with raised margins and scaling (Fig. 18.3). The well-known rash, with a butterfly pattern extending over both cheeks and bridge of the nose, is relatively uncommon and not specific to lupus erythematosus. Photosensitivity rashes are common. Renal involvement (proteinuria and haematuria) is frequently seen and often associated with hypertension. Relatively

Table 18.4 Manifestations of systemic lupus erythematosus

System	Main lesions
Skin	Rash
Joints	Arthritis Polyarthralgia
Serous membranes	Pericarditis Pleurisy
Cardiovascular	Endocarditis (Libman–Sacks) Myocarditis Raynaud phenomenon
Lungs	Pneumonitis
Kidney	Nephritis
Neurological	Cranial nerve palsies Neuroses Psychoses Strokes
Eye	Conjunctivitis Retinal damage
Gastrointestinal	Hepatomegaly Pancreatitis
Blood	Sjögren syndrome Anaemia Purpura

Fig. 18.3 Raynaud syndrome in lupus.

minor disturbances of mood, and depressive or hysterical behaviour, are common, while central nervous system (CNS) involvement is potentially fatal. Ocular lesions may affect 20–25%, and serositis can cause pleurisy or occasionally pericarditis and peritonitis (polyserositis) (Fig. 18.4).

Cardiac lesions typically cause myocarditis, which leads to cardiac failure; there is a higher risk of infarction, and a characteristic (Libman–Sacks) endocarditis can also develop. Murmurs are more often caused by anaemia.

Women who have SLE can pass antibodies across the placenta, which can cause fetal heart block (see Sjögren syndrome).

General management

The American College of Rheumatology diagnostic criteria for SLE are based on the presence of at least four of the following:

- Malar rash
- Discoid rash

Fig. 18.4 Lupus erythematosus.

- Photosensitivity
- Oral ulcers
- Arthritis
- Serositis (pleuritis or pericarditis)
- Renal disorder (persistent proteinuria or cellular casts)
- Neurological disorder (seizures or psychosis)
- Haematological disorder (anaemia, leukopenia or lymphopenia on two or more occasions, thrombocytopenia)
- An immunological disorder (positive lupus erythematosus cell preparation, anti-DNA or anti-Sm, false positive Venereal Disease Reference Laboratory [VDRL] test).

Initial screening includes ESR, autoantibodies (e.g. ANA; Box 18.1), a full blood count, liver and kidney function tests, syphilis screen (VDRL), lupus erythematosus cell test, urinalysis and blood chemistries. No single laboratory test can definitely prove or exclude SLE, but anti-Sm antibody or high-titre anti-native DNA antibody is an important indication (see Table 18.3); anti-dsDNA is peculiar to SLE and the titre of anti-DNA antibodies correlates well with disease activity. About 70% of patients have antibodies against double-stranded RNA (anti-dsRNA) or against hybrid RNA/DNA molecules. Other autoantibodies (e.g. anti-SS-A and anti-SS-B) may be helpful. About 40% of patients also have antibodies directed against phospholipid – and about 15% of patients have the antiphospholipid syndrome (APS; see later).

Biopsies of skin or kidney using immunofluorescent staining techniques can support the diagnosis of SLE.

Most patients appear to do well in the long term either with non-steroidal anti-inflammatory drugs (NSAIDs) or, if these are

Box 18.1 Investigation findings in systemic lupus erythematosus

- Antinuclear antibodies
 - Anti-DNA antibodies, especially anti-double-stranded DNA (crithidial)
 - Anti-RNA antibodies
- Circulating antibodies to platelets and other blood cells
- Raised erythrocyte sedimentation rate
- Hypergammaglobulinaemia
- Hypocomplementaemia
- Lupus erythematosus cell phenomenon
- Rheumatoid factor (30%)
- Venereal Disease Reference Laboratory (VDRL) false positive

ineffective, on low doses of corticosteroids taken on alternate days. Other treatment options currently available include hydroxychloroquine and other immunosuppressive medications (e.g. azathioprine, ciclosporin, cyclophosphamide, mycophenolate or sirolimus), as well as a range of biological agents (abatacept, abetimus, anakinra, atacicept, belimumab, edratide, efalizumab, epratuzumab, infliximab, rituximab, rontalizumab, sifalimumab and tocilizumab). SLE has a 5-year survival rate of more than 90%.

Dental aspects

Oral lesions, which typically consist of erythematous areas, erosions or white patches, fairly symmetrically distributed and resembling lichen planus, may be seen in 10–20% of patients with SLE and are rarely an early feature. Slit-like ulcers may also be seen near the gingival margins. The best management of erosive lesions of SLE in the oral mucosa is uncertain but corticosteroids, often in high doses, may be the only effective treatment. Biopsies of oral lesions show irregular epithelial thinning and acanthosis, basement membrane thickening, liquefaction degeneration of the basal cell layer and an irregularly distributed chronic inflammatory infiltrate. Vasculitis is inconstant. Immunofluorescent staining shows lumpy deposits of immunoglobulins and complement perivascularly and along the basement membrane of lesions, and under normal skin or mucosa in up to 90% of patients with SLE. Sjögren syndrome is associated in up to 30%. Antimalarials, sometimes used to control SLE, can cause lichenoid oral lesions or occasionally oral hyperpigmentation.

Surgery may exacerbate SLE symptoms and, if elective, should therefore be postponed until lupus activity subsides. Hospitalization may be required for otherwise minor procedures and postoperative discharge may be delayed.

Tetracyclines may cause photosensitivity rashes while sulphonamides or penicillins may lead to deterioration in SLE. Bleeding tendencies are caused by thrombocytopenia; circulating anticoagulants rarely cause a bleeding tendency – rather they predispose to thrombosis. Other aspects to consider are corticosteroid or other immunosuppressive therapy (Ch. 35), renal disease (Ch. 12) and anaemia (Ch. 8).

Drug-induced lupus (Table 18.5) has some features similar to those of SLE, particularly pleuropericardial inflammation, fever, rash, arthritis and serological changes. The clinical and serological signs of the lupus erythematosus usually subside gradually after the offending drug is discontinued.

Table 18.5 Drugs associated with lupoid reactions

Drugs having a proven association with LE	Drugs having a possible association with LE
Chlorpromazine	Beta-blockers
Hydralazine	Captopril
Isoniazid	Carbamazepine
Methyldopa	Cimetidine
Procainamide	Etanercept
	Ethosuximide
	Methimazole
	Phenazine
	Phenytoin (diphenylhydantoin)
	Quinidine

Discoid lupus erythematosus

General aspects

Discoid lupus erythematosus (DLE) is essentially a mucocutaneous disease in which the rashes may be indistinguishable from those of SLE, but serological abnormalities are typically absent or minor, there are no serious systemic effects and it only rarely progresses to SLE.

Clinical features

DLE is characterized by a rash, usually on the face or other sun-exposed areas, or by mucosal lesions. The skin lesions are patchy, crusty, sharply defined plaques that may scar. DLE may cause patchy, bald areas on the scalp, and hypopigmentation or hyperpigmentation in older lesions. Arthralgia is a frequent complaint.

General management

Lesional biopsy will usually confirm the diagnosis. Topical and intralesional corticosteroids are usually effective for localized lesions; antimalarial drugs may be needed for more generalized lesions.

Dental aspects

Oral mucosal lesions can be a feature of DLE and may also simulate lichen planus, but the lesions are less often symmetrically distributed and the pattern of striae is typically less well defined or conspicuous. Nevertheless, differentiation can be difficult and biopsy is essential. Even this may not be diagnostic and, occasionally, histological appearances that are intermediate between those of lichen planus and lupus erythematosus are seen. Management is as for the oral lesions of SLE but DLE may have some malignant potential.

RELAPSING POLYCHONDritis

Relapsing polychondritis (RP) is a severe, episodic and progressive inflammatory condition associated with antibodies to cartilage-specific collagen types II, IX and XI. RP affects cartilaginous structures, predominantly those of the ears, nose and laryngotracheobronchial tree. Other affected structures may include the eyes, cardiovascular system, peripheral joints, skin, middle and inner ear, and CNS. Aphthous-like oral ulceration has been described and the MAGIC variant of Behçet syndrome is a differential diagnosis. Management is with systemic corticosteroids.

RHEUMATOID ARTHRITIS

See Chapter 16.

SJÖGREN SYNDROME

General aspects

Sjögren syndrome (SS) is the association of dry mouth (hyposalivation) with dry eyes. It mainly affects middle-aged or older women. SS affects up to 5% of women and 0.5% of men.

Primary SS ('sicca syndrome') is the association of dry mouth with dry eyes in the absence of any connective tissue disease. Secondary SS refers to the association of dry mouth and dry eyes with another connective tissue disease – usually rheumatoid arthritis (RA) and, less frequently, thyroiditis, primary biliary cirrhosis, SLE, progressive systemic sclerosis or polymyositis. It is unclear how distinct the various forms are. The initial definition and diagnostic criteria for SS were the presence of 'keratoconjunctivitis sicca ("dry eyes"), xerostomia ("dry mouth") and RA or other connective tissue disease', and 'two of the three are generally considered sufficient for the diagnosis'. Patients who developed the dry eye/mouth components of SS without developing RA were initially labelled as having the 'sicca syndrome', and later 'primary SS', while those with RA who usually developed the dry eye/mouth components after onset of their joint disease were labelled as having 'secondary SS'.

SS is an autoimmune exocrinopathy. Lacrimal, salivary and other exocrine glands are infiltrated by lymphocytes and plasma cells, causing progressive acinar destruction and often multisystem disease. The aetiology may involve genetic factors; a range of loci have been implicated (Box 18.2). SS-A and SS-B autoantibodies activate caspase-3 and apoptosis, which could be responsible for impaired salivary secretory function. In SS, several neuroendocrine system functions are also impaired. Anti-muscarinic type 3 receptor (α-M3R) autoantibodies in SS inhibit intracellular trafficking of aquaporin-5 (AQP5), the water transport protein, leading to secretory dysfunction. Raised T-helper 1 (Th1) cytokines (IL-10 and IL-6) are seen in SS and correlate with the clinical manifestations of disease. High levels of cytokines from Th1 (IL-2, IL-2) and Th2 (IL-6, IL-10), and chemokines (CKs) CXCL13, CCL21 and CXCL12, which play roles in lymphoid tissue organization and the development of lymphoid malignancies, are expressed in salivary glands of patients with SS and mucosa-associated lymphoid tissue (MALT) lymphoma. Th1, Th2, Th17 and Reg (the regenerating gene) may also be involved in SS pathogenesis.

Clinical features

SS is characterized by dryness of all mucosae. Dry mouth can be a real complaint and salivary glands may swell (see below), but the most important effects are on the eyes, where drying causes keratoconjunctivitis

sicca. This can ultimately lead to impairment or loss of sight. Patients with dry eyes may have no symptoms or may complain of grittiness, burning, soreness, itching or inability to cry. They may wake in the morning with a pustular exudate in the eyes or crusting at the canthus, or have infections of the lids (Fig. 18.5). Lacrimal glands may swell.

Raynaud phenomenon or other autoimmune manifestations are common. Multisystem disease can manifest with extraglandular complications, as shown in Table 18.6 and Figure 18.6.

Extraglandular disease may precede exocrine problems by years and is found in 50% of SS-1. Fatigue, fever and Raynaud phenomenon are common early on; later complications include glomerulonephritis, lymphoma and skin problems (itching or cracking). Vaginal dryness causing painful intercourse is a frequent complaint. Lung disease can result from aspiration or bronchial dryness. Bronchitis, tracheobronchitis and laryngotracheobronchitis are common. Renal disease (interstitial nephritis) is an important complication. Peripheral nervous system involvement may present with carpal tunnel syndrome, peripheral neuropathy or cranial neuropathy such as trigeminal neuropathy. Gastrointestinal complaints may include dysphagia, heartburn, abdominal pain and swelling, anorexia, diarrhoea and weight loss.

Autoimmune thyroid disorders can appear as either an overactive thyroid (Graves disease) or an underactive thyroid (Hashimoto thyroiditis). Nearly half of the people with autoimmune thyroid disorder also have SS, and many people with SS show evidence of thyroid disease.

Fig. 18.5 Sjögren syndrome: dry eyes.

Table 18.6 Sjögren syndrome

- Interleukin-10
- Immunoglobulin kappa-chain allotype KM1
- SS-A1
- STAT4
- Tumour necrosis factor

Fig. 18.6 Sjögren syndrome.

Women who have SS can pass autoantibodies across the placenta into the fetal circulation, which can lead to heart block. Though it can be fatal, the long-term outlook for the child with heart block is generally good, but most require pacemakers, usually for life.

About 5% of people with SS develop lymphomas, mainly people with SS-1. Most (45–75%) are MALT lymphomas, usually affecting the parotid salivary glands. Risk factors for lymphoma are shown in Box 18.3.

Allergic drug reactions are frequent to penicillins and cephalosporins. Systemic reactions to trimethoprim present with CNS symptoms or aseptic meningitis. There are also rare associations of SS with a number of conditions (Box 18.4).

General management

Screening questions to assess ocular and oral symptoms (Box 18.5) may help identify patients. Dehydration, drugs, irradiation and infections can also cause dry mouth and dry eyes, and should be ruled out (Box 18.6).

There is no single gold standard test or agreement on criteria for diagnosing SS. Diagnosis is often based on American–European Consensus criteria (Table 18.7).

An ophthalmological examination is important; a Schirmer test shows impaired lacrimation (Fig. 18.7) and an ocular staining score and tear break-up time are useful. Serum autoantibodies, especially antinuclear antibodies SS-A (Ro: Robair) or SS-B (La: Lattimer), are a common diagnostically helpful and non-invasive approach. Hypergammaglobulinaemia is seen mainly as a result of rheumatoid factor.

Box 18.3 Risk factors for lymphoma in Sjögren syndrome

- Cryoglobulinaemia
- Hypocomplementaemia C4
- Monoclonal gammopathy
- Palpable purpura
- Peripheral neuropathy
- Persistent bilateral parotid swelling
- Reduced CD4 lymphocytes
- Vasculitis

Box 18.4 Rare associations with Sjögren syndrome

- Hereditary angioedema
- Phenytoin
- Primary amyloidosis
- Sarcoidosis
- Sweet syndrome
- Ulcerative colitis and selective IgA deficiency

Box 18.5 Screening questions for dry mouth and dry eyes

- Have you had a daily feeling of dry mouth for more than 3 months?
- Have you had recurrently or persistently swollen salivary glands as an adult?
- Do you frequently drink liquids to aid in swallowing dry foods?
- Have you had a daily feeling of persistent troublesome dry eyes for more than 3 months?
- Do you have a recurrent sensation of sand or gravel in the eyes?
- Do you use a tear substitute more than 3 times a day?

Box 18.6 Conditions to be differentiated from Sjögren syndrome

- Drugs
- Irradiation
- Infections (hepatitis C virus [HCV], human immunodeficiency virus [HIV] and human T-cell lymphotropic virus 1 [HTLV-1])
- Infiltrative diseases:
 - Amyloidosis
 - Haemochromatosis
 - Hyperlipoproteinaemias (types II, IV, V)
 - IgG₄ syndrome
 - Sarcoidosis
 - Graft-versus-host disease

Salivary flow rates can confirm the presence and degree of hyposalivation but are non-specific. Whole saliva collected without stimulation by allowing the patient to dribble into a sterile container over a measured period is now regarded as the best form of sialometry. A value below 1.5 mL/15 min is regarded as abnormal. Parotid output after stimulation with 10% citric acid can also be objectively determined by using a suction (Lashley or Carlsson–Crittenden) cup over the parotid duct orifice or by cannulation of the duct, but has no advantage. A value below 1.0 mL/min is regarded as abnormal.

Table 18.7 Diagnostic criteria (American–European) for Sjögren syndrome^a

Type	Criteria	Detail
I Ocular symptoms	A positive response to at least one of the following questions:	1. Have you had daily ocular symptoms or persistent, troublesome dry eyes for >3 months? 2. Do you have a recurrent sensation of sand or gravel in the eyes? 3. Do you use tear substitutes >3 times a day?
II Oral symptoms	A positive response to at least one of the following questions:	1. Have you had a daily feeling of dry mouth for >3 months? 2. Have you had recurrently or persistently swollen salivary glands as an adult? 3. Do you frequently drink liquids to aid in swallowing dry food?
III Ocular signs	That is, objective evidence of ocular involvement defined as a positive result for at least one of:	1. Schirmer's 1 test, performed without anaesthesia (<5 mm in 5 min) 2. Rose Bengal score or other ocular dye score (>4 according to van Bijsterveld's scoring system)
IV Histo-pathology	In minor salivary glands (obtained through normal-appearing mucosa)	Focal lymphocytic sialadenitis evaluated by an expert histopathologist, with a focus score > 1, defined as a number of lymphocytic foci (which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes) per 4 mm ² of glandular tissue
V Salivary gland involvement	Objective evidence of salivary gland involvement, defined by a positive result for one of the following:	1. Unstimulated whole salivary flow, 1.5 mL in 15 min 2. Parotid sialography showing the presence of ductal sialectasis (punctate, cavitory or destructive pattern) without evidence of obstruction in the major ducts 3. Salivary scintigraphy showing delayed uptake, reduced concentration and/or delayed excretion of tracer
VI Auto-antibodies	Presence in the serum of the following autoantibodies:	Antibodies to Ro (SS-A) or La (SS-B) antigens, or both

^aNot universally accepted. Many now undertake ultrasonography.

Table 18.8 Sjögren syndrome – comparison of subtypes

Feature	Primary	Secondary
Other connective tissue disease	–	+
Ocular involvement	More severe	Less severe
Extraglandular manifestations	More common	Less common
Oral involvement	More severe	Less severe
Recurrent sialadenitis	More common	Less common
Risk of lymphoma	More common	Less common
Human leukocyte antigen (HLA) associations	HLA-DR3	HLA-DR4, HLA-B8
Rheumatoid factor	50%	90%
Anti-SS-A (Ro)	5–10%	50–80%
Anti-SS-B (La)	50–75%	1–5%
Rheumatoid arthritis precipitin (RAP) ^a	5%	75%

^aAlso known as SS-C.

Labial gland biopsy is one of the more specific investigations. The parotid glands are chiefly affected but the changes usually are also present in the other glands, including the minor labial glands (such as in the lower lip). Labial gland biopsy is easier and safer, and usually reflects the parotid changes. Ultrasound in particular is non-invasive and inexpensive, and is considered positive for SS if the major glands show hypoechoic areas, echogenic streaks and/or irregular gland margins. It is also helpful in excluding lymphoma.

Other investigations may include sialography, scintigraphy and magnetic resonance imaging (MRI). Sialography, though non-specific and time-consuming, is helpful but is of course contraindicated if there is acute parotitis. Hydrostatic instillation of contrast medium typically shows a snowstorm appearance (punctate sialectasis) in well-established cases. Scintigraphy measures radioactive pertechnetate uptake and concentration in the major glands, but involves the use of radioisotopes, depends on the availability of specialized equipment and appears to have little place. MRI is helpful.

Sialochemistry is theoretically helpful; SS alters the protein profile and brings about a change in the composition of saliva with an increase in the levels of lactoferrin, beta₂-microglobulin, sodium, lysozyme C and cystatin C, and a decrease in salivary amylase and carbonic anhydrase.

Primary SS (SS-1) tends to be a more aggressive disorder than secondary SS (SS-2; Table 18.8). Management is largely symptomatic, though there have been attempts at immunosuppression to control the disease process. This may increase the risk of lymphomatous change. Cyclophosphamide may help control renal and vascular disease, and polyneuropathy. Mizoribine, a nucleoside produced by *Eupenicillium brefeldianum* with antibiotic, cytotoxic and immunosuppressive activity, may be effective. Mycophenolate, epratuzumab (anti-CD22 monoclonal antibody) and rituximab (anti-CD20 monoclonal antibody) may be helpful. Anti-TNF biological agents (infliximab, etanercept), ciclosporin, azathioprine, hydroxychloroquine, methotrexate and NSAIDs are of no reliable value.

Lymphoma predictors include swelling of salivary glands, lymph nodes, liver or spleen; vasculitis; lung infiltrates; fever; neuropathy or purpura; or blood changes (hypergammaglobulinaemia, anaemia, hypocomplementaemia, cryoglobulinaemia or hypocomplementaemia). Lymphomas may be best diagnosed with high-resolution computed tomography (CT), MRI, MRI contrast sialography (gadolinium MRI with fat subtraction) or ultrasonography and biopsy. They may respond to chemotherapy but rituximab may also be used.

**Fig. 18.7** Schirmer strip to test lacrimal flow.

Dental aspects

Oral involvement in SS results in discomfort caused by the poor salivary flow, obvious dryness of the mucosa in severe cases, and erythema and lobulation of the tongue. Apart from its dryness, the oral mucosa may appear normal but the supervention of candidal infection causes redness and soreness.

The other main effects of persistent hyposalivation can include difficulty in speaking, swallowing or managing dentures; disturbed taste sensation; accelerated caries; and susceptibility to oral candidosis and ascending (bacterial) sialadenitis.

Swelling of the parotid salivary glands is seen in a minority. Rarely, these glands can also be persistently painful. Late onset of salivary gland swelling, especially in sicca syndrome, may indicate development of a lymphoma (see Box 18.3).

Dry mouth may be helped symptomatically by simple methods. Frequently sipping water or sugar-free drinks, sucking ice or using frequent, liberal rinses of a salivary substitute (mouth-wetting agent) containing carboxymethyl cellulose or mucin may help.

Salivation may be stimulated by sialogogues. Simply chewing sugar-free gum or sucking citrus or malic acid lozenges may help salivation. Pilocarpine 5 mg three times daily with meals, or pyridostigmine, may improve salivation if any functional tissue remains, but systemic effects such as sweating, diarrhoea and blurred vision may be troublesome and there may be arrhythmias. Cevimeline is a newer alternative.

Preventive dental care is important. Patients have a tendency to consume a cariogenic diet because of the impaired sense of taste. This must be avoided and caries should also be controlled by fluoride applications and amorphous calcium phosphate. Use of a chlorhexidine mouthwash will help to control periodontal disease and other infections. Denture hygiene is important because of susceptibility to candidosis; antifungal treatment is often also needed.

Infections should be treated. Generalized soreness and redness of a dry oral mucosa is typically caused by *Candida albicans* and often associated with angular stomatitis. Antifungal treatment is given as rinses of nystatin, or topical miconazole or fluconazole. Acute complications, such as ascending parotitis, should be treated with antibiotics. Pus should be sent for culture and antibiotic sensitivities, but in the interim, a penicillinase-resistant penicillin, such as flucloxacillin in combination with metronidazole, should be started because of the possible presence of anaerobes.

No crowns should be constructed until caries is controlled and there are no new lesions for more than 1 year.

Patients with SS who need dental treatment may not be good candidates for general anaesthesia (GA) because of the tendency to respiratory infections. It is important to lubricate the eyes and throat, to humidify the gases, to avoid drying agents (e.g. nicotine, atropine, phenergan), to be conscious of the possibility of cervical spine involvement in RA, to maintain body heat (because of Raynaud disease) and to consider renal function.

There may also be problems in management related to the associated connective tissue disease and complicating factors such as anaemia (Ch. 8).

There is a higher incidence of drug allergies in SS. Trimethoprim may induce a systemic reaction of fever, headache, backache and meningeal irritation (trimethoprim-induced aseptic meningitis).

IGG₄ SYNDROME

Mikulicz disease (MD) was the term given to the condition of persistent salivary and lacrimal gland enlargement. MD has been included in the differential diagnosis of SS-1, but it represents a unique condition

Box 18.7 Diagnostic features of IgG₄ disease

- Visual confirmation of symmetrical and persistent swelling in more than two lacrimal and major salivary glands
- Prominent IgG₄-positive mononuclear cell infiltration of lacrimal and salivary glands
- Exclusion of other diseases that present with glandular swelling, such as Sjögren syndrome, sarcoidosis and lymphoproliferative disease
- IgG₄ raised serum levels

with persistent lacrimal and salivary gland enlargement, few autoimmune reactions and good responsiveness to glucocorticoids, leading to the recovery of gland function. The diagnostic features are shown in Box 18.7.

Many cases previously classified as Mikulicz disease, Küttner tumour and orbital pseudotumour (idiopathic orbital inflammation), however, show increased numbers of IgG₄-positive plasma cells, and some also show elevated levels of serum IgG₄, supporting the concept of IgG₄-associated sialadenitis/dacroadenitis. Complications include autoimmune pancreatitis, retroperitoneal fibrosis, tubulo-interstitial nephritis, autoimmune hypophysitis and Riedel thyroiditis, in all of which IgG₄ is involved. IgG₄ syndrome thus differs from SS, and is associated with raised serum IgG₄ concentrations and a prominent infiltration of IgG₄-expressing plasmacytes in the lacrimal and salivary glands. Mikulicz disease is therefore now termed systemic IgG₄-related plasmacytic disease.

In IgG₄ syndrome, the incidence of dry eyes, dry mouth and arthralgias is lower compared to SS, while allergic rhinitis, bronchial asthma, sclerosing pancreatitis, interstitial nephritis and interstitial pneumonitis are more common. Also, IgG₄ syndrome is *not* associated with anti-Ro/SS-A and anti-La/SS-B autoantibodies; and only a few patients have rheumatoid factor (RF) and ANA (low serum titres). There is good response to systemic corticosteroids or anti-CD20 (rituximab).

SCLERODERMA

General aspects

Scleroderma, from the Greek, means hard skin (*skleros* – hard; *derma* – skin), and is an uncommon disorder affecting about 2 in 10 000 people. It results from antinuclear antibodies against topoisomerase or centromeres causing fibroblasts to produce excess collagen. A gene that codes for fibrillin-1 may put some people at risk for scleroderma. Perivascular macrophage infiltration and endothelial cell damage with increased collagen and extracellular matrix are the main features.

Suspected triggers for scleroderma include viral infections (especially cytomegalovirus), drugs (e.g. taxanes or bleomycin), and adhesive and coating materials or organic solvents (e.g. vinyl chloride or trichloroethylene).

Women develop scleroderma at a rate up to ten times higher than men, possibly because of oestrogen; silicone breast implants have been blamed but no evidence found.

Clinical features

Scleroderma can be localized, which can be incapacitating, or systemic, which affects a number of organs and can be life-threatening. *Localized scleroderma* is limited to the skin and related tissues and, in some cases, the underlying muscle, but never progresses to a systemic form.

Localized types of scleroderma are recognized. *Morphoea* (from the Greek for 'form' or 'structure') is characterized by local patches

Fig. 18.8 Coup de sabre.

of scleroderma. The first signs of the disease are reddish patches of skin, most often on the chest, stomach and back, that thicken into firm oval-shaped areas. The centre of each patch becomes whitish with violet borders. These patches sweat very little and have little hair growth. Morphoea generally fades out in 3–5 years, but patients are often left with darkened skin patches and, in rare cases, muscle weakness.

Linear scleroderma (*coup de sabre* or ‘sword cut’) has a single line or band of thickened and/or abnormally coloured skin that usually runs down an arm or leg, but in some cases runs down the side of the face (Fig. 18.8).

Scleroderma (systemic sclerosis; SSc) involves deeper tissues (blood vessels and major organs) and often the skin. It appears in one of three forms:

- *Limited scleroderma* typically comes on gradually and affects the skin only in certain areas: the fingers, hands, face, lower arms and legs. Many people with limited disease have CREST: calcinosis – calcium deposits typically on the fingers, hands, face and trunk, and on the skin above the elbows and knees; Raynaud phenomenon; oesophageal dysfunction; sclerodactyly – thick and tight skin on the fingers, making it difficult to bend or straighten the fingers; and telangiectasias (Fig. 18.9).
- *Diffuse scleroderma* typically develops suddenly, affecting the hands, face (Figs 18.10 and 18.11), upper arms, upper legs, chest and stomach in a symmetrical fashion (e.g. if one arm or one side of the trunk is affected, the other is also affected). About one-third develop severe renal, pulmonary, gastrointestinal or cardiac disease.
- *Sine scleroderma* resembles either limited or diffuse systemic sclerosis, causing changes in the lungs, kidneys and blood vessels, but not the skin. However, it is heterogeneous with two main subsets. One is a diffuse cutaneous form with early onset of pulmonary, cardiac and renal complications and associated in 30% with anti-topoisomerase antibodies. The other is a limited

Fig. 18.9 CREST syndrome. Calcinosis and Raynaud phenomenon are shown here.

Fig. 18.10 Scleroderma. Finger telangiectasia.

Fig. 18.11 Scleroderma. Fish-mouth.

cutaneous form of disease with somewhat similar features but with sclerosis limited to the skin, such as CREST, with late visceral complications, and often (70%) associated with anti-centromere antibodies.

Systemic scleroderma classically presents with Raynaud phenomenon, often associated with joint pains (polyarthralgia) and skin becoming thinned, stiff, tethered, pigmented and marked by prominent fine

Fig. 18.12 Scleroderma.

blood vessels (telangiectases or spider naevi) and eventually limiting movement. There is also dysphagia and reflux oesophagitis; pulmonary involvement, which leads to impaired respiratory exchange and, eventually, dyspnoea and pulmonary hypertension; and renal damage secondary to vascular disease – typically a late feature, leading to hypertension, and an important cause of death (Fig. 18.12). There appears also to be an increased incidence of cancer of the oesophagus and of oral cancer.

General management

Scleroderma should be differentiated from undifferentiated connective tissue disease, overlap syndromes and eosinophilic fasciitis (EF); the latter involves the fascia, causing muscles to become encased in collagen, with contractures, and sometimes leading to disfigurement and problems with joint motion and function.

Diagnostically useful autoantibodies include anti-centromere antibodies (in up to 90% of people with limited systemic sclerosis) and anti-topoisomerase-1 antibodies (in 40% of people with diffuse SSc). PM-Scl1 antibodies suggest muscle involvement. Other laboratory findings are a raised ESR, normochromic anaemia and abnormal nailfold capillaroscopy.

There is no specific treatment, though hydroxychloroquine, methotrexate, ciclosporin, IFN- α and mycophenolate have been used; newer therapies include anti-transforming growth factor-beta (anti-TGF- β), stem cell transplantation and antagonists to endothelin. Medications for specific problems include iloprost to treat pulmonary hypertension, cyclophosphamide for lung fibrosis, angiotensin-converting enzyme inhibitors (ACEIs) for scleroderma-related kidney disease and nifedipine for Raynaud phenomenon.

The 5-year survival rate in severe forms is about 50%.

Fig. 18.13 Lip splitting during surgery in scleroderma (courtesy JP Shepherd).

Dental aspects

Some 80% of patients have manifestations in the head and neck region; in 30% the symptoms start there. Involvement of the face causes characteristic changes in appearance, notably narrowing of the eyes and mask-like restriction of facial movement (Mona Lisa face). Constriction of the oral orifice can cause progressively limited opening of the mouth (fish-mouth; see Fig. 18.11). The submucosal connective tissue may also be affected and the tongue may become stiff and less mobile (chicken tongue).

The mandibular angle, condyle or coronoid process may be resorbed or rarely there is gross extensive resorption of the jaw. Occasionally, involvement of the peri-articular tissues of the temporomandibular joint together with the microstomia so limit access to the mouth as to make dental care and/or treatment more or less impracticable (Fig. 18.13).

Sjögren syndrome develops in a significant minority, but very frequently when systemic sclerosis is associated with primary biliary cirrhosis. Since self-care can be challenging and there may be xerostomia, it is not surprising that there are often more decayed, missing or filled teeth. Toothbrush-handle modifications or powered brushes and flosses, fluorides, dietary control and management of dry mouth may help. The dental facility should be kept at a temperature and humidity that the patient finds comfortable. Otherwise, the main problems of systemic sclerosis are caused by dysphagia and pulmonary, cardiac or renal disease as potential contraindications for GA.

A recognized but uncommon feature seen in fewer than 10% of cases is widening of the periodontal membrane space without tooth mobility. Trigeminal neuropathy may occur. There may be a predilection to carcinoma of the tongue.

Penicillamine therapy may cause loss of taste, oral ulceration, lichenoid reactions and other complications. Nifedipine for Raynaud phenomenon may cause gingival swelling.

A typical manifestation of morphoea is involvement of the side of the face, causing an area of scar-like contraction aptly described as *coup de sabre*. Morphoea in childhood is believed to be one cause of facial hemiatrophy.

POLYMYOSITIS AND DERMATOMYOSITIS

General aspects

Polymyositis and dermatomyositis are rare, immunologically mediated inflammatory myopathies. Polymyositis, if associated with skin

lesions, is known as dermatomyositis. The conditions usually develop between the fifth and sixth decades, women being affected twice as often as men.

Clinical features

Polymyositis onset is characteristically insidious with pain and weakness, usually of the pelvic girdle and proximal limb muscles, especially the legs. Eventually, in severe cases, speaking and swallowing may become difficult and weakness may make patients bedridden. Ultimately, atrophy, contracture and calcinosis of muscles can develop. Other complications may include myocarditis and fibrosing alveolitis.

Dermatomyositis is characterized by a dusky and violaceous (Gottron, or heliotrope) rash with a butterfly distribution across the bridge of the nose and adjacent cheeks. This may spread to the upper part of the body or hands. Small, ulcerated skin lesions may develop over bony prominences. In a minority, Raynaud phenomenon is associated and there can be features of other connective tissue diseases, particularly scleroderma, myasthenia gravis or Hashimoto thyroiditis, especially in those with dermatomyositis.

Malignant disease may arise, particularly in dermatomyositis – typically, ovarian, lung, pancreatic, stomach and colorectal cancers, Waldenström macroglobulinaemia or non-Hodgkin lymphoma.

General management

Serum enzymes aldolase, creatinine phosphokinase [CPK] and aspartate transaminase [AST] may be raised, but the diagnosis is confirmed by electromyography (EMG) and muscle biopsy (shows muscle necrosis and regeneration and inflammation).

Treatment is with immunosuppressants (corticosteroids or others) but these are less effective when there is malignant disease.

Dental aspects

Oral lesions in polymyositis/dermatomyositis may be present in 10–20%; they are variable in character and mainly comprise dark or purplish mucosal erythema and oedema. Small whitish patches, occasionally with shallow ulceration, may also develop and bear some resemblance to lichen planus or lupus erythematosus.

Dental management may be complicated by corticosteroid therapy or associated disorders, such as other connective tissue diseases, including Sjögren syndrome. A minority have pharyngeal weakness.

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is an undifferentiated connective tissue disease presenting as a multisystem disorder with Raynaud phenomenon and features of two or more of the following connective tissue diseases: SLE, scleroderma and polymyositis. MCTD may evolve into one of several major connective tissue diseases or to an overlap syndrome. Patients have anti-ribonucleoprotein antibody (anti-U1-68 kD antibody) but no anti-Smith autoantibody (anti-Sm Ab).

Sjögren syndrome is the main complication of dental interest, but mouth ulcers or sensory changes may be seen.

ANTIPHOSPHOLIPID SYNDROME (HUGHES SYNDROME)

Antiphospholipid syndrome (APS) is characterized by persistently raised antibodies against membrane anionic phospholipids (i.e. the

antiphospholipid antibodies [aPL], anticardiolipin antibody [aCL] and antiphosphatidylserine) or their associated plasma proteins, predominantly beta₂ glycoprotein I (apolipoprotein H). The antibodies are deposited in small vessels, leading to intimal hyperplasia and hypercoagulability due to lupus ‘anticoagulant’, and causing venous or arterial thromboses in cerebral, renal, pulmonary, cutaneous and cardiac arteries. Transient ischaemic attacks, migrainous headaches, Raynaud syndrome and livedo reticularis are thus common. Primary APS is seen in isolation; secondary APS is associated with SLE or another connective tissue disease such as Sjögren syndrome.

Warfarin is the most effective treatment known. Thromboses or a bleeding tendency, and pulmonary and systemic hypertension are the main factors possibly complicating dental care.

ANTI-SYNTHEASE SYNDROME

Anti-synthetase syndrome is a rare, chronic inflammatory muscle disease characterized by myositis (polymyositis, dermatomyositis), arthritis, interstitial lung disease and Raynaud phenomenon. There are elevated muscle enzymes and anti-Jo-1 antibodies, directed against aminoacyl-tRNA synthetase. Corticosteroids and cyclophosphamide produce symptomatic improvement.

VASCULITIS SYNDROMES

Vasculitis (blood-vessel inflammation, which may affect the veins, arteries and capillaries) is characterized by an inflammatory infiltrate in and around blood vessels, and secondary narrowing or blockage of the vessels, which can cause manifestations in any organ system, including the CNS and peripheral nervous system. Under normal conditions, immune complexes of interlocking antigens and antibodies are rapidly removed from the bloodstream by splenic macrophages and liver Kupffer cells. If, however, they continue to circulate, they become trapped in blood vessels, kidneys, lungs, skin or joints, activating complement and thus initiating vasculitis and tissue damage. Immune complexes may form in autoimmune diseases; in persistent low-grade infections (e.g. malaria and viral hepatitis); or in response to environmental antigens, such as mouldy hay (e.g. farmer’s lung) or drugs (e.g. serum sickness). Vasculitic disorders are rare but include:

- Behçet disease (Ch. 11)
- eosinophilic polyangiitis with granulomatosis (formerly called Churg–Strauss syndrome)
- CNS angiitis (granulomatous angiitis)
- giant cell arteritis (temporal or cranial arteritis; Ch. 13)
- Kawasaki disease (Chs 5 and 37)
- periarteritis nodosa
- rheumatoid arthritis (Ch. 16)
- scleroderma (see earlier)
- Sjögren syndrome (see earlier)
- SLE (see earlier)
- Takayasu disease (Ch. 37)
- polyangiitis with granulomatosis (formerly called Wegener granulomatosis).

Clinical features

Vasculitis disorders, or syndromes, give rise to a range of symptoms. Those affecting the CNS and PNS can cause: headaches; fever; weight loss; confusion leading to dementia; joint and muscle pains; paralyses

or numbness; and visual disturbances. Vasculitis may be potentially fatal.

General management

Treatment for a vasculitis syndrome often includes corticosteroids, but some may also require other immunosuppressive drugs, such as cyclophosphamide.

ANTINEUTROPHIL CYTOPLASMIC ANTIBODY (ANCA)-ASSOCIATED VASCULITIDES

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis affects small to medium-sized blood vessels and causes chronic inflammatory diseases. Possible causal factors include occupational exposure to silica (e.g. farming, construction work), antithyroid and antihypertensive drugs (propylthiouracil and hydralazine), and microbial agents, particularly *Staphylococcus aureus* (chronic nasal carriage has been associated with a higher incidence of relapse in granulomatosis with polyangiitis).

General aspects

Neutrophil priming causes the cytoplasmic ANCA (c-ANCA) antigens proteinase 3 (PR3) and myeloperoxidase (MPO) to be expressed on the neutrophil cell membrane, where they are accessible to ANCA. Neutrophils activated by ANCA degranulate, produce reactive oxygen species, and release proteolytic enzymes that damage blood vessel walls.

ANCA-associated systemic diseases include:

- granulomatosis with polyangiitis (formerly Wegener granulomatosis)
- microscopic polyangiitis
- eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss syndrome).

Prevalence is generally higher in men over 65 years.

Clinical features

Manifestations may include destructive upper airway disease, pulmonary nodules, renal and pulmonary inflammatory disease, rapidly progressive glomerulonephritis, skin vasculitis with systemic illness, mononeuritis multiplex, subglottic stenosis of the trachea, and retro-orbital mass leading to end-organ damage, particularly renal disease.

Presentation is often with prodromal ‘flu-like’ generalized symptoms lasting weeks or months, such as fever, polymyalgia, polyarthralgia, headache, malaise, anorexia and weight loss. Some patients present with focal disease, such as rash, bloody–purulent rhinitis, scleritis, arthritis, ear, nose and throat problems (hearing loss, otalgia, bloody rhinorrhoea, otorrhoea, sinusitis, nasal crusting and recurrent otitis media), or mouth ulcers or characteristic gingival swelling. About 50% of patients have skin manifestations, such as rash or tender nodules. Other symptoms include:

- eyes and nervous system: unexplained conjunctivitis combined with general symptoms, uveitis, unilateral proptosis, and paresis of the ocular motor nerves (granulomatosis with polyangiitis)
- lungs: slowly developing cough and shortness of breath, possibly with bloody–purulent sputum, bilateral infiltrates on radiography that do not respond to antibiotics, non-tuberculous cavitating lesions (granulomatosis with polyangiitis), alveolar haemorrhage (microscopic polyangiitis)

- skin: bursts of small cutaneous vasculitis elements, pyoderma gangrenosum and oedema
- kidneys: haematuria, proteinuria, hypertension, decreasing renal function (granulomatosis with polyangiitis and microscopic polyangiitis). Renal involvement manifests with early detectable haematuria, red cell and other casts, and proteinuria.

General management

Blood tests may show leucocytosis, thrombocytosis, normochromic–normocytic anaemia and a raised serum creatinine. Urinalysis should be performed, for haematuria and proteinuria. Chest radiography may show infiltrates, nodules or cavitations in the lung parenchyma.

Although the ANCA test is positive in most cases, 5–10% of patients do not develop ANCA. Neither does a negative ANCA test exclude the presence of other non-ANCA-associated small- and medium-vessel vasculitic syndromes. ANCA assay is associated with a raised ESR or C-reactive protein (CRP). Indirect immunofluorescence (IIF) is more sensitive but enzyme-linked immunosorbent assay (ELISA) is more specific. Other conditions that can be associated with a positive ANCA test result include:

- inflammatory bowel disease
- chronic infections
- autoimmune conditions
- use of several drugs.

A diagnosis of ANCA-associated vasculitis is confirmed by biopsies obtained from sites of active disease, showing vasculitis, giant cells, ‘geographical necrosis’ and granulomas.

Remission is usually induced with high-dose corticosteroids and cyclophosphamide, followed by remission maintenance treatment.

GRANULOMATOSIS WITH POLYANGIITIS (FORMERLY WEGENER GRANULOMATOSIS: WG)

General aspects

Granulomatosis with polyangiitis is an uncommon, potentially fatal disease characterized by vasculitis associated with giant cells, necrotizing granulomatous lesions in the respiratory tract (Fig. 18.14) and glomerulonephritis. A limited form of the disease is confined primarily to the lung or oral cavity.

WG is an autoimmune inflammatory disease, involving c-ANCA directed at neutrophil proteinase 3 (PR-3). Neutrophils and endothelial cells are involved in early lesions as both targets and promoters of inflammation.

Many patients are nasal carriers of *Staph. aureus*.

Clinical features

Granulomatosis with polyangiitis comprises the triad of nasopharyngeal inflammation, pulmonary cavitation and renal disease. Upper respiratory involvement typically presents as chronic sinusitis that fails to respond to treatment. The lungs are involved in more than 90% and the kidneys in 75%. It typically terminates in a focal necrotizing glomerulonephritis.

General management

In granulomatosis with polyangiitis the cytoplasmic type of ANCA is found in more than 88% of patients and is virtually diagnostic.

Fig. 18.14 Granuloma in polyangiitis with granulomatosis. Lung involvement.

p-ANCA (directed at myeloperoxidase) is not found. Chest radiography and examination of urine for blood or sediment can indicate pulmonary or renal involvement. Biopsy shows inflammatory changes with giant cells. A necrotizing vasculitis is the main pathological feature but is not seen in gingival biopsies, where small arteries are lacking. This arteritis may, however, be seen in palatal lesions caused by downward spread of the disease from the nasopharynx. Granuloma formation is characteristic but the granulomas may be difficult to see.

Corticosteroids and cyclophosphamide are effective if given early enough. Trimethoprim–sulfamethoxazole may be effectively used alone in disease restricted to the upper aerodigestive tract. In others, it may mitigate some of the adverse effects of cytotoxic agents and may prevent relapse. Etanercept and infliximab are under trial as therapies.

Dental aspects

Granulomatosis with polyangiitis can occasionally produce a characteristic and apparently pathognomonic form of gingivitis as its initial manifestation, where the gingivae are swollen and red, and have a strawberry-like texture. Mucosal ulceration and delayed healing of extraction sockets are complications of the later stages of disease, particularly if renal failure develops.

Dental management may be complicated by renal failure, respiratory disease or corticosteroid, other immunosuppressive or cytotoxic therapy.

POLYARTERITIS NODOSA (PERIARTERITIS NODOSA)

General aspects

Polyarteritis nodosa (PAN) is a multisystem immune-complex disease characterized by necrotizing vasculitis affecting mainly small and medium-sized arteries; it most frequently targets middle-aged men. ANCA appears to play a significant role in causing endothelial damage; perinuclear ANCA (p-ANCA; antimyeloperoxidase) is often found in microscopic polyarteritis (MPA). c-ANCA (antiproteinase 3) has also been described but is more often seen in polyangiitis with granulomatosis. Increased serum IFN- α and IL-2, and a moderate rise in TNF- α and IL-1 β , may enhance endothelial damage by activating endothelial cells and polymorphonuclear neutrophil leukocytes (PMNLs).

The precipitating factor is often unidentified but may be microbial or a drug. Hepatitis B virus has been implicated in up to 40%

Fig. 18.15 Purpura due to vasculitis.

of patients, and other infective agents occasionally involved include hepatitis C virus, human immunodeficiency virus (HIV), cytomegalovirus, parvovirus B19, human T-lymphotropic virus 1 (HTLV-1) or *Streptococcus* species. Drugs (e.g. thiouracil, iodides and sulphonamides) may occasionally be responsible.

Clinical features

PAN has protean manifestations as a result of the capricious distribution of the lesions anywhere in the body. Fever, anorexia, weight loss, myalgia, arthralgia, purpura (Fig. 18.15) and peripheral neuropathies are common but non-specific. Abdominal involvement, with pain, nausea, vomiting or diarrhoea, is seen in over 60%. Renal disease affects 50%. Tender skin nodules may be palpable over inflamed vessels. Hypertension and angina are common.

General management

Leukocytosis, eosinophilia, raised ESR, pANCA, hypergammaglobulinaemia and sometimes a false positive test for rheumatoid factor may be found. Albuminuria or haematuria is common. Angiography may demonstrate arterial aneurysms (early PAN) or vascular occlusions (late PAN). Histological examination of clinically involved tissue is needed to confirm the diagnosis.

The prognosis is poor in untreated disease; up to 60% die within 1 year. Systemic corticosteroids give a 5-year survival rate of over 40%. Cyclophosphamide may also be of value.

Allergic granulomatosis is a closely related disease characterized by fever, asthma and eosinophilia.

Dental aspects

Dental management may be complicated by corticosteroid therapy and immunosuppression; hepatitis B antigen carriage; hypertension

and cardiac disease; or renal disease. Submucosal nodules, haemorrhage or oral ulcers are rare manifestations. Facial palsy or other cranial neuropathies may be occasional complications.

Immunity, inflammatory disorders, immunosuppressive and anti-inflammatory agents

19

KEY POINTS

- Autoinflammatory disorders are increasingly recognized
- Anti-inflammatory therapies are more commonly used and directed at cytokines
- Immunosuppressive therapy has many beneficial effects but predisposes to infections and neoplasia

This chapter discusses innate and acquired immunity and inflammation, autoinflammatory disorders and immunosuppressive therapy.

INNATE IMMUNITY AND INFLAMMATION

Innate immunity includes basic mechanisms of resistance to infection, such as epithelial anatomical barriers of skin and mucous membranes, cilia, secretions such as saliva and tears, and the innate inflammatory response. The latter is characterized by increased localized blood flow and capillary permeability (inflammation), releasing soluble factors that recruit phagocytes (neutrophils and macrophages), which restrict and engulf invasive microorganisms.

Inflammation is initiated and maintained by mediators, especially complement and cytokines – small proteins that specifically also affect the behaviour of immune cells (immunocytes). Cytokines, including interleukins, lymphokines and cell signal molecules such as tumour necrosis factors and interferons, regulate the intensity or duration of immune responses by stimulating or inhibiting proliferation of various immunocytes, or by modulating their secretion of other cytokines or antibodies.

COMPLEMENT

The complement system is a plasma protein sequence (cascade) involving at least nine plasma proteins. When activated, this sequence releases important mediators of inflammation and chemotaxis (C3a and C5a), compounds capable of opsonizing microorganisms for

phagocytosis (C3b), and an attack complex (C5–9) capable of damaging cell membranes (Fig. 19.1). There are three complement pathways – classical, lectin and alternative – that differ in the manner in which they are activated (triggering agents include bacterial lipopolysaccharides [LPS] and immune [antigen/antibody] complexes), though all produce C3 convertase – the key enzyme. The system is controlled by inhibitors such as C1 esterase inhibitor, decay accelerating factor (DAF), membrane inhibitor of reactive lysis (MIRL) and homologous restriction factor (HRF).

CYTOKINES

Cytokines are a family of proteins – interferons, tumour necrosis factors, transforming growth factors, interleukins, chemokines and colony-stimulating factors – that act in concert with inhibitors and soluble receptors to regulate immune responses.

Interferons (IFNs) are one of the most important natural defences against viral infection. IFN- α and IFN- β are antiproliferative for virally infected and other cell types. IFN- γ is involved in cell-mediated immune responses, via Th1 lymphocytes; is antagonistic to interleukin 4 (IL-4); activates macrophages; and induces expression of class II major histocompatibility complex (MHC) antigens.

Tumour necrosis factors (TNFs) are important in inflammation and antitumour immunity. TNF- α is secreted by a variety of cells, including T and B lymphocytes, macrophages, natural killer (NK) cells, endothelial cells and keratinocytes. TNF- α primes both endothelial cells and neutrophils for adhesion, is chemotactic for inflammatory cells and can signal cells to begin apoptosis (programmed cell death). It is a death activator, triggering the proteolytic caspase cascade that culminates in apoptosis. It can also activate nuclear factor kappa B (NF- κ B) and activator protein 1 (AP-1), leading to the induction of several genes and inflammation. It can also initiate and perpetuate an inflammatory response through upregulating adhesion molecules on microvascular endothelial cells, and enhance expression of MHC class I and II antigens, and co-stimulatory molecules on dendritic cells (DCs) and macrophages. Matrix metalloproteinase (MMP) production by stromal cells is induced, which may lead to tissue remodelling

Fig. 19.1 Complement pathways.

Table 19.1 Main cytokines

Proinflammatory cytokines	Anti-inflammatory cytokines
Tumour necrosis factor (TNF-alpha)	IL-4, IL-10 and IL-11
Interferons (IFNs)	
Alpha	
Beta	
Interleukins (ILs)	
1	
6, 15, 17 and 18	

Box 19.1 Chemokines

- C chemokines – attract T-cell precursors to the thymus
- CC chemokines – induce migration of monocytes, and dendritic and natural killer (NK) cells
- CXC chemokines – specifically induce the migration of neutrophils
- CX3C chemokines – chemoattractant and adhesion molecule

and the enhanced TNF-mediated secretion of keratinocyte growth factor (KGF). TNF can also induce fever, either directly via stimulation of prostaglandin E2 (PGE2) synthesis by the hypothalamic vascular endothelium, or indirectly by inducing release of the pyrogen interleukin 1 (IL-1), and can stimulate collagenase and PGE2 production. TNF also induces hepatic acute-phase reactant protein production.

TNF-β – from T and B cells, NK cells and astrocytes – mediates fibroblast and endothelial cell proliferation, important in wound healing.

Transforming growth factor beta (TGF-β) is part of a protein superfamily that includes inhibins, activins and bone morphogenetic protein (BMP), which can affect development, haemopoiesis, wound healing and tissue repair. TGF-β has a crucial role in cell-cycle regulation and apoptosis, via the SMAD (name derived from a fusion of gene names *sma* [in *Caenorhabditis elegans*] and *Mad* [in *Drosophila*]) or the DAXX (death domain-associated protein) pathways.

Interleukins and their functions are diverse. Over 33 interleukins have been identified, most originating from T cells, some macrophages and mast cells, or from B cells or other cells (Appendix 19.1).

Cytokines that promote inflammation are termed proinflammatory cytokines; others are anti-inflammatory (Table 19.1).

Chemokines (chemoattractant cytokines)

Historically known under names such as the SIS family of cytokines, SIG family of cytokines, SCY family of cytokines, platelet factor-4 superfamily or intercrines, chemokines are classified into four groups (Box 19.1).

Colony-stimulating factors (CSFs) are glycoproteins that bind to haemopoietic cell receptors to drive differentiation. Those most relevant to the immune response are shown in Box 19.2.

ACUTE-PHASE RESPONSE

In response to injury, infection, physical trauma or malignancy, neutrophils and macrophages secrete several cytokines (most notably IL-1, IL-6, IL-8 and TNF-α), which cause the liver to produce *acute-phase reactants* – proteins whose plasma concentrations increase in response to, and suppress, inflammation (Table 19.2).

C-reactive protein (CRP) and serum amyloid A protein (SAA) are critical in the innate immune response. CRP can bind to some bacteria

Box 19.2 Colony-stimulating factors (CSFs)

- CSF1: macrophage CSF (M-CSF)
- CSF2: granulocyte–macrophage CSF (GM-CSF; sargramostin)
- CSF3: granulocyte CSF (G-CSF; filgrastim)

Table 19.2 Acute-phase reactants

Protein	Main functions
Alpha ₁ -antichymotrypsin	A serpin, which downregulates inflammation
Alpha ₁ -antitrypsin	A serpin, which downregulates inflammation
Alpha ₂ -macroglobulin	Inhibits coagulation and fibrinolysis
Caeruloplasmin	Inhibits microbial iron uptake
Complement	See text
C-reactive protein (CRP)	Binds to phosphorylcholine in bacterial membranes and phosphatidyl ethanolamine in fungal membranes activating the classical complement pathway
D-dimer protein	Fibrin degradation product
Factor VIII	Coagulation factor
Ferritin	Inhibits microbial iron uptake
Fibrinogen	Coagulation factor
Haptoglobin	Inhibits microbial iron uptake
Mannan-binding protein (MBP) or lectin (MBL)	Binds to microbial mannose-rich glycans to act as an opsonin, and also activates the lectin pathway
Plasminogen	Coagulation factor
Prothrombin	Coagulation factor
Serum amyloid A	Recruits immunocytes to inflammatory sites
von Willebrand factor	Coagulation factor

and fungi, activating complement and inflammation, as can SAA, which can also stimulate macrophages to phagocytose debris. Most organisms that tend to be invasive are ingested by phagocytes, including blood neutrophils (polymorphonuclear neutrophilic leukocytes) and tissue macrophages (‘phage’ = eating up), which kill most organisms. However, some (i.e. all viruses, and bacteria such as those causing tuberculosis or brucellosis) survive inside cells, including phagocytes, and then the immune system is the main defence. Clinically, this positive acute-phase response appears within 12 hours and can be measured by determining CRP levels or the erythrocyte sedimentation rate (ESR). The acute-phase response is also characterized by leukocytosis, fever, and alterations in the metabolism of many organs. In contrast, there is a negative acute-phase response with decreases in albumin, transferrin, transthyretin and insulin growth factor I.

ACQUIRED IMMUNE RESPONSE

The main activity of the immune system is protection against infections. Immunocytes (leukocytes) are mainly lymphocytes and they produce humoral (antibody; mainly B-cell) or cell-mediated (mainly T-cell) responses that are central to the immune defences. B lymphocytes evolve into plasma cells, which produce antibodies to protect against extracellular organisms (Fig. 19.2). Antigens are processed by antigen-presenting cells (APC) and presented to T lymphocytes, which fulfil most other immune functions (i.e. cell-mediated immunity [CMI]). Macrophages and polymorphs are the main professional phagocytes; macrophages and macrophage-like cells

Fig. 19.2 Essentials of immunity. APC = antigen-presenting cell; PMNL = polymorphonuclear leukocyte.

Fig. 19.3 Reticuloendothelial system. APC = antigen-presenting cell.

are widely distributed in the lymphoreticular (reticuloendothelial) system (Fig. 19.3).

More than 70 types of leukocyte are recognized and defined by their cluster of differentiation (CD) antigens, which in turn are recognized by monoclonal antibodies.

Immunocytes are, in large part, regulated by cytokines produced by a variety of cells. Cytokines produced by lymphocytes are termed lymphokines, and those that act between leukocytes are called interleukins

Table 19.3 Immunoglobulins

Classes	Comments
IgA	Secreted by exocrine glands and helps to protect mucosal surfaces
IgD	Of unclear function
IgE	Important in the mediation of atopic allergy but has a role in the defence against parasites
IgG	Essential for protection against bacterial infections, by such functions as neutralizing toxins, activating complement or promoting phagocytosis
IgM	(opsonization)

(see Appendix 19.1). Cytokines may also induce systemic effects, such as the acute-phase response (see above).

The movement of leukocytes between the blood and tissues depends on leukocyte–endothelial cell adhesion molecules known as selectins, integrins and the immunoglobulin gene superfamily (IgSF; intercellular adhesion molecules [ICAMs] and lymphocyte functional antigen 3), and over 20 other proteins.

HUMORAL IMMUNITY

Antibodies are immunoglobulins. B cells carry surface immunoglobulins and also receptors for immunoglobulin G (IgG; CD32) and complement-activated components C3d (CD21) and C3b (CD35). Antibody production is modulated by T lymphocytes, which either assist (T-helper cells) or moderate (T-suppressor cells). The many cytokines involved include IL-1 to IL-7 and B-cell growth factor (BCGF). Immunoglobulins (antibodies) are of different classes (Table 19.3).

Complement and polymorphonuclear leukocytes (PMNLs) are essential to phagocytosis and inflammation. Cell-mediated responses are usually protective, and macrophages are also phagocytic.

PHAGOCYTES AND OTHER CELLS

Macrophages and dendritic cells intimately involved in antigen processing and the transference of information to lymphocytes are called antigen-processing cells (APCs). Phagocytes (PMNLs and macrophages) are attracted towards antigens, via activated complement after an antigen–antibody reaction, and can ingest and often kill microbes that are opsonized (i.e. coated by specific antibody and activated complement components). During phagocytosis or attempted phagocytosis of, for example, immune complexes, these phagocytes may discharge degradative enzymes (lysosomal enzymes), which can cause local tissue damage.

Large granular lymphocytes (LGLs; or null cells) are non-phagocytic cells that mediate NK cell activity and antibody-dependent cellular cytotoxicity (ADCC) – the binding and lysis of antibody-coated target cells. NK cells recognize malignant or foreign cells by a non-immune mechanism.

Basophils and mast cells have surface receptors for IgE, and contain histamine, prostaglandins, leukotrienes and proteases. They are involved in immune responses to parasites and in the immediate type of hypersensitivity responses (Ch. 17).

Prostaglandins (Table 19.4) and leukotrienes (Table 19.5) are produced from eicosanoids – lipids produced by the oxygenation of arachidonic acid from omega-3 fatty acids in fish oils, or released from cells by phospholipase A2. The enzyme cyclo-oxygenase (COX) produces prostaglandins and thromboxane, while the enzyme 5-lipoxygenase produces leukotrienes.

Table 19.4 Important prostaglandins (PGs)

Prostaglandin	Sites of origin	Effects
PGD ₂	Mast cells	Bronchoconstriction, vasodilatation and inhibition of platelet aggregation
PGI ₂ (prostacyclin)	Endothelium	Vasodilatation and inhibition of platelet aggregation
PGE ₂	Epithelium, dendritic cells	Inhibition of lymphocyte proliferation, cytokine production and neutrophil function

Table 19.5 Leukotrienes (LTs)

Leukotriene	Causes
LTB ₄	Neutrophil chemotaxis, mucus secretion, cell growth
LTC ₄ (formerly termed slow-reacting substance A)	Vascular permeability, smooth muscle contraction, mucus production
LTD ₄	
LTE ₄	

CELL-MEDIATED IMMUNITY

Antigens are processed by antigen-presenting cells, such as macrophages and Langerhans cells in epithelia, and presented to T cells in association with class I or II MHC molecules. T lymphocytes originate in bone marrow but differentiate within and are under the control of the thymus (hence T), acquiring immunological competence there, a process that requires the normal functioning of purine metabolism. T cells all have T-cell receptors, highlighted by the CD3 surface marker. When activated by antigens, T lymphocytes produce lymphokines, which, among other activities, can modulate nearby cells, particularly macrophages, resulting in CMI (type IV immune responses). These are particularly important in the defence against some intracellular bacteria, such as mycobacteria, and against viruses and fungi, graft rejection, graft-versus-host reaction, delayed hypersensitivity and defences against cancer cells.

Circulating T lymphocytes differentiate into CD4 cells – mainly helper T cells that are antigen-processing and can recognize MHC class II antigens, and can induce B-cell differentiation, induce CD8 cytotoxic T-cell proliferation, produce various soluble mediators (lymphokines) and regulate erythropoiesis. Healthy adults usually have CD4+ T-cell counts of 1000 or more per mm³ of blood. CD4 helper T cells are either Th1 or Th2. Th1 cells secrete IL-2 and IFN-γ; they provide help for the generation of cytotoxic T cells involved in type IV immune responses (Ch. 17) and are suppressed by IL-10. Th2 secrete IL-4, 5, 6 and 10, which both help B cells to produce IgG, IgA and IgE, and regulate the production of other cytokines – and thereby the immune response. Th2 cells are involved in type II and type III immune reactions and are suppressed by interferon.

Circulating T lymphocytes can also differentiate into CD8 cells, which recognize MHC class I antigens and are one type of cytotoxic or suppressor T cell; they are important in eliminating virus-infected cells.

To summarize, T-cell proliferation and differentiation are regulated by many cytokines, including interleukins, interferons, tumour necrosis factors and transforming growth factors. Cytokines generally function as local signals for cell growth, differentiation, activation, inhibition, apoptosis or chemotaxis, but may also induce systemic effects such as acute-phase responses (fever, CRP, osteoclast activation, platelet release) induced by IL-1, IL-6 and TNF.

EVALUATION OF B-LYMPHOCYTE FUNCTION

The initial screening for B-lymphocyte function is an assay of serum IgG, IgA and IgM. There are four subclasses of IgG, and selective deficiencies of these can develop. Thus, when there is a strong suspicion of a humoral immunodeficiency based on clinical grounds but the total IgG is normal, quantitative measurement of individual subclasses is indicated.

Assessment of antibody function is necessary. Antibody titres after immunization with protein antigens (e.g. tetanus or diphtheria toxoids) and polysaccharide (e.g. pneumococcal capsular polysaccharides) are most convenient (immunization with live viral vaccines must be avoided, as the person may be immunocompromised). If immunoglobulin levels and/or antibody titres are low, more advanced tests of B-lymphocyte numbers and function are needed.

EVALUATION OF T-LYMPHOCYTE FUNCTION

Indirect information about T-lymphocyte function may be obtained by counting peripheral blood T lymphocytes. The total number of T lymphocytes (CD2 or CD3), T-helper lymphocytes (CD4) and T-suppressor/cytotoxic lymphocytes (CD8) in peripheral blood can be quantified with appropriate monoclonal antibodies.

Delayed-type hypersensitivity (DTH) skin tests use a panel of ubiquitous antigens to screen for T-cell function. A positive test generally indicates intact T-cell function and CMI, but requires prior exposure and sensitization to the antigen, which may not have happened. Also, a positive DTH skin test to some antigens does not guarantee that the patient will have normal CMI to all. Furthermore, some normal individuals may have transiently depressed DTH reactions during viral infections. Skin testing for DTH measures not only T-lymphocyte responses but also the afferent (receptor) arc of the cell-mediated immune response. Thus, most adults show DTH to tuberculin in the tuberculin (Mantoux) test, since they have had previous contact with *Mycobacterium tuberculosis* or bacilli Calmette–Guérin (BCG). A positive response in apparently well people is generally an index of ‘waiting immunity’ to the disease and usually does not mean that mycobacteria are actively causing cell-mediated tissue damage. A recent change from negative to positive in the absence of vaccination implies recent exposure, and prophylactic treatment may be indicated. By contrast, a negative tuberculin reaction indicates susceptibility to infection or occasionally that overwhelming infection is established – all CMI has been used up in an attempt to combat the infection. In such cases, successful treatment may allow CMI to return and a negative Mantoux test can then become positive.

It is possible also, in specialized laboratories, to measure several different cytokines involved in T- and B-lymphocyte regulation (e.g. IL-2, IFN-γ).

EVALUATION OF PHAGOCYTIC FUNCTION

A white blood cell count and differential are the first essentials. Assessment of phagocyte function requires *in vitro* assays of directed cell movement (chemotaxis), ingestion (phagocytosis) and intracellular killing (bactericidal activity).

EVALUATION OF THE COMPLEMENT SYSTEM

Most complement components can be detected using antibody-sensitized sheep erythrocytes in a total haemolytic complement assay (CH50 assay), since this assay requires the functional integrity of C1 to C9.

Table 19.6 Main autoinflammatory syndromes

Disease	Inheritance	Acronym	Gene and protein defect	Main features apart from fever and rashes	Management
Familial Mediterranean fever	AR	FMF	MEFV	Serositis, synovitis, amyloidosis	Colchicine
Tumour necrosis factor receptor-associated periodic syndrome	AD	TRAPS	TNFRS1A	Abdominal pain, migratory myalgia, rash, periorbital oedema, mouth ulcers, amyloidosis	Corticosteroids Etanercept (TNF inhibitor) Colchicine
Hyperimmunoglobulin D syndrome	AR	HIDS	MVK	Abdominal pain, diarrhoea, arthralgia, mouth ulcers	Simvastatin, anakinra (IL-1 receptor antagonist)
Mevalonate aciduria	AD	MA		Learning disability, failure to thrive, progressive visual impairment and cerebellar ataxia, dysmorphic features	Corticosteroids
Neonatal-onset multisystem inflammatory disease	AD	NOMID	CIAS1	Chronic meningitis, hearing and vision loss	Anakinra
Muckle–Wells syndrome	AD	MWS		Urticaria, arthralgia, deafness, amyloidosis	
Familial cold autoinflammatory syndrome	AD	FCAS		Urticaria, amyloidosis	
Pyogenic sterile arthritis, pyoderma gangrenosum, acne	AD	PAPA	PSTPIP1/CD2BP1	Arthritis, headache, abdominal pain, mouth ulcers	Anakinra Etanercept
Blau syndrome	AD	–	CARD15 or NOD2	Arthritis, uveitis	Anakinra
Periodic fever, aphthous stomatitis, pharyngitis, adenitis	Not known	PFAPA	Not known	Pharyngitis, adenitis, mouth ulcers	Corticosteroids Cimetidine
Chronic recurrent multifocal osteomyelitis	AD	CRMO	LPIN2 and Lipin2	Chronic recurrent multifocal osteomyelitis	Antimicrobials

AD/AR = autosomal dominant/recessive.

Deficiencies of alternative pathway components factors D, H and I and properdin can be detected by a haemolytic assay using activators of the alternative pathway, such as unsensitized rabbit erythrocytes. Individual components are detected by specialized functional and immunochemical tests.

AUTOINFLAMMATORY DISEASES (PERIODIC SYNDROMES)

General aspects

The autoinflammatory diseases (periodic syndromes) are rare disorders of innate immunity, often hereditary, which involve an ongoing imbalance between factors promoting and those inhibiting inflammation. The abnormalities seen include aberrant responses to pathogen-associated molecular patterns (PAMPs), including lipopolysaccharide (LPS) and peptidoglycan; neutrophilia; and dysregulation of the proinflammatory cytokines IL-1 β and/or TNF- α , or the receptors for these cytokines.

Clinical features

Periodic syndromes usually begin from childhood and are characterized by fluctuating or recurrent episodes of fever and generalized inflammation, affecting the surfaces, joints, eyes and/or skin.

Patients with the autoinflammatory syndromes generally are well between abrupt episodes of fever and systemic inflammation, but some develop amyloidosis.

General management

Diagnosis is supported by evidence of elevated acute-phase response during attacks, and often a positive family history and ethnic background. Genetic testing is indicated. Many of the syndromes have a specific treatment (Table 19.6).

Dental aspects

Aphthous-like oral ulceration has been reported as one manifestation in periodic fever, aphthous stomatitis, pharyngitis, adenitis (PFAPA); familial Mediterranean fever (FMF); hyperimmunoglobulinaemia D and periodic fever syndrome; tumour necrosis factor receptor-associated periodic syndrome (TRAPS); and pyogenic sterile arthritis, pyoderma gangrenosum, acne (PAPA).

Chronic recurrent osteomyelitis has been recorded in the jaws in chronic recurrent multifocal osteomyelitis. There is a suggested association of FMF with Behçet disease.

PERIODIC FEVER, APHTHOUS STOMATITIS, PHARYNGITIS, ADENITIS (MARSHALL SYNDROME)

PFAPA is not a familial disease. Attacks usually appear in pre-school children as recurrent fever with aphthous-like stomatitis, pharyngitis and cervical lymphadenitis. Long-term sequelae have not been reported and most children eventually grow out of it. Diagnostically, raised ESR, leukocyte count, fibrinogen and serum IgD have been found. PFAPA often responds well to corticosteroids, cimetidine or tonsillectomy.

DEFICIENCY OF THE INTERLEUKIN-1 RECEPTOR ANTAGONIST (DIRA)

Deficiency of interleukin-1 receptor antagonist IL-1Ra (DIRA) is caused by inherited mutations in the gene *IL1RN* that encodes IL-1Ra. This antagonist binds to the same cell receptors as does IL-1 and blocks its inflammatory actions, so without IL-1Ra, the IL-1-induced systemic inflammation is uncontrolled. Mutations causing DIRA are rare, but more common in people of Puerto Rican or Dutch descent. Features include serious and potentially fatal bone swelling, pain and deformity; periosteitis; and skin pustulosis. Most children develop features from birth to 2 weeks of age and most respond to anakinra.

DEFICIENCY OF THE INTERLEUKIN-36-RECEPTOR ANTAGONIST

Aberrant interleukin-36Ra structure and function cause secretion of proinflammatory cytokines, hyperleukocytosis and raised C-reactive protein and generalized pustular psoriasis.

IMMUNOSUPPRESSIVE THERAPY

See also Chapter 35.

Where inflammation can become harmful, attempts can be made to suppress the immune response or block cytokine action. Most immunosuppressive drugs predominantly depress cell-mediated responses and autoantibody production more strongly than normal antibody production.

Immunosuppressive therapy is widely used, especially to suppress rejection in transplant recipients (bone marrow, kidney, liver, pancreas, heart and heart–lung; Ch. 35), to treat autoimmune and connective tissue diseases, and to control tumours – especially lymphoproliferative neoplasms (Ch. 8).

Immunosuppressive therapy inevitably predisposes patients significantly to infections, particularly viral, fungal, mycobacterial and protozoal ones, since T-cell immunity is largely depressed; patients are also predisposed to malignant disease (Kaposi sarcoma, lymphomas and squamous cell carcinomas of the skin, cervix and lip), most of which are virally related. Infections may be opportunistic (i.e. involve microorganisms that are normally commensal), may spread rapidly and often may be clinically silent or atypical.

Immunosuppressive strategies now attempt to be more selective in their effects on the immune response by using biological agents (also termed targeted immune modulators [TIMs]) and biological response modifiers [BRMs]) designed to inhibit the harmful effects of upregulated proinflammatory cytokines (e.g. TNF- α , IL-1 and receptor, IFN- β , IFN- α , IL-6, IL-15, IL-17 and IL-18). Potential therapeutic strategies may augment the activity of anti-inflammatory cytokines (e.g. IL-4, IL-10 and IL-11) (see below).

Systemic non-biological immunomodulators are used in oral health care in mucosal disease:

- Pemphigus
- Severe, resistant or systemic lesions in:
 - aphthae or aphthous-like ulceration
 - Behçet disease
 - Crohn disease/orofacial granulomatosis (OFG)
 - erythema multiforme
 - lichen planus
 - pemphigoid, etc.

They are also used in other conditions:

- Bell palsy
- Giant cell arteritis
- Vasculitis.

Most affect cytochrome P450-3A4 and P-glycoprotein drug pathways, and interact with foods/medications. All may have serious adverse effects, including:

- teratogenicity
- infections
- malignant disease:
 - basal cell carcinomas
 - Kaposi sarcomas (KS)
 - lymphomas and lymphoproliferative disorders (e.g. post-transplant lymphoproliferative disease [PTLD])
 - melanomas
 - squamous cell carcinomas of skin, lip, cervix, external genitalia and perineum.

SYSTEMIC NON-BIOLOGICAL IMMUNOMODULATORS

Drugs such as azathioprine, cyclophosphamide and chlorambucil are cytotoxic to cells, including some immunocytes; they thus act as fairly crude immunosuppressive agents and adverse effects are common (Appendix 19.2). *Calcineurin inhibitors* bind to immunophilins (cyclophilin and macrophilin) and block receptor expression, T-cell activation and cytokine release. Calcineurin inhibitors (cyclosporin and tacrolimus) may enhance tumour development through mechanisms independent of host immunity. In contrast, inhibitors of the mammalian target of rapamycin (mTOR), including sirolimus and everolimus, are newer immunosuppressants that have antineoplastic properties.

BIOLOGICS (BIOLOGICAL RESPONSE MODIFIERS)

(Appendix 19.3; see also Chapter 35.)

Biologics are produced mainly by recombinant DNA technology and are usually:

- substances almost identical to key signalling proteins
- monoclonal antibodies (mAbs)
- receptor constructs, or fusion proteins.

Biological response modifiers (BRMs) block the inflammatory and immune responses, acting on immunocytes directly or via cytokines, inhibiting cellular activation and inflammatory gene transcription by various means.

Some are antibodies, soluble receptors or natural antagonists; others are small molecules that specifically inhibit intracellular, cell–cell and cell–matrix interactions intrinsic to inflammatory and immune processes. Examples are shown in Appendices 19.3 and 19.4.

Biologic therapies aim to modulate lymphocytes or cytokines. They include:

- TNF α inhibitors
- lymphocyte modulators
- interleukin inhibitors.

TNF α inhibitors (etanercept, adalimumab, infliximab, golimumab, certolizumab, natalizumab) bind and/or neutralize soluble (both circulating and within tissue) and membrane-bound TNF α , so blocking its effects upon target inflammatory cells.

T-cell modulators act on specific CD antigens. Alefacept targets CD2+ on memory T and NK cells. B-cell modulators, such as rituximab, act by

targeting CD20, selectively depleting circulating B cells. An anti-CD28 is also available (abatacept).

Interleukin inhibitors include an IL-1 antagonist (anakinra) and an IL-6 antagonist (tocilizumab).

Labelled indications for use of BRMs include rheumatoid arthritis, ankylosing spondylitis, psoriasis, Crohn disease, ulcerative colitis and malignancies such as non-Hodgkin lymphoma. Off-label applications include pemphigus, recurrent aphthous stomatitis and Behçet disease, mucous membrane pemphigoid, lichen planus, orofacial granulomatosis and Sjögren syndrome.

One of the advantages of BRMs is that they act specifically to neutralize targeted immune components so there *should*, in theory, be relatively few adverse effects. They are administered by injection or infusion, and the most common adverse effect is a mild skin reaction at the injection site. All are injected preparations, with schedules varying with the condition being treated. Infliximab and rituximab must be given as periodic intravenous infusions; etanercept and adalimumab are given as regular subcutaneous injections; and alefacept is given as weekly intramuscular injections. Some patients develop headaches during infusion, and there may be an increased susceptibility to infection – a serious risk to patients already prone to infection (e.g. diabetics) or who have an active infection such as tuberculosis or hepatitis B virus (Tables 19.7 and 19.8). Immunomodulatory mAbs have an inherent risk for adverse immune-mediated drug reactions in humans, such as infusion reactions, cytokine storms, immunosuppression and autoimmunity. Other long-term effects are not yet clear (see also Chs 29 and 35). At least 30 therapeutic mAbs are marketed in a variety of indications, and have already had profound impacts on fields such as oncology, rheumatology, neurology, cardiology and gastroenterology. However, biologics can have a high cost and significant adverse effects, and the efficacy of murine human mAbs can be limited by development of human antichimeric antibodies.

Biologics suppress the immune system and carry an increased risk of infections, which, in rare cases, can be serious. These agents undoubtedly can have serious potential adverse effects but they are generally considered safe. People with tuberculosis, heart failure or multiple sclerosis should not take biologics because they can bring on these conditions or make them worse. In rare cases, some people taking TNF inhibitors have developed certain cancers such as lymphoma. Natalimumab increases the risk of a rare, potentially fatal brain infection – progressive multifocal leukoencephalopathy (PML). Common side-effects from biologic use include headache, 'flu-like symptoms, nausea, rash, injection site pain and infusion reactions.

Use of biologics does require precautionary considerations, including screening for coexisting medical conditions. Before prescribing biologics, it is crucial to check for potential problems, such as active liver infection or tuberculosis. Monitoring includes laboratory tests and possibly regular checks for cancer (Box 19.3).

Screening for, and use in, comorbid conditions are described below.

Viral infections

In patients with hepatitis B virus (HBV), hepatitis C virus (HCV) and human immunodeficiency virus (HIV) infection receiving biologics, viral reactivation may occur, with specific cautions and caveats related to use. Recommendations are that screening for risk factors for HBV, HCV and HIV should be carried out before commencing therapy with either TNFα inhibitors or rituximab. If previous viral infection is diagnosed, a full risk/benefit assessment should be undertaken before any proposed use, and HBV

Table 19.7 Main groups of biological response modifiers

Actions	Examples	Names
Antibodies against immunocytes	Anti-B-lymphocyte CD20, proliferation and activation	Rituximab
	Anti-T-lymphocyte migration and cytotoxicity	Alefacept Efalizumab
	Anti-CD3	Visilizumab
	Anti-T-cell activation	Abatacept
	Anti-CD22	Epratuzumab
Cytokine inhibitors	Anti-tumour necrosis factor (TNF)	Adalimumab Certolizumab Etanercept Infliximab Onercept
	Anti-interferon-gamma (IFNλ)	Apilimod Fontolizumab
	Anti-interleukin 1 (IL-1)	Anakinra
	Anti-IL-2 receptors	Basiliximab Daclizumab
	Anti-α ₄ -integrin Selectin inhibitors	Natalizumab Efomycine
Others		

immunization should be considered in prospective patients considered at risk. However, most authorities advocate significant caution in patients with HBV or HCV and HIV infection, and use of any agents in active disease is generally contraindicated. If used, where relevant, HBV serology titres, serum aminotransaminases and HCV-RNA should be monitored. While anti-TNF therapy has been given in HIV infection, only those with controlled disease and whose immune competence is not especially low (e.g. CD4 count over 200 and HIV viral load below 60 000 mm³) should be considered eligible. Therapy must be given in combination with antiretroviral therapy (ART), and viral load and CD4 count should be monitored during biological therapy. Although rituximab can be used in HIV infection, limited data are available for its use in autoimmune conditions with coexistent HIV infection, and there are no clear recommendations for such use. As such, use of any agents is generally contraindicated. Alefacept is specifically contraindicated in HIV infection, as it reduces CD4 count.

Bacterial infections

Reactivation of mycobacterial infections with anti-TNF therapy is well recognized, and indeed, this can present with orofacial manifestations. It is crucial, therefore, that all patients in whom these agents may potentially be used should be screened for mycobacterial infections, especially tuberculosis, with consideration of prophylactic anti-tuberculosis therapy if there is evidence of latent disease and definitive anti-tuberculosis treatment in active disease. In contrast, there is no evidence of an increased frequency of tuberculosis with rituximab. It has been suggested that serious infections with rituximab may be more likely in patients being treated for mucocutaneous disease. Consequently, biological therapy should not be started in the presence of significant infection and clinical vigilance for such events is advocated; treatment should be stopped if serious infection develops. In clinical practice, any potential source of infection should be treated prior to initiation of anti-TNF therapies. An increased risk of surgical site perioperative infection has also been reported with anti-TNFα therapy; the general guidance is that, where possible, biological

Table 19.8 *Biological response modifiers in current clinical use*

Agent	Actions	Administration	Adverse effects	Monitoring
Adalimumab	Tumour necrosis factor alpha (TNF α) inhibitor; initiates complement-mediated cell lysis	Subcutaneous	Respiratory tract infections, dizziness, headache, neurological sensation disorders, cough, nasopharyngeal pain, diarrhoea, abdominal pain, mouth ulcers, increased hepatic enzymes, rash, pruritus, musculoskeletal pain, injection site reaction, pyrexia, fatigue	Pre-treatment purified protein derivative (PPD) screening, other recommended screening Liver function tests (LFTs), full blood count (FBC), antinuclear antibodies (ANA), anti-double-stranded (anti-ds) DNA, hepatitis B and C viruses (HBV/HCV), human immunodeficiency virus (HIV)
Alefacept	CD2 antagonist fusion protein; impairs memory T cells	Intramuscular	Lymphopenia, malignancies, infections, hypersensitivity reactions	CD4+ T lymphocyte counts every 2 weeks
Anakinra	Interleukin 1 (IL-1) inhibitor	Subcutaneous	Neutropenia, 'flu-like symptoms, infections	Pre-treatment PPD screening Blood platelets White cell count (WBC) Haemoglobin and haematocrit LFTs C-reactive protein (CRP) Other
Efalizumab	CD11a inhibitor; blocks interaction of lymphocyte function-associated antigen 1 (LFA-1) and intercellular adhesion molecule 1 (ICAM-1)	Subcutaneous	Leukocytosis and lymphocytosis, 'flu-like symptoms, infections, hypersensitivity, psoriasis, arthralgia, arthritis, back pain, raised alkaline phosphatase, thrombocytopenia, injection site reactions	Pre-treatment PPD screening Blood platelets WBC Haemoglobin and haematocrit LFTs CRP Other
Etanercept	TNF α inhibitor; blocks TNF receptor	Subcutaneous	Infections, reactions at injection site, allergic reactions, cardiac failure, lupus-like syndrome	Pre-treatment PPD screening/possible screening for tuberculosis FBC LFTs ANA and anti-ds DNA
Infliximab	TNF α inhibitor; initiates complement-mediated cell lysis	Intravenous	Infusion reaction and hypersensitivity, infections, respiratory infection, hepatitis B reactivation, serum sickness-like reaction, headache, vertigo, dizziness, nausea, abdominal pain, raised hepatic transaminases, urticaria, rash, hyperhidrosis, lymphoma and other malignancies	Pre-treatment PPD screening Possible monitoring and screening for: LFTs ANA and anti-DNA HBV, HCV, HIV FBC
Rituximab	Anti-CD 20; depletes B cells	Intravenous	Infections, human anti-chimeric antibodies, leukopenia, neutropenia, infusion-related reactions, angioedema, nausea Cardiac reactions, dyspnoea, bronchospasm, gastrointestinal effects, progressive multifocal leukoencephalopathy (PML) due to JC virus	FBC with differential and platelets, peripheral CD20+ cells HBV screening Signs or symptoms of PML (focal neurological deficits: hemiparesis, visual field deficits, cognitive impairment, aphasia, ataxia and/or cranial nerve deficits) Cardiac monitoring

treatment should be stopped prior to surgery and reintroduced following satisfactory postoperative healing. When rituximab is used in the organ transplant setting, numerous reports exist of postsurgical infection; some studies identifying at least a trend towards increased risk, although some report that the incidence may be no greater than that for other transplant regimens. However, with such insufficient data available, it remains true that a potential impact on wound healing and infectious complications exists with rituximab, and similar cautions as for TNF α blockers should be applied. Concerns have been raised regarding reports of infective endocarditis in patients receiving biological therapies. Although some of these have included infection with atypical organisms, others have been caused by oral commensals such as *Streptococcus intermedius*.

Other effects

TNF α inhibitors may also be associated with an increased risk of malignancy. They should not be given in patients with multiple sclerosis and must be used with caution in patients with a history of other demyelinating diseases, such as optic neuritis and Guillain-Barré syndrome. Cardiac failure is aggravated during TNF α blockade.

TNF α inhibitors use in pregnancy may cause fetal adverse effects, in particular those of the VACTERL spectrum – a syndrome usually seen in embryos and fetuses, characterized by abnormalities of vertebrae, anus, cardiovascular tree, trachea, oesophagus, renal system and limb-buds, and associated with the administration of sex hormones during early pregnancy. Rituximab treatment during pregnancy is

Box 19.3 *Uses of, concerns about and contraindications to biological therapies***Eligibility**

- Disease that is severe, or intolerant of or resistant to standard systemic therapy
- Patients fully informed of risks and benefits, and the fact that treatment is off label

Contraindications

- Hypersensitivity to agent
- Active infections
- Severe heart failure
- Pregnancy and lactation (rituximab)
- Demyelinating disease (tumour necrosis factor alpha [TNF α] inhibitors)
- Active or recent (10 y) malignancy (except non-melanoma skin cancer)

Pre-treatment screening

- History and physical examination
- Blood tests:
 - Full blood picture
 - Liver function tests
 - Screen for viruses (human immunodeficiency virus, hepatitis B or C virus)
 - Serum immunoglobulin levels
- Chest radiograph
- Purified protein derivative (PPD)
- Assess vaccination necessity; no live vaccines; give inactivated vaccines

Adverse events

- Hypersensitivity reactions (including anaphylaxis)
- Reactivation of latent tuberculosis, or progression of recently acquired infection
- Viral reactivation
- Exacerbation of cardiac failure
- Potential for malignancy, especially lymphoma (TNF α inhibitors)
- Cutaneous and mucocutaneous reactions
- Opportunistic infections (particularly fungal)
- Progressive multifocal leukoencephalopathy (PML)

Monitoring

- Infection throughout treatment
- New or exacerbation of cardiac dysfunction
- Central nervous system demyelinating disorders
- Malignancy (compliance with national screening programmes)

specifically contraindicated and should be avoided in lactating women. A variety of adverse effects has been reported with administration of TNF α blockers, involving approximately 20% of patients, and ranging from minor reactions at injection sites to hypersensitivity reactions and anaphylaxis. Mucocutaneous drug eruptions may be seen in patients receiving biological therapies.

Monitoring during biological therapy

Monitor the following every 3–6 months:

- Cardiac function
- Neurological status
- Full blood count
- Liver function tests
- In patients taking alefacept, CD4+ T-cell count every 2 weeks.

Screen for tuberculosis annually.

APPENDIX 19.1 INTERLEUKINS (ILS)

(Modified from Wikipedia)

Name	Main sources	Functions
IL-1	Macrophages	Activates T cells. Induces IL-6. Generates prostaglandins. Induces acute-phase reaction and fever
IL-2	Th1 cells	T-cell growth and apoptosis
IL-3	T cells	Haemopoietic cell growth
IL-4	Th2 cells, just activated naive CD4+ cell, memory CD4+ cells, mast cells	Proliferation of B cells, and development of T cells and mast cells. Important role in allergic response (immunoglobulin E [IgE])
IL-5	Th2 cells	B-cell and eosinophil differentiation and IgA production
IL-6	Macrophages, Th2 cells	Activates many cells inducing acute-phase reaction and inflammation
IL-7	Stromal cells of the red marrow and thymus	B-, T- and natural killer (NK)-cell survival, development and homeostasis
IL-8	Macrophages, epithelial cells, endothelial cells	Neutrophil chemotaxis
IL-9	T cells, specifically by CD4+ helper cells	T-cell and mast-cell growth
IL-10	Monocytes, Th2 cells, mast cells	T-cell and mast-cell growth
IL-11	Bone marrow stroma	Plasma-cell growth
IL-12	Macrophages	Induces interferon-gamma (IFN-γ)
IL-13	Th2 cells	Induces IgE
IL-14	T cells and certain malignant B cells	B-cell growth
IL-15	Mononuclear phagocytes (and some other cells) following infection by virus(es)	Induces production of T and B cells, and NK-cell growth

(Continued)

Name	Main sources	Functions
IL-16	A variety of cells (including lymphocytes and some epithelial cells)	CD4-cell chemoattractant
IL-17	T cells	Induces IL-6, IL-8 and granulocyte colony-stimulating factor inflammatory cytokines
IL-18	Macrophages, liver	Induces production of IFN- γ
IL-19	T cells	–
IL-20	Monocytes	Regulates keratinocyte proliferation and differentiation
IL-21	T cells	Induces proliferation in NK cells and cytotoxic T cells
IL-22	T cells	Activates signal transducers and activators of transcription (STAT)1 and STAT3, and increases production of acute-phase proteins such as serum amyloid A, α_1 -antichymotrypsin and haptoglobin in hepatoma cell lines
IL-23	Macrophages	Increases angiogenesis but reduces CD8 T-cell infiltration
IL-24	T cells, macrophages	Tumour suppression, wound-healing and psoriasis
IL-25	Mast cells	Induces IL-4, IL-5 and IL-13 production, which stimulates eosinophil expansion
IL-26	T cells	Enhances IL-10 and IL-8 secretion, and epithelial cell expression of CD54
IL-27	Dendritic cells	Regulates B- and T-lymphocyte activity
IL-28	Dendritic cells	Defence against viruses
IL-29	Dendritic cells	Defences against microbes
IL-30	–	Is one chain of IL-27
IL-31	T cells	Possible role in skin inflammation
IL-32	T cells	Induces monocytes and macrophages to secrete tumour necrosis factor alpha, IL-8 and CXCL2
IL-33	Stroma cells, fibroblasts	Induces helper T cells to produce cytokines

APPENDIX 19.2 IMMUNOMODULATORY NON-BIOLOGICAL AGENTS

Mode of action	Main adverse effects	Main interactions with	Main contraindications	Monitoring/cautions
<i>Azathioprine</i>				
Thiopurine methyltransferase (TPMT) metabolizes to active mercaptopurine (MP), which acts as a purine analogue and blocks nucleotides and DNA synthesis, and inhibits lymphocyte division	Arrhythmias	Allopurinol	Absolute:	Assay TPMT in whites/blacks, inosine triphosphate pyrophosphatase (ITPA) in Japanese
	Fatigue	Angiotensin-converting enzyme inhibitors (ACEIs)	Bone marrow hypofunction	Bone marrow suppression in low TPMT or ITPA
	Gastrointestinal	Aspirin	Low enzyme TPMT	Blood (full blood count [FBC] every 2 weeks, then every 3 months) irrespective of TPMT status
	Haematological (leukopenia early, usually)	Ciclosporin	Hepatic disease	Blood pressure
	Hypersensitivity (in 3–42 days fever, myalgia, arthralgia, liver/kidney)	Clozapine	Hypersensitivity to azathioprine /6-MP	Hypersensitivity
	Hypotension	Co-trimoxazole	Infections	Infections (viruses: HBV, HCV, HIV, VZV)
	Liver damage (hepatitis)	Cyclophosphamide	Pancreatitis	Liver damage (liver function tests)
	Nausea	Febuxostat	Pregnancy and lactation	Malignancy (examination, Pap test, faecal occult blood [FOB])
	Pancreatitis	Immunosuppressants	Vaccines (live)	Renal damage (renal function tests)
	Renal damage (nephritis)	Mesalazine	Relative:	
	Carcinogenicity	Methotrexate	Pre-malignancy: skin, cervix, ?oral	
	Non-melanoma skin cancer (>10 y and ultraviolet radiation)	Osalazine	Renal disease	

(Continued)

Mode of action	Main adverse effects	Main interactions with	Main contraindications	Monitoring/cautions
Ciclosporin Calcineurin inhibitor Binds to immunophilin (cyclophilin) and resultant complex inhibits calcineurin and thus interleukin 2 (IL-2) Ciclosporin prevents dephosphorylation of nuclear translocation of nuclear factor of activated T cells (NFAT) and thus blocks cytokine IL-2	Non-Hodgkin lymphoma (often year 1 and Epstein–Barr virus or inflammatory bowel disease)	Ribavirin	Viruses: hepatitis B/C (HBV/HCV), human immunodeficiency virus (HIV), varicella zoster (VZV), herpes simplex (HSV), human papillomavirus (HPV)	
	Teratogenicity	Sulfasalazine Trimethoprim Warfarin Grapefruit juice and cytochrome P450 inhibitors Cytostatic drugs Muscle relaxants		
	Allergy	Allopurinol	Hypertension	Blood (FBC and lipids)
	Blood dyscrasias (anaemia, thrombocytopenia)	Aminophylline	Porphyria	Blood pressure
	Gingival swelling (drug-induced gingival overgrowth; DIGO)	Analgesics	Pregnancy	Infections
	Hearing defects	Antibiotics (doxycycline, erythromycin)	Renal disease	Liver damage (liver function tests)
	Hepatotoxicity	Anticonvulsants		Neoplasia
	Hirsutism	Antifungals (azoles)		Renal damage (renal function tests)
	Hyperglycaemia	Carbamazepine, phenytoin, isoniazid, rifampicin, phenobarbital and other drugs that induce CYP3A4 – may lower ciclosporin concentrations. Drugs that inhibit cytochrome P450-3A4 may raise ciclosporin levels and risks of toxicity		
	Hypertension	Acute renal failure, rhabdomyolysis, myositis, and myalgias when taken concurrently with statins		
Colchicine Interferes with tubulin and polymorphonuclear leukocyte (PMNL) motility, and blocks IL-1 via NALP3 inflammasome	Hypomagnesaemia Muscle pain Nephrotoxicity Neurotoxicity/fits/tremors Peptic ulceration Teratogenicity			
	Diarrhoea	Antibiotics (clarithromycin, erythromycin, telithromycin)	Cardiac disease	Blood (FBC)
	Hair loss	Antifungals (fluconazole, itraconazole, ketoconazole)	Hepatic disease	Infections
	Myelotoxicity (anaemia; neutropenia)	Ciclosporin	Older patient	Liver damage (liver function tests)
	Neuromyopathy	Fibrates	Pregnancy	Neoplasia
		Protease inhibitors	Renal disease	
		Statins Grapefruit juice and cytochrome P450 inhibitors

Mode of action	Main adverse effects	Main interactions with	Main contraindications	Monitoring/cautions
<i>Corticosteroids</i>				
Transactivate IL-10	Immunosuppression	Acetazolamide	Diabetes	Blood glucose
Annexin A1 (lipocortin-1)	Adrenal insufficiency	Aminoglutethimide	Hypertension	Blood pressure
I κ B (inhibitor of nuclear factor kappa B)	Hyperglycaemia (increased gluconeogenesis, insulin resistance and impaired glucose tolerance – ‘steroid diabetes’)	Antacids	Osteoporosis	Bone mineral density
Tyrosine aminotransferase	Appetite stimulation and weight gain – visceral and truncal fat deposition (central obesity), expansion of malar fat pads, increased plasma amino acids, increased urea formation, negative nitrogen balance	Antihypertensives	Peptic ulcer	Eyes
Trans-repression of IL-1, 2, 6, 8	Raised blood pressure	Carbamazepine	Tuberculosis	Infections
Vascular endothelial growth factor (VEGF)	Increased skin fragility, dilatation of small blood vessels and easy bruising	Carbenoxolone		Urea and electrolytes
Cyclo-oxygenase-1 (COX-1)	Reduced bone density (osteoporosis, osteonecrosis, higher fracture risk)	Coumarin anticoagulants		Weight
Prostaglandins (PGs)	Muscle breakdown (proteolysis), weakness	Diuretics		Cautions required include:
Tumour necrosis factor (TNF)	Anovulation, menstrual period irregularity, pubertal delay	Hormonal contraceptives		Calcium supplements
Interferon-gamma (IFN γ)	Growth failure	Hypoglycaemics		Vitamin D
Inducible nitric oxide synthetase (iNOS)	Central nervous system excitation (euphoria, psychosis)	Insulin		Antiresorptive medication (bisphosphonates)
Chemokines	Glaucoma, cataracts	Liver enzyme inducers/inhibitors		Warning card
Adhesion molecules	Bone: avascular necrosis/osteoporosis	Non-depolarizing muscle relaxants		
Glucocorticoid response elements	Eyes: cataract/central serous retinopathy/glaucoma	Oestrogens		
Anti-inflammatory genes/molecules, e.g. lipocortin-1, IL-10 and IL-1ra	Gastrointestinal	Phenobarbital		
Lipocortin (macrocortin) upregulated	Growth impairment	Phenytoin		
Leukotrienes, PGs and thromboxanes	Hepatic	Primidone		
COX-1 and COX-2 expression also suppressed	Hyperglycaemia, hyperlipidaemia, hypertension	Rifabutin, rifampicin		
Corticosteroids also induce I κ B subtype α , reducing NF- κ B translocation to the nucleus, thus decreasing proinflammatory cytokines	Infections (tuberculosis, etc.)	Salicylates		
Glucocorticoids also reduce microvascular permeability, mast cells and eosinophils	Malignancy?	Vaccines		
Corticosteroids may reduce inflammation by reversing increased capillary permeability, suppressing PMNLs and decreasing inflammatory cytokines	Mental			
	Renal			
	Skin: bruising, hirsutism, striae			
	Teratogenicity?			
	Weight gain

Monoclonal antibody/fusion protein	Common names	Targets	Applications
Palivizumab	Synagis	Respiratory syncytial virus	Respiratory syncytial virus
Panitumumab	Vectibix	EGFR	Cancers
Ranibizumab	Lucentis	VEGF	Age-related macular degeneration
Raxibacumab	ACthrax	<i>Bacillus anthracis</i>	Anthrax
Rilonacept	Arcalyst	IL-1	Autoinflammatory disease
Rituximab	Rituxan or Mabthera	CD20	NHL, RA
Sunitinib	Sutent	Tyrosine kinase	Cancers (renal)
Tocilizumab	Actemra	IL-6R	RA
Tofacitinib	Xeljanz	Janus kinases	RA
Tositumomab	Bexxar	CD20	NHL
Trastuzumab	Herceptin	ErbB2 (Her 2)	Breast cancer
Ustekinumab	Stelara	IL-12, IL-23	Psoriasis

APPENDIX 19.4 USES OF BIOLOGICS IN ORGAN DISEASE

Cytokines

- Interferons (IFNs)
- Interleukins (ILs)

Haematopoietic growth factors

- Erythropoietins
- Colony-stimulating factors (CSFs)

Enzymes

- Thrombolytics
- Aldurazyme
- Rasburicase

Monoclonals

- Anti-IL2R (basiliximab)
- Anti-immunoglobulin E (IgE; omalizumab)

Fusion proteins

- Tumour necrosis factor receptor (TNFR) linked to Fc of IgG (etanercept)
- Lymphocyte function-associated antigen 3 (LFA3TIP) fused IgG1 heavy chain (alefacept)

Oncology

- Alemtuzumab (Campath)
- Bavacizumab (Avastin)
- Cetuximab (Erbix)
- Ibritumomab (Zevalin)
- Rituximab (Rituxan)
- Trastuzumab (Herceptin)

Cardiology

- Abciximab (ReoPro)
- Fibrinolytics

Pulmonary system

- Omalizumab (anti-IgE)
- Dornase alfa (Pulmozyme)

- Lebrikizumab (humanized monoclonal antibody that binds IL-13 – being developed for asthma treatment)
- Montelukast (leukotriene receptor antagonist)

Infections

- IFN α (hepatitis C virus)
- Palivizumab (Synagis; antibody to respiratory syncytial virus)

Dermatology

- Alefacept (anti-LFA3)
- Efalizumab (Raptiva; anti-CD11a)
- Becaplermin (Regranex; platelet-derived growth factor)
- Palifermin (keratinocyte growth factor)

Hereditary disorders

- IFN γ

Arthritis

- Infliximab (Remicade; anti-TNF)
- Etanercept (Enbrel; Fc TNFR)
- Anakinra (IL-1RA)
- Adalimumab (Humira; anti-TNF)

Neurology

- IFN β
- Tissue plasminogen activator
- Botulinum toxin

Autoimmune disorders

- Etanercept
- Adalimumab
- Infliximab
- Rilonacept
- Canakinumab
- Epratuzumab

KEY POINTS

- Immunodeficiencies are mainly secondary to malnutrition, drugs or infections
- Immunodeficiencies predispose to infections and neoplasms
- The world epidemic of HIV continues, despite new therapies

Immunodeficiencies are states that result from a defect in the immune response, and predispose to recurrent infections, especially of skin, mucosae and respiratory tract (Fig. 20.1). An immunodeficient patient is often somewhat ponderously referred to as an 'immunocompromised host'. Human immunodeficiency virus (HIV) disease and the resultant acquired immune deficiency syndrome (AIDS) constitute a major immunodeficiency and public health issue worldwide but other important and common causes of secondary immune defects are immunosuppressive therapy and malnutrition (Table 20.1). Vitamin D deficiency is also now recognized as causing failure of immune activation. Primary (genetically determined) immune defects are mostly rare, apart from selective immunoglobulin A (IgA) deficiency.

The most important consequence of all immunodeficiencies is an abnormal susceptibility to infections, frequently caused by organisms of such low pathogenicity as rarely to affect the normal individual (opportunistic infections). Candidosis, herpetic infections and *Pneumocystis jiroveci* (*P. carinii*) pneumonia (Table 20.2) are common. Immunocompromised people are also prone to various malignant neoplasms, some virally related.

Immunodeficiency diseases can affect any component of the immune system but often do not produce clinical pictures that are precisely

Fig. 20.1 Immune defects and infections.

Table 20.1 Causes of immunodeficiency

Infections					
Mucocutaneous	Gastrointestinal	Respiratory	Meningitis; encephalitis	Neoplasms	Others
Herpes simplex	Cryptosporidiosis	<i>Pneumocystis jiroveci</i> (<i>P. carinii</i>)	Creutzfeldt–Jakob agent	Kaposi sarcoma (Kaposi sarcoma herpesvirus, KSHV)	Thrombocytopenia
Herpes zoster	Microsporidiosis	Aspergillosis	Papova viruses	Lymphomas (EBV)	Lupus erythematosus
Cytomegalovirus (CMV)	Isosporiasis	Candidosis	<i>Cryptococcus neoformans</i>	Squamous cell carcinoma (cervix, anus) (HPV)	Encephalopathy
Epstein–Barr virus (EBV)	Giardiasis	Cryptococcosis	<i>Toxoplasma gondii</i>		Drug allergies
Human herpesvirus 8		Histoplasmosis			
Human papilloma viruses (HPV)		Zygomycosis (mucormycosis)			
Molluscum contagiosum		Strongyloidiasis			
Non-tuberculous mycobacteria		Tuberculosis			
<i>Candida</i> species		Non-tuberculous mycobacterioses			
<i>Staphylococcus aureus</i>		Legionellosis			
Histoplasmosis		<i>Pseudomonas aeruginosa</i>			
		<i>Staphylococcus aureus</i>			
		<i>Streptococcus pneumoniae</i>			
		<i>Haemophilus influenzae</i>			
		Toxoplasmosis			
		CMV			

predictable from the immune defect. Infections do vary in character as a consequence of the nature of the immune defect; the kinds of microorganisms to which the patient is exposed; and attempts at treatment (for example, broad-spectrum antibiotics used to control bacterial infections increase the risk of fungal infections such as candidosis). Thus, in T-cell disorders (such as HIV disease), cell-mediated immunity is principally affected but antibody production may also be impaired, so common infections are with fungi, viruses and certain bacteria - such as candida, herpesviruses and mycobacteria.

SECONDARY IMMUNE DEFECTS

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

HIV is the virus that can lead to AIDS. HIV (a lentivirus or retrovirus) infects CD4+ helper T lymphocytes, causing AIDS after an average of 10 years in the untreated, and has spread worldwide to create a global pandemic. In 2012 there were over 2 million new infections and 34 million infections recorded worldwide; there was a three-fold rise in individuals over 50 years of age in the UK and one-third of those infected in the UK remained undiagnosed. HIV is found worldwide, and disease patterns are changing as a result of increasing travel and the emergence of new pathogens, such as multidrug-resistant tuberculosis, and the appearance of exotic infections in temperate zones. HIV weakens the immune system, putting persons with HIV or AIDS at risk for many different types of infections. In untreated AIDS, the mortality rate is virtually 100%, although antiviral drugs can significantly impede disease progress.

GENERAL ASPECTS

AIDS was first recognized in 1981 in young men who have sex with men (MSM) in the USA. Sporadic cases have since been identified as long ago as 1959 in Central Africa (where the virus appears to have crossed the species barrier from chimpanzee monkeys).

In June 1981, five cases of *Pneumocystis carinii* (now *jiroveci*) pneumonia were reported in five young males; all suffered from cytomegalovirus infections. Later the same year in the USA, a series of previously healthy MSM who developed *Pneumocystis carinii* pneumonia and mucosal candidiasis were reported, with the suggestion that infection could have been caused by a cellular immunodeficiency. These publications present the first proven cases of what later was termed AIDS. As the first AIDS patients were MSM, it was initially believed that the illness was provoked by peripheral vasodilator drugs ('poppers'), especially amyl nitrite, used by male homosexuals to increase sexual activity. Nevertheless, by the end of 1981, a few cases of AIDS appeared in intravenous drug users, suggesting an infectious aetiology. AIDS was also recognised in all populations, mainly in heterosexuals. After the discovery of the aetiological virus (then termed human T-lymphotropic virus: HTLV-3), retrospective analyses confirmed the presence of the causal virus, which became known as HIV, in the tissues of a Norwegian sailor who died in 1976 and an Afro-American adolescent who died in 1969, and in the plasma of a Congolese male obtained from 1959.

Ten years after HIV was defined, the use of a standardized method to quantify its plasma concentration (viral load) became adopted worldwide. The viral replication rate is stable at every stage of the disease, being estimated at about 10^{9-10} new virions a day. Its assessment is important in the follow-up of infected patients and in the choice of therapeutic approach.

HIV transmission

HIV is transmitted via body fluids, mostly by:

- sexual intercourse – semen, blood and possibly saliva may contain HIV
- contaminated blood, blood products and donated organs
- contaminated needles – intravenous drug users and needlestick injuries
- vertical transmission (mother to child) – *in utero*, during childbirth and via breast milk.

HIV is spread primarily by sexual intercourse, via:

- having unprotected sex with someone who is HIV-infected: Not using a condom when having sex with a person who has HIV is a risk. Unprotected anal sex is riskier than unprotected vaginal sex. Among MSM, unprotected receptive anal sex is riskier than unprotected insertive anal sex. Unprotected oral sex can be a risk, but is a much lower risk than anal or vaginal sex.
- having multiple sex partners or another sexually shared infection (SSI). This can increase the risk of HIV infection.
- sharing needles, syringes, rinse water or other equipment used to prepare drugs of abuse for injection.
- being born to an infected mother. HIV can be passed from mother to child during pregnancy, birth or breast-feeding.

Less common modes of HIV transmission include:

- being damaged or 'stuck' with an HIV-contaminated needle or other sharp object
- receiving HIV-contaminated blood transfusions, blood products or organ/tissue transplants
- receiving unsafe or unsanitary injections or other medical or dental practices
- eating food that has been pre-chewed by an HIV-infected person
- being bitten by an HIV-infected person
- being in contact with HIV-infected blood or blood-contaminated body fluids and broken skin, wounds or mucous membranes
- engaging in 'French' or deep open-mouth kissing with an HIV-infected person if there is bleeding in the latter's mouth (this presents an extremely remote chance that HIV could be transmitted)
- undergoing tattooing or body piercing using unsafe or unsanitary procedures.

HIV cannot reproduce outside the body and is *not* spread by:

- air
- water
- insects, including mosquitoes
- social contact, like shaking hands or sharing cups or dishes
- closed-mouth or 'social' kissing
- saliva, tears or sweat – provided blood is absent; there is no documented case of HIV being transmitted by spitting.

The virus is transmitted mainly by intimate sexual contact and can infect anyone who practises risky behaviours, such as having sexual contact with an infected person or someone whose HIV status is unknown without using a condom. Sexual transmission of HIV is more likely during HIV seroconversion or in advanced AIDS, by receptive anal intercourse, or where there is genital ulceration. Saliva and breast milk may contain HIV, but transmission via the orogenital

route is uncommon. Reports that HIV virions are present in a cell-free state in saliva have not been confirmed and saliva contains inhibitory factors. However, saliva transmission may result from human bites.

Heterosexual intercourse is the main mode of transmission worldwide; it is an important route in developing countries in Africa and Asia, and is increasingly important in the developed world, where it is responsible for 25–50% of cases. MSM remain a major risk group in developed countries. In the UK, the number of young men diagnosed with HIV has more than doubled in the last decade and, in 2012, almost half of new cases were infected through sex between men. With antiretroviral therapy, more people with HIV now survive and this has resulted in a rise in the number of new cases of HIV infection – especially in MSM – along with increasing use of the Internet to make contact with new partners; greater substance abuse and use of medications to treat erectile dysfunction; and a rise in unsafe sexual practices. Unfortunately, multidrug-resistant HIV (MDR-HIV) has appeared, with a rapid progression to AIDS.

HIV spread by contaminated needles and syringes is an important route in injecting drug users. Persons infected with HIV, especially those who abuse drugs intravenously or/and are sexually promiscuous, may also be co-infected with other agents, including viruses, such as HTLV-1, HTLV-2 and hepatitis viruses, and other SSIs (Ch. 32). Transmission by needlestick injury is an occasional risk for health-care professionals (HCPs; see later and Ch. 31) and others.

Transmission of HIV can also occur via infected blood or blood products, including plasma, or tissues, such as in transplantation, but screening of blood and plasma for HIV antibody and heat treatment of clotting factor concentrates have substantially reduced the risk in developed countries. All HIV antibody-positive individuals are potentially infective and must not be allowed to donate blood, organs for transplantation or semen for artificial insemination. Rarely, some seronegative but infected blood (collected during the incubation period before antibodies are detectable) can still transmit HIV. Haemophiliacs, initially a risk group for HIV, now form only a small proportion of HIV patients.

Children can contract HIV intrapartum or via breast milk; approximately one-quarter of all untreated pregnant women infected with HIV pass the infection to their babies, and the figure rises to one-third if the infant is breast-fed. Antiretroviral drugs reduce this type of transmission (Box 20.1).

There is no reliable evidence for transmission of HIV by non-sexual social contact or by insect vectors such as mosquitoes or bedbugs. Studies of families of HIV-infected people have shown clearly that HIV is not spread through casual contact, such as the sharing of food utensils, towels and bedding, swimming pools, spas, telephones or lavatory seats.

Prevention of HIV/AIDS can thus be achieved by measures such as the use of condoms, the cessation of needle-sharing, screening blood and tissue before transfer to a recipient, and the use of antiretroviral drugs for children born to HIV-infected mothers.

HIV pre-exposure prophylaxis

Daily oral tenofovir disoproxil fumarate 300mg (TDF)/emtricitabine 200mg (FTC) is available as antiretroviral pre-exposure prophylaxis (PrEP) to reduce the risk for HIV acquisition. By 2013, four trials had compared HIV infection rates in participants randomized to receive PrEP compared with rates in participants on placebo. No serious toxicities were identified, efficacy was around two-thirds and there was no evidence of adverse effects among fetuses exposed to TDF or FTC. Daily oral TDF/FTC use has been shown to be safe in reducing the risk for sexual HIV acquisition when used consistently. The efficacy

Box 20.1 Main antiretroviral agents

1. Reverse transcriptase inhibitors

Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)

- Abacavir (ABC)
- Didanosine (ddI)
- Emtricitabine (FTC)
- Lamivudine (3TC)
- Stavudine (d4T)
- Tenofovir (TDF)
- Zidovudine (AZT, ZDV)

Non-nucleotide reverse transcriptase inhibitors (NNRTIs)

- Delavirdine (DLV)
- Efavirenz (EFV)
- Etravirine (ETR)
- Nevirapine (NVP)
- Rilpivirine (RPV)

2. Protease inhibitors (PIs)

- Atazanavir (ATV)
- Darunavir (DRV)
- Fosamprenavir (FPV)
- Indinavir (IDV)
- Lopinavir (LPV)
- Nelfinavir (NFV)
- Ritonavir (RTV)
- Lopinavir/ritonavir (LPV/r)
- Saquinavir (SQV)
- Tipranavir (TPV)
- Amprenavir (APV)

3. Integrase inhibitor

Raltegravir (RAL)

4. Entry inhibitor

Fusion inhibitors

- Enfuvirtide (ENF, T-20)

CCR5 antagonist

- Maraviroc (MVC)

of TDF/FTC for HIV prevention is dependent on adherence to daily doses of medication; PrEP long-term safety in HIV-uninfected adults or following fetal exposure is not yet determined.

Centers for Disease Control and Prevention (CDC) guidance for clinicians considering using PrEP for adults at very high risk for HIV acquisition through heterosexual sex is as follows:

- TDF/FTC is contraindicated for PrEP in persons with unknown or positive HIV status.
- TDF/FTC daily can be safe and effective in reducing HIV infection in women and men at very high risk for acquiring HIV from penile–vaginal sex.
- PrEP use may be one option to help protect HIV-negative partners in discordant couples during attempts to conceive.
- Before beginning PrEP and if not pregnant at initiation, women of reproductive age should have a regular documented pregnancy test while receiving PrEP.

Further information is available at: <http://www.cdc.gov/hiv/prep/> (accessed 30 September 2013).

HIV epidemiology

HIV-1, the most common virus causing AIDS, has spread to all continents to create a global pandemic with the most devastating consequences ever known to humankind. A further virus, HIV-2, which originated in sooty mangabey monkeys, predominates in West Africa, and has also now spread to many countries, including Central Africa, Europe, the USA and South America; at present, however, there are few HIV-2 infections in developed countries.

An estimated 20 million people have died from AIDS since the epidemic was recognized. Estimates are that over 40 million HIV cases had developed worldwide by 2008 – more than 1 in every 100 sexually active adults. The difference between numbers estimated and reported is due to underdiagnosis (especially in the developing world); under-reporting and delayed reporting; and false extrapolation of basic information derived from Africa and MSM.

Probably 75% of cases worldwide are located in Africa, about 10% in Latin America, about 7% in the USA, about 5% in Asia and slightly less in Europe. However, epidemics are progressing in Asia, especially India and China, and in Eastern Europe. In the USA, the CDC estimated that, by 2008, gay and bisexual men of all races were the group most heavily affected by HIV, accounting for 53% of all new infections, and the impact of HIV was greater among blacks than any other racial or ethnic group, with an HIV incidence rate seven times higher than that of whites and almost three times higher than that of Latinos. Currently, HIV infection is the commonest cause of death in US men aged 25–44 years, and the third commonest cause of death in women of this age.

In the UK, HIV infection is the fourth most common cause of death in men aged 25–44 years. New HIV diagnoses in the UK in 2011 showed a slight decrease on 2010 and continued a year-on-year decline from the peak in 2005. The overall decline in new diagnoses is largely due to fewer reported cases among heterosexuals, who probably acquired their infection abroad. The number of new HIV diagnoses in MSM surpassed new diagnoses in heterosexuals. Half of those diagnosed in 2011 probably acquired their infection through sex between men. Continued low numbers of HIV diagnoses were made in people who inject drugs and through other exposures. All infections acquired through receipt of blood/tissue products diagnosed since 2002 were acquired outside of the UK.

Pathogenesis

The HIV viruses are ribonucleic acid (RNA) viruses. HIV-1 and HIV-2 differ in antigens and nucleic acids but are transmitted similarly, have similar biological properties and are both capable of causing disease. HIV-2 may progress more slowly and cause less profound immunosuppression. HIV-1/HIV-2 co-infection can occasionally be acquired. However, the remaining discussion relates to HIV-1.

HIV-1 can be classified into two major groups: M, which contains ten genetically distinct subtypes (A to J), and O, which contains several very heterogeneous viruses. The B virus is found in USA, Europe and Central Africa.

HIV contains several so-called 'core' proteins and is surrounded by an envelope made up of 'coat' proteins; one of these, the viral cover glycoprotein (gp 120), interacts with a cell surface protein receptor (CD4). The external layer or cover presents 72 external projections where glycoproteins (gp41, gp120) are placed, as well as a number of proteins derived from the host cells, such as beta₂-microglobulin and the alpha and beta chains of the human leukocyte antigen (HLA)-DR. Chemokine (co-)receptors are also involved, the most important

being CCR5, the main monocyctotropic cell receptor; chemokines (RANTES, MIP-1 α MIP-2 β); and the CXCR4 (fusine), which is inside the lymphotropic cells and whose natural linkage is stromal-derived factor 1 (SDF1) chemokine. There are several viral variants with different tropisms to CCR5 and CXCR4, which have the capacity for interaction with different co-receptors such as CCR2, CCR3, BONZO and BOB; they are sometimes capable of penetrating a cell using multiple co-receptors. The importance of RANTES and SDF lies in their capability to compete for the same HIV receptors, blocking the viral cycle by preventing virus penetration.

CD4 cells are mainly helper-inducer T lymphocytes, monocytes and macrophages, Langerhans cells, brain glial cells and some colonic cells. Brain tissue, in particular the cells of monocyte-macrophage lineage, can become infected with HIV. Neurological damage may also be mediated by the production of factors that affect neuronal cell function or neural transmitters by HIV-infected macrophages. Most HIV is tropic for various chemokines such as CC CKR-5 (CCR5-tropic virus or R5), involved in HIV-cell attachment; a few patients appear able to resist infection because of altered expression of this chemokine or the emergence of CXCR4-tropic virus strains (X4). Some HIV strains show dual tropism. HIV-1 variants that use the co-receptor CCR5 for entry (R5; macrophage tropic) predominate in early infection, while variants that use CXCR4 emerge during disease progression. Some late-stage variants use CXCR4 alone (X4; T-cell tropic), while others use both CXCR4 and CCR5 (R5X4; dual tropic). One coat protein, p24, is particularly antigenic and antibodies to p24 form the basis for most serological testing (the HIV test). The coat proteins are subject to considerable variability, making vaccine development difficult.

After interaction of the viral particle and receptors, the virus coat merges with the cell membrane, losing the external capsule, while the nucleocapsid penetrates the cytoplasm, releasing viral RNA. The genetic material is set inside the core, constituted by two identical RNA strands of positive polarity, nucleoproteins and several enzymes necessary to complete the viral cycle which eukaryote cells lack. HIV also contains enzymes involved in its pathogenicity – reverse transcriptase (which can transcribe DNA from RNA, i.e. in the reverse direction; hence 'retrovirus') and proteases. A retrotranscription is produced in the infected cell by a number of reactions in which DNA polymerase, RNAase and inverse transcriptase (from the virion) are involved. A DNA double strand develops from the RNA genome of the virus. This viral DNA is carried to the cell core, forming part of the host genome, due to the action of the viral integrase and other proteins such as Vpr, p17 and Nef, and becoming the integrated provirus. In the CD4 lymphocytes at rest, the viral genome is incompletely retrotranscribed and the integration process ends only when the cell becomes active. These proviruses lack pathogenic capability and, thus, preventing cellular activation would avoid the virus cytopathic effect.

The messenger RNA is carried to the cytosol and processed in different transcripts of different sizes, via the action of the Rev viral protein, leading to the synthesis of viral proteins by the polysomes. The absence of Rev protein would provoke the gathering of messenger RNA in the cell core.

Viral proteins synthesized and forming a single long chain have to be processed (cut) in order to become structural elements of the nucleocapsid and the viral coat, as well as to form proteins of enzymatic activity (transcriptase, ribonuclease, integrase and protease). In this process, although it is the protease action that is essential in the production of viral particles, turning the p55 pre-protein precursors into p24, p17, p9, p6 nucleocapsid proteins and the gp160 ones into gp41 and gp120, different viral proteins such as Vif and Vpu are also involved. These are potential targets for therapy.

Finally, the viral genome, covered by the nucleocapsid, projects into the cellular membrane within a layer of proteins, such as viral beta₂-microglobulin and gp41 and gp120; the virus is then released.

After primary infection with HIV, acute viraemia results in widespread dissemination of HIV. The virus is trapped in follicular dendritic cells in lymphoid tissue germinal centres and there is expansion of a subset of CD8 cells that are precursors of HIV-specific cytotoxic T cells. Proinflammatory cytokines, including interleukin-6 (IL-6), tumour necrosis factor, gamma-interferon and IL-10, are also over-expressed and may represent an unsuccessful attempt at a protective response. Dendritic cells are involved in the initiation and propagation of HIV infection in CD4 cells.

Antibodies to HIV develop and appear in the serum within 6 weeks to 6 months from infection (seroconversion) but, within this window, the patient may be seronegative (though HIV may be detected by the polymerase chain reaction; PCR). The seroconversion clinical illness is a battle between the virus and the host. Usually, the virus has been proliferating unchecked prior to this point; therefore infectivity is maximal and thereafter wanes (although never dropping to zero). There is then a variable latent period that can last years, until HIV infection manifests with HIV disease and, ultimately, with AIDS.

CLINICAL FEATURES

Infection with HIV may be staged according to its clinical features (Table 20.3). After primary infection with HIV, an acute viraemia results in widespread dissemination of the virus. Antibodies to HIV develop and appear in the serum within 6 weeks to 6 months of infection (seroconversion). One-third of individuals develop a clinical seroconversion illness 3–6 weeks after infection, resembling glandular fever; this is often severe and is termed the acute retroviral syndrome (ARS). Sometimes there is neurological involvement or a rash or mouth ulcers (Fig. 20.2). HIV infection may then remain asymptomatic for a median time of about 10 years. However, despite having circulating (and thus diagnostic) antibodies, people are also able to transmit the disease in the interim. Persistent generalized lymphadenopathy may become evident (Fig. 20.3). As HIV damages CD4 cells in the immune and nervous systems, the risk of development of severe immunodeficiency, and symptoms of disease, rises. HIV damage to CD4+ lymphocytes leads to a lymphopenia over about 6 months to 10 years, a fall in the ratio of helper (CD4+) to suppressor (CD8+) lymphocytes, a profound defect in cell-mediated immune reactivity, and *HIV disease*, which manifests with infections (see Fig. 20.2) as the CD4 count falls to about 500/mm³, and the CD4+ to CD8+ T-lymphocyte ratio falls. HIV disease manifests in a variety of clinical syndromes, commonly including infections (Fig. 20.4), neoplasms, and neurological and autoimmune disorders (Table 20.4). The CDC definition of *AIDS* comprises a CD4 count of less than 200/mm³ of blood in a patient infected with HIV and a clinical condition associated

with advanced HIV disease – such as pulmonary tuberculosis (TB), *Pneumocystis* pneumonia, recurrent episodes of pneumonia or invasive cervical carcinoma.

Patients can, however, develop a range of infections (viral, mycobacterial, fungal and parasitic), malignancies (malignant neoplasms,

Fig. 20.2 HIV progression.

Fig. 20.3 Acute HIV infection – seroconversion illness.

Table 20.3 Centers for Disease Control and Prevention (CDC) classification of HIV infection

CDC stage	Presentation
1	Primary seroconversion illness
2	Asymptomatic disease
3	Persistent generalized lymphadenopathy (PGL)
4a	AIDS-related complex (ARC) but no AIDS-defining conditions
4b–d	AIDS (AIDS-defining illness)

Fig. 20.4 Herpes zoster in HIV/AIDS.

Table 20.4 Main manifestations of HIV/AIDS	
Main manifestations	Comments
Opportunistic infections	Mainly fungal and viral
Neoplasms	Mainly Kaposi sarcoma and lymphoma
Neurological disorders	Mainly dementia
Autoimmune disorders	Mainly purpura

including melanoma, basal cell carcinoma, Kaposi sarcoma, lymphomas and squamous cell carcinomas of the skin and lip, and carcinoma of the cervix, external genitalia and perineum) and encephalopathy. Loss of weight and wasting are common in AIDS and, in Africa, is called ‘slim disease’ (Figs 20.5 and 20.6). The onset of AIDS may be influenced by the HIV virus titre, patient age, gender, drug habits, immunogenetics and other factors. Clinical disease is most likely to appear when the CD4 counts fall to low levels, where the infected person has depressed defences for other reasons (e.g. diabetes or malnutrition), and where there is high exposure to potential pathogens (e.g. TB, cryptosporidiosis or histoplasmosis).

In the developed world, about 20% of HIV-infected people develop AIDS within 5 years, and 50% at 10 years; nearly all will have developed AIDS at 20 years unless treated. Some HIV-infected individuals have, or are vulnerable to, a host of co-morbid conditions, including other infections (e.g. fungal/viral infections, hepatitis, SSIs, TB), substance abuse, mental illness and homelessness.

A very small minority of people appear resistant to HIV infection, mostly because of a mutation in the *CCR5* gene called CCR5-delta32, which inhibits HIV binding to CD4 cells. A very few HIV-infected persons (about 2%) inherently appear not to develop AIDS over periods as long as 15 years, mostly because they retain active cytotoxic T cells.

The 2008 CDE Case Definition for HIV infection in adults is as follows (http://www.cdc.gov/osels/ph_surveillance/nndss/casedef/aids2008.htm; accessed 30 September 2013):

- Stage 1:
No AIDS-defining condition (see below), and either CD4+ T-lymphocyte count of more than 500 cells/microlitre or CD4+ T-lymphocyte percentage of total lymphocytes of ≥ 29
- Stage 2:
No AIDS-defining condition, and either CD4+ T-lymphocyte count of 200–499 cells/microlitre or CD4+ T-lymphocyte percentage of total lymphocytes of 14–28

Fig. 20.5 AIDS.

Fig. 20.6 Slim disease in HIV/AIDS.

- Stage 3 (AIDS):
CD4+ T-lymphocyte count of <200 cells/microlitre or CD4+ T-lymphocyte percentage of total lymphocytes of <14 or documentation of an AIDS-defining condition. Documentation of an AIDS-defining condition supersedes a CD4+

T-lymphocyte count of ≥ 200 cells/microlitre and a CD4+ T-lymphocyte percentage of total lymphocytes of >14

Or criteria for HIV infection are met and at least one of the AIDS-defining conditions has been documented.

AIDS-defining conditions

These are listed as:

- candidiasis of bronchi, trachea or lungs
- candidiasis of oesophagus
- cervical cancer, invasive
- coccidioidomycosis, disseminated or extrapulmonary
- cryptococcosis, extrapulmonary
- cryptosporidiosis, chronic intestinal (>1 month's duration)
- cytomegalovirus disease (other than liver, spleen or nodes), onset at age >1 month
- cytomegalovirus retinitis (with loss of vision)
- encephalopathy, HIV-related
- herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis or oesophagitis (onset at age >1 month)
- histoplasmosis, disseminated or extrapulmonary
- isosporiasis, chronic intestinal (>1 month's duration)
- Kaposi sarcoma
- lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- lymphoma, Burkitt (or equivalent term)
- lymphoma, immunoblastic (or equivalent term)
- lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis* of any site, pulmonary, disseminated or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jiroveci* pneumonia
- pneumonia, recurrent
- progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- toxoplasmosis of brain, onset at age >1 month
- wasting syndrome attributed to HIV.

Opportunistic infections

Opportunistic infections are common and resistant to treatment. The pattern of infections varies geographically and with time. For example, histoplasmosis affects mainly AIDS patients from endemic areas of the USA and tuberculosis is seen mainly in AIDS in Africa. Fungal, bacterial, protozoal and viral infections that may be seen are described below.

Fungi

Pneumocystis jiroveci (*P. carinii*) pneumonia is a common fungal (previously thought to be a protozoon) lung infection in patients with HIV/AIDS; it is seen up to 80% and is the immediate cause of death in up to 20%. Features include cough, dyspnoea, fever and malaise. Treatment is often with co-trimoxazole or pentamidine. Clindamycin/primaquine, atovaquone and dapsone/trimethoprim are alternatives. *Pneumocystis*

Fig. 20.7 Thrush in HIV/AIDS.

pneumonia is the most common opportunistic infection in people with HIV disease. People with CD4 cell counts under $200/\text{mm}^3$ have the highest risk of developing it.

Candidosis (candidiasis) is extremely common in the mouth (Fig. 20.7) and vagina, and virtually all patients experience it. HIV infection should be suspected in a young or youngish person who develops thrush without any apparent precipitating factor.

Cryptococcus neoformans is a mycosis that is the main cause of meningitis in AIDS and is especially common in Africa. It is treated with amphotericin or/and an azole.

Histoplasmosis, usually as disseminated disease, mainly affects persons from endemic areas in the Americas. The same applies to coccidioidomycosis. Both infections are treated with amphotericin or/and an azole.

Penicillosis (infection with *Penicillium marneffei*) is seen in some areas of Thailand.

Bacteria

Tuberculosis is particularly common in Africa and is spreading in the West, where some 5% of patients now have lung infection with *Mycobacterium tuberculosis*, which is increasingly multidrug-resistant. TB can affect other sites, including the central nervous system (CNS). Since it can spread by droplets, it is becoming a major public health problem.

Atypical mycobacteria are found in about 40% of AIDS patients in the West, though double that number are actually infected. Over 95% of these are *Mycobacterium avium* complex (MAC) infections – *M. avium* and *M. intracellulare*.

Protozoa

Toxoplasmosis, due to the protozoon *Toxoplasma gondii*, affects about 15% of AIDS patients, and particularly involves the CNS. It is treated with pyrimethamine and sulfadiazine. Leishmaniasis may be seen.

Gastrointestinal protozoal infections (cryptosporidia, microsporidia, *Isospora belli*) often cause intractable diarrhoea.

Viruses

Herpes simplex virus can produce severe erosive lesions around the mouth, genitals, anus or other orifices, and may be seen intraorally and in the oesophagus. It can involve the skin and eyes. It is treated with aciclovir or foscarnet.

Herpes zoster can be severe, painful and incapacitating. It is treated with aciclovir or foscarnet.

Cytomegalovirus (CMV) is the most dangerous viral infection, capable of widespread lesions, especially ulceration throughout the gastrointestinal tract, and retinitis. It is treated with ganciclovir, foscarnet or cidofovir.

Epstein–Barr virus (EBV) is associated with oral hairy leukoplakia (Fig. 20.8) and with lymphomas.

Human papillomavirus (HPV) infections produce warty lesions.

Neoplasms

Various neoplasms are seen in HIV/AIDS – often virally related.

Kaposi sarcoma (an otherwise exceedingly rare tumour of endothelial cells among elderly persons) is seen almost exclusively in sexually transmitted HIV infection in MSM, associated with human herpesvirus 8 (HHV-8; Kaposi sarcoma herpesvirus, KSHV) and accounts for about 80% of neoplasms in AIDS. It often affects the gastrointestinal tract, skin, respiratory tract, mouth or lymph nodes. It is atypical in its early age of onset, distribution (particularly in the head and neck area) and greater malignancy (Fig. 20.9).

Lymphomas, mostly non-Hodgkin B cell lymphomas, are also seen in AIDS (Fig. 20.10); they frequently affect the brain and are often related to EBV. A diffuse infiltrative lymphocytosis syndrome (DILS) can cause asymptomatic bilateral parotid swelling; since patients with DILS can develop lymphomas, periodic observation is mandatory.

Carcinomas of the cervix and of the anus are increased in HIV disease and caused by HPVs.

Fig. 20.8 Hairy leukoplakia in HIV/AIDS.

Fig. 20.9 Kaposi sarcoma in HIV/AIDS.

Neurological disorders

HIV can cause a variety of neurological symptoms, culminating in encephalopathy (AIDS-related dementia) and death. In addition, intracranial infections (mainly parasitic, viral or fungal) are common. Up to two-thirds of AIDS patients develop a dementia complex, with personality changes, ataxia and convulsions; about 15% of AIDS patients develop CNS toxoplasmosis, while 10% develop cryptococcal meningitis. Spinal cord disease is seen in about 20% and may progress to bladder and bowel dysfunction.

Neurological manifestations can be acute, with fever, malaise, depression, fits, facial palsy and neuropathies affecting the extremities. Myelopathy or neuropathy can cause weakness of the legs, sometimes paraesthesiae and, in severe cases, ataxia and incontinence. Subacute encephalopathy affects about 30% of AIDS patients, who gradually develop a confusional state associated with fever and depression; the patient eventually may become bedridden and incontinent. Chronic meningitis may precede more typical features of AIDS and is characterized by fever, headache, meningeal signs and cranial nerve palsies (typically affecting nerves V, VII and VIII). Brain tumours, particularly lymphomas, are also common complications of HIV/AIDS. Peripheral and cranial neuropathies, and myopathy, are relatively common.

Autoimmune disorders

Autoimmune disorders, particularly thrombocytopenic purpura, are relatively common in HIV disease. Drug allergic reactions are common, mostly to co-trimoxazole, and may cause erythema multiforme.

HIV infection in children

Infection with HIV in children causes them to appear ill and stunted, and promotes staphylococcal and streptococcal infections, such as otitis media, rashes and diarrhoea, as well as fungal and viral infections.

Normal CD4/CD8 ratios may persist late in the disease and lymphopenia is uncommon. Humoral immunity is more severely affected than in adult HIV disease and may long precede changes in T-lymphocyte subsets. Bacterial infections are relatively more common because of depressed humoral immunity. Generalized lymphadenopathy and hepatosplenomegaly are often the first signs and chronic parotitis is a common presenting feature. Neurological disease develops in the great majority. Interstitial lymphoid pneumonitis is particularly

Fig. 20.10 Lymphoma in HIV/AIDS.

characteristic. Hypergammaglobulinaemia is also severe and 13% have thrombocytopenic purpura.

B-cell lymphomas are the most common tumours but Kaposi sarcoma is rare and affects the skin particularly infrequently. Other systemic effects of HIV infection in children include renal disease and cardiomyopathy.

GENERAL MANAGEMENT

Diagnosis of HIV infection

Diagnosis of HIV infection is made on suspicion, especially if there is a supportive history; clinical criteria, if present; and, after appropriate consent, laboratory investigations. Lymphopenia, low CD4 counts in the blood, and a low CD4:CD8 ratio (normal value is about 2, which falls to about 0.5 in AIDS) are typical but not specific findings. HIV infection must be confirmed by testing for HIV and all results must be kept confidential. Relatives *cannot* give consent for an HIV test. Most HIV tests detect HIV serum antibodies, but it takes some time – 2–8 weeks – to produce enough antibodies to be detected by the antibody test. This ‘window period’ can vary from person to person and the HIV viral load may be very high at this time, as is the likelihood of transmitting HIV to sex or needle-sharing partners. Most HIV-infected people (97%) will develop detectable serum antibodies in the first 3 months, but a few will take longer, so a follow-up test more than 3 months after the last potential exposure to HIV is prudent. All those infected will have detectable serum antibodies to HIV by 6 months.

Conventional HIV serological tests sent to a laboratory give results within a week or two; rapid HIV tests can produce results in as little as 20 minutes. A positive HIV serological test result means that a person may have been infected with HIV, but all positive HIV test results, whether from conventional or rapid tests, must be verified by a second ‘confirmatory’ HIV test. Thus HIV antibody screening tests (e.g. reactive enzyme immunoassay [EIA]) should be confirmed by a positive

result from a supplemental HIV antibody test (e.g. Western blot or indirect immunofluorescence assay test) *or* a positive result or report of a detectable quantity from any of the following HIV virological (i.e. non-antibody) tests:

- HIV nucleic acid (DNA or RNA) detection test (e.g. PCR)
- HIV p24 antigen test, including neutralization assay
- HIV isolation (viral culture).

Note that a negative (i.e. undetectable or non-reactive) result from an HIV virological test (e.g. viral RNA nucleic acid test) does *not* rule out the diagnosis of HIV infection.

HIV testing should be offered not only as part of a sexual health screen but also to:

- anyone with one of a number of ‘clinical indicator diseases’
- patients with specific lifestyle or demographic characteristics
- all adults in all health-care services if HIV prevalence is high.

No patient with signs of HIV infection should be discharged as uninfected solely on the basis of one negative HIV test result; neither should they be told that they have HIV infection without the knowledge that the laboratory has confirmed the test result using the above criteria. Treat the results of any HIV tests and a diagnosis of HIV infection or AIDS with confidentiality. Considerable care is needed regarding the social and psychological consequences of HIV infection. More information on HIV testing is available at: <http://www.aidsmap.com/UK-guidelines/page/1321555/> (accessed 30 September 2013).

The mortality rate from AIDS was virtually 100% but, although there is still no effective treatment for the underlying immune defect, antiretroviral therapy (ART) employs drugs that can significantly impede the progress of HIV infection; these include nucleoside analogues, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, entry/fusion inhibitors and integrase inhibitors. Treatment with a combination of these drugs is termed active ART. Early intervention with ART (Tables 20.5, 20.6, 20.7 and 20.8) is usually beneficial.

Table 20.5 Antiretroviral drugs, cautions and adverse effects: nucleoside reverse transcriptase inhibitors (NRTIs)^a

Generic name (abbreviation)	Trade name	Possible orofacial adverse effects	Other main adverse effects	Cautions with drugs used in oral health care
Abacavir (ABC)	Ziagen	Erythema multiforme, ulcers	Lactic acidosis, nausea, diarrhoea, life-threatening rash; human leukocyte antigen (HLA)-B*5701 screening (for hypersensitivity reaction), lipodystrophy	No significant interactions
Didanosine (ddI)	Videx	Erythema multiforme, dry mouth, facial lipoatrophy	Nausea, diarrhoea, lactic acidosis, mitochondrial dysfunction leading to pancreatitis, abnormal liver function, peripheral neuropathy, retinal damage	Ciprofloxacin Ganciclovir Itraconazole Ketoconazole
Emtricitabine (FTC)	Emtriva	Hyperpigmentation, swelling	Lactic acidosis, pruritus, hyperpigmentation, lipodystrophy	No significant interactions
Lamivudine (3TC)	Epivir	Dry mouth	Nausea, diarrhoea, mitochondrial dysfunction leading to pancreatitis, abnormal liver function, neuropathy, lipodystrophy, clefts	No significant interactions
Stavudine (d4T)	Zerit	Facial lipoatrophy	Neuropsychiatric reactions, mitochondrial dysfunction leading to pancreatitis, abnormal liver function, lactic acidosis, neuropathy	No significant interactions
Tenofovir disoproxil (TDF)	Viread	Facial lipoatrophy	Renal tubular damage, hypophosphataemia	No significant interactions
Zidovudine (azidothymidine; AZT, ZDV)	Retrovir	Erythema multiforme, hyperpigmentation, lichenoid drug reaction, facial lipoatrophy	Nausea, diarrhoea, myelotoxicity, lactic acidosis, myopathy	Fluconazole Ganciclovir

^aThere are also combinations of these; zalcitabine (dideoxycytidine; DDC) is no longer marketed.

Table 20.6 Antiretroviral drugs, cautions and adverse effects: non-nucleoside reverse transcriptase inhibitors (NNRTIs)

Generic name (abbreviation)	Trade name	Possible orofacial adverse effects	Other main adverse effects	Cautions with drugs used in oral health care
Delavirdine (DLV)	Rescriptor (not licensed in UK)	Erythema multiforme, ulcers	Interference with liver drug-metabolizing enzymes	Carbamazepine Clarithromycin Dapsone Midazolam
Efavirenz (EFV)	Sustiva	Erythema multiforme, swelling, burning mouth, clefts	Interference with liver drug-metabolizing enzymes, lipodystrophy, neuropsychiatric reactions	Buprenorphine Carbamazepine Itraconazole Ketoconazole Midazolam Prednisolone (prednisone) Voriconazole
Etravirine (ETR)	Intelence	Erythema multiforme, ulcers	Hypersensitivity	Clarithromycin Fluconazole Itraconazole Posaconazole Voriconazole
Nevirapine (NVP)	Viramune	Erythema multiforme, ulcers, swelling, taste disturbance, lichenoid drug reaction, dry mouth, burning mouth	Induction of liver drug-metabolizing enzymes, abnormal liver function, lipodystrophy	Fluconazole Ketoconazole
Rilpivirine (RPV)	Edurant	Swelling	Liver problems, lipodystrophy, severe depression and suicidal thoughts	Ketoconazole

Table 20.7 Antiretroviral drugs, cautions and adverse effects: protease inhibitors (PIs)^a

Generic name (abbreviation)	Trade name	Possible orofacial adverse effects	Other main adverse effects	Cautions with drugs used in oral health care
Atazanavir (ATV)	Reyataz	Erythema multiforme, swelling, ulcers	Nephrolithiasis, prolongation of QR interval, lipodystrophy, interference with liver drug-metabolizing enzymes, dyslipidaemia, neurological effects	Clarithromycin Colchicine Midazolam Paracetamol (acetaminophen) Posaconazole Voriconazole
Darunavir (DRV)	Prezista	Erythema multiforme, swelling, dry mouth	ECG changes, neuropathy, weight changes, lipodystrophy, interference with liver drug-metabolizing enzymes, dyslipidaemia	Carbamazepine Ciclosporin Clarithromycin Colchicine Fluticasone Itraconazole Ketoconazole Midazolam Voriconazole
Fosamprenavir (FPV)	Telzir/Lexiva	Erythema multiforme, swelling, perioral paraesthesia, parotid lipomatosis	Nephrolithiasis, lipodystrophy, interference with liver drug-metabolizing enzymes, dyslipidaemia	Colchicine Posaconazole
Indinavir (IDV)	Crixivan	Cheilitis (retinoid-like effect), parotid lipomatosis, dry mouth, taste disturbance	Nephrolithiasis in 40%, interference with liver drug-metabolizing enzymes, oesophagitis, haemolysis, lipodystrophy	Carbamazepine Clarithromycin Colchicine Ketoconazole Itraconazole Midazolam
Nelfinavir (NFV)	Viracept	Parotid lipomatosis, dry mouth, clefts	Nausea, diarrhoea, interference with liver drug-metabolizing enzymes, dyslipidaemia, lipodystrophy	Carbamazepine Colchicine Ciclosporin Desipramine Ketoconazole Midazolam Tacrolimus

(Continued)

Table 20.7 (Continued)

Generic name (abbreviation)	Trade name	Possible orofacial adverse effects	Other main adverse effects	Cautions with drugs used in oral health care
Ritonavir (RTV)	Norvir	Perioral paraesthesia, parotid lipomatosis, dry mouth, taste disturbance, swelling	Nausea, diarrhoea, interference with liver drug-metabolizing enzymes, flushing, dyslipidaemia, lipodystrophy, arrhythmias	Amitriptyline Carbamazepine Clarithromycin Colchicine Diazepam Fentanyl Fluoxetine Fluticasone Itraconazole Ketoconazole Metronidazole Midazolam Phenytoin Prednisolone Tacrolimus
Saquinavir mesylate (SQV)	Invirase	Erythema multiforme, ulcers, parotid lipomatosis, dry mouth, taste disturbance	Nausea, diarrhoea, interference with liver drug-metabolizing enzymes, dyslipidaemia, lipodystrophy, arrhythmias	Alprazolam Amitriptyline Carbamazepine Dexamethasone Diazepam Fluticasone Itraconazole Midazolam Tacrolimus
Tipranavir (TPV)	Aptivus	Erythema multiforme, swelling, ulcers	Hepatotoxicity and bleeding tendency, lipodystrophy, dyslipidaemia	Carbamazepine Clarithromycin Colchicine Fluconazole Midazolam

^aThere are also combinations; amprenavir (trade name Agenerase) is no longer marketed; saquinavir (trade name Fortovase) is no longer marketed.

Table 20.8 Newer antiretroviral drugs, cautions and adverse effects

Generic name (abbreviation)	Trade name	Possible orofacial adverse effects	Other main adverse effects	Cautions with drugs used in oral health care
<u>Fusion inhibitor</u>				
Enfuvirtide (ENF)	Fuzeon	Swelling, sinusitis	Hypersensitivity, neuropathy, hypotension, interference with liver drug-metabolizing enzymes, pneumonia	No significant interactions
<u>Entry inhibitors: CCR5 co-receptor antagonist</u>				
Maraviroc (MVC)	Selzentry/ Celsentri	Taste disturbance	Liver problems, cardiovascular problems	Ketoconazole
<u>Integrase strand transfer inhibitor</u>				
Raltegravir (RAL)	Isentress	Erythema multiforme, dry mouth	Diarrhoea, abdominal pain	No significant interactions

Patients on ART are monitored by regular CD4 counts and plasma viral load levels, which correlate well with clinical response. Adverse effects are common and adherence to therapy is important to avoid the development of drug-resistant variants.

Patients with low CD4 counts are given antimicrobials as prophylaxis against opportunistic infections. Individuals should also be offered psychological support to help them come to terms with their illness and should be educated on measures necessary to prevent further spread of infection. At CD4 counts below 200/microlitre, patients

are at high risk of *Pneumocystis jiroveci* infection; at counts below 100/microlitre, CMV and *Mycobacterium avium-intracellulare* are risks.

Antimicrobial prophylaxis

Antimicrobial prophylaxis and therapeutic and supportive treatment may help prolong and improve the quality of life in HIV disease. Drugs available to help treat opportunistic infections are shown in Table 20.9.

Table 20.9 Antimicrobial agents for infections in HIV disease

Antimicrobial	Used for
Aciclovir	Herpes simplex and zoster infections
Foscarnet and ganciclovir	Cytomegalovirus infections
Fluconazole	Yeast and other fungal infections
Trimethoprim/sulfamethoxazole (TMP/SMX), atovaquone or pentamidine	<i>Pneumocystis jiroveci</i> pneumonia
Rifabutin	Prophylaxis against <i>Mycobacterium avium</i> complex (MAC) infection
Isoniazid	Tuberculosis

Vaccines

Attempts to produce a safe and effective vaccine against HIV encounter development problems, not least because the proteins of HIV can undergo changes. Some candidate vaccines are currently in the initial phases of testing in humans. Post-exposure vaccination (e.g. with killed virus, envelope subunits or recombinant vaccinia vectors in combination with viral subunits) may have provided some clinical benefit, but long-term detailed trials are still required before it is known whether such vaccines can provide reliable control of HIV.

Immune Reconstitution Syndrome (IRIS)

Profoundly immunodeficient people treated with ART may develop the immune reconstitution inflammatory syndrome (IRIS) – a paradoxical worsening or recurrence of opportunistic infections and symptoms. IRIS can be seen in HIV/AIDS, where it affects 8% to over 30% of patients, and also may affect immunosuppressed individuals.

General aspects of IRIS

IRIS development appears to be linked not only to increases in CD4 cells, but also to higher CD8 cell counts induced by ART. Raised CD8 cells may be a prime factor contributing to worsening of both herpes zoster and hepatitis B or C symptoms after the initiation of ART. Increased activity of IL-2 and IL-12 may contribute. Though most individuals starting ART are not likely to experience IRIS, AIDS patients are more at risk if they are put on ART for the first time, or if they have recently been treated for an opportunistic infection.

Clinical features of IRIS

While IRIS, by definition, heralds a return to a healthier immune system, a range of common conditions can occur or be exacerbated (Table 20.10); these can be serious, even fatal.

The two common IRIS scenarios are the ‘unmasking’ of occult opportunistic infectious pathogens, which needs appropriate antimicrobial therapy, and the ‘paradoxical’ symptomatic relapse of a prior infection despite microbiological treatment success, which usually resolves spontaneously. IRIS can have a range of effects, including TB, MAC infections, cytomegalovirus retinitis, disseminated cryptococcosis and Kaposi sarcoma. IRIS is characterized by a greater disease burden, a low CD4-cell nadir and, for *M. tuberculosis*, a shorter time period between diagnosis and initiation of ART. Many cases of IRIS have atypical presentations. For example, the hallmarks of IRIS in a person previously responding to treatment for TB might be a new

Table 20.10 Manifestations of immune reconstitution inflammatory syndrome (IRIS)

Known infections	Other conditions
Cryptococcus	Aphthous-like ulcers
Cytomegalovirus	Castleman disease
Hepatitis viruses	Eosinophilic folliculitis
Herpes simplex	Graves disease
Herpes zoster	Myopathy
Histoplasmosis	Non-Hodgkin lymphoma
Human herpesvirus 8	Progressive multifocal leukoencephalopathy
Leprosy	Sarcoidosis
<i>Mycobacterium avium</i>	Systemic lupus erythematosus
Papillomavirus	
<i>Pneumocystis</i>	
Tuberculosis	

or worsening fever, new effusions, new or worsening lymphadenopathy, and other uncharacteristic reactions, rather than progression of lung disease itself. Mild shingles or a local *M. avium* infection without bacteraemia, both seen in IRIS, would be unusual in an HIV-positive person not taking ART.

GENERAL MANAGEMENT OF IRIS

Treatment of IRIS is continuation of the current HIV medication regimen; antimicrobial medications to treat infection; and corticosteroids to suppress the inflammatory process temporarily.

DENTAL ASPECTS OF HIV/AIDS

Immunologically stable (undetectable viral load and T-cell (CD4) count over 200/mL) HIV-positive patients on ART may be considered the best dental treatment risk. However, patients with profound immunodeficiency (those with neutropenia and/or CD4 T-lymphocyte count below 200/mL) may require antibiotic cover with metronidazole, amoxicillin plus clavulanic acid, or clindamycin before surgery or after maxillofacial injuries.

There is a theoretical interaction of local anaesthesia (LA) with PIs, and PIs such as indinavir and nelfinavir can enhance benzodiazepines. Bleeding can be aggravated by non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin or indometacin; codeine and paracetamol (acetaminophen) are safer analgesics (the interaction with zidovudine, inducing granulocytopenia, appears rarely to be clinically significant). Of note, however, HIV disease is a major risk factor for adverse drug reactions; the incidence of reactions to ampicillin is inversely proportional to CD4+ cell counts. Dental treatment should be carried out with the standard precautions and additional attention given to the possibility, though small, of postoperative infection and prolonged haemorrhage.

It is unethical to withhold treatment from any patient on the basis of a moral judgment that the patient's activities or lifestyle might have contributed to the condition for which treatment was being sought. There is a move towards normalization and mainstreaming of oral health-care provision but many HIV-infected individuals have concerns about privacy; the additional stigma and social implications of their infection may prevent them from accessing general dental services – at least in their locality. It is therefore critical to ensure that there is a strict

adherence to data protection and patient confidentiality; the patient should be reassured that none of their details will be discussed, even with their physicians, unless permission is sought from the patient.

Medical consultation is mandatory for symptomatic HIV-infected patients before any dental surgical procedure, although no serious postoperative complications have been found in most instances. There have been no systematic studies involving dental implants, orthognathic surgery, periodontal therapy, prophylaxis, or scaling and root planing, and only one study on endodontics, which reported few immediate complications. Prospective studies on dental implants showed a 100% success rate at 6 months for both HIV and controls, with no difference in clinical outcomes. The prevalence of complications following tooth extractions in HIV-infected persons overall is estimated at about 5%, similar to that achieved in HIV-negative patients, and most complications are mild (alveolitis and delayed healing) and easily treated. Postoperative bleeding is unusual, even in thrombocytopenic patients. Factors increasing the potential for postoperative complications are shown in [Box 20.2](#).

Box 20.2 Factors increasing the potential for postoperative complications in HIV/AIDS

- Low CD4 count
- High viral load
- Low lymphocyte count
- Neutropenia
- Bleeding tendency (i.e. thrombocytopenia, liver damage, etc.)
- Another concomitant infection

Most patients with HIV disease have head and neck and oral manifestations at some time ([Table 20.11](#)). Oral lesions are most likely to appear when the CD4 cell count is low and are often controlled, at least temporarily, by ART. Cervical lymphadenopathy is an almost invariable feature at some stage of HIV disease and AIDS. Persistent generalized lymphadenopathy (PGL) is common. Oral features are classified as strongly, less commonly or possibly associated with HIV infection ([Table 20.12](#)). Oral candidosis (usually thrush or erythematous candidosis) is common; it is often the initial manifestation and seen in 50% of patients. Oral candidosis is frequently associated with oesophageal candidosis and is also a predictor of liability to systemic opportunistic infections; the latter, but not the former, is an AIDS-defining illness. Conventional antifungal treatment is indicated initially, although fluconazole may be required, especially if there is oesophageal infection. Azole resistance is a growing problem.

Infections with herpes simplex virus, varicella zoster virus, CMV, EBV, human herpesvirus 6 (HHV-6) and KSHV are common. Herpes simplex infections are usually intraoral, sometimes severe and persistent, but rarely disseminate; they usually respond well to aciclovir. Severe herpes zoster may be seen. CMV may cause mouth ulcers. EBV has been implicated in hairy leukoplakia and some lymphomas (see later). Hairy leukoplakia, though characteristic of HIV, can be seen very rarely in other patients, mainly those who are immunocompromised. It derives its name from the raised white areas of thickening, usually on the lateral borders of the tongue. The EBV capsid antigen can be identified in the prickle cell layer. It appears not to be pre-malignant. Less common oral and perioral infections include venereal warts. Mycobacterial oral ulcers and oral histoplasmosis or

Table 20.11 Features, diagnosis and management of orofacial lesions of HIV infection

Frequency	Condition	Clinical features	Diagnosis	Management
Common	Candidosis ^a	White removable lesions or red lesions, typically in the palate	Clinical plus investigations; smear, culture, rinse or biopsy	Antifungals (fluconazole most effective)
	Hairy leukoplakia ^a	White non-removable lesions, almost invariably bilaterally on the tongue	Clinical plus cytology; deoxyribonucleic acid (DNA) studies or biopsy	None usually but podophyllin or aciclovir effective
	Kaposi sarcoma ^a	Purple macules leading to nodules, seen mainly in the palate	Clinical plus investigations; biopsy	Liposomal anthracyclines or paclitaxel chemotherapy. Vinblastine intralesionally. Alitretinoin gel, interferon-alpha intralesionally; cryotherapy and photodynamic therapy reportedly effective
Uncommon	Periodontal disease	Linear gingival erythema, necrotizing gingivitis or periodontitis	Clinical	Oral hygiene, plaque removal, chlorhexidine, metronidazole
	Aphthous-like ulcers	Recurrent ulcers anywhere but especially on mobile mucosae	Clinical plus investigations; possibly biopsy	Corticosteroids or thalidomide or granulocyte colony-stimulating factor
	Herpesvirus infections (herpes simplex, cytomegalovirus, varicella zoster)	Chronic ulcers often on tongue, hard palate or gingivae Zoster increased by ART	Clinical plus investigations; cytology, electron microscopy, DNA studies or biopsy	Antivirals
	Papillomavirus infections	Warty lesions, increased by ART	Clinical plus investigations; DNA studies, possibly biopsy	Excise or remove with heat, laser or cryoprobe, imiquimod, interferon-alpha or podophyllin
	Salivary gland disease	Hyposalivation and sometimes salivary gland enlargement	Clinical plus investigations; sialometry, possibly biopsy	Salivary substitutes and/or pilocarpine or cevimeline
	Lymphomas	Lump or ulcer in fauces or gingivae	Clinical plus investigations; biopsy	Chemotherapy or radiation or both. Ifosfamide, mesna and rituximab on trial
Rare	Mycobacterial infections, deep fungal infections Osteomyelitis, neuropathies			

^aAntiretroviral therapy (ART) reduces manifestations.

Table 20.12 World Health Organization classification of oral lesions in HIV/AIDS

Group I lesions strongly associated with HIV infection	Group II lesions less commonly associated with HIV infection	Group III lesions possibly associated with HIV infection
Candidosis	Atypical ulceration (oropharyngeal)	A miscellany of rare diseases
Erythematous	Idiopathic thrombocytopenic purpura	
Hyperplastic	Dry mouth	
Thrush (pseudomembranous)	Salivary gland diseases	
Hairy leukoplakia (Epstein-Barr virus; EBV)	Unilateral or bilateral swelling of major salivary glands	
HIV gingivitis	Viral infections (other than EBV)	
Necrotizing ulcerative gingivitis	Cytomegalovirus	
HIV periodontitis	Herpes simplex virus	
Kaposi sarcoma (human herpesvirus 8)	Human papillomavirus (wart-like lesions): condyloma acuminatum, focal epithelial hyperplasia and verruca vulgaris	
Non-Hodgkin lymphoma (EBV)	Varicella zoster virus: herpes zoster and varicella	

cryptococcosis, as well as sinusitis, gingivitis or periodontitis, may be seen. Major aphthae increase in frequency and severity with the severity of the immunodeficiency. Giant persistent aphthous-like ulcers respond to thalidomide (which needs to be given with caution and never to potentially pregnant women). Post-extraction infections, osteomyelitis after jaw fractures and cancrum oris (noma) have very occasionally been seen.

Kaposi sarcoma in 50% of patients is oral or perioral, and often an early oral manifestation, presenting as a red or purple macule or a nodule, usually on the palate. Oral and salivary gland lymphomas also develop more frequently in patients with AIDS than in a normal population; EBV is implicated.

In childhood HIV disease, chronic parotitis is common and virtually pathognomonic (see Table 20.12). Chronic oral candidosis is present in 75% and is the single most common mucocutaneous manifestation. Most types of oral candidosis may be seen, most frequently in the form of persistent thrush. Difficulties in swallowing usually indicate candidosis of the oesophagus. Unlike normal children, those with AIDS are frequently subject to recurrent intraoral as well as labial herpetic infection. Initially, the infection responds to intravenous aciclovir but becomes more resistant as AIDS progresses. Shingles is rare in normal children but can be an early sign of AIDS in a child, and tends to be more severe and painful.

Drug interactions

Possible drug interactions with drugs used in oral health care are shown in Table 20.13.

Anaesthetic agents may induce pharmacodynamic changes to affect the efficacy and toxicity of antiretrovirals (ARVs), and pharmacokinetic effects of ARVs can affect the absorption, distribution, metabolism and elimination of anaesthetic drugs. Pharmacodynamic

Table 20.13 Possible oral health-care drug interactions in HIV-infected patients^a

Drug used in oral health care	May interact with	Possible consequences
Azole antifungals: Miconazole Fluconazole Itraconazole Ketoconazole	Terfenadine (astemizole and cisapride withdrawn because of interaction)	Arrhythmias and cardiotoxicity
	Anticoagulants Antacids Didanosine H ₂ antagonists Omeprazole	Anticoagulants potentiated Azole absorption impaired
Benzodiazepines	Azole Indinavir Ritonavir	Benzodiazepines enhanced
Carbamazepine	Indinavir Lopinavir Nevirapine Saquinavir	Antiretroviral reduced
Corticosteroids	Ritonavir	Corticosteroids enhanced
Erythromycin	Ritonavir Saquinavir	Erythromycin enhanced Arrhythmias
Fluconazole	Rifabutin Zidovudine	Uveitis from rifabutin toxicity Zidovudine enhanced
Ganciclovir	Zidovudine	Zidovudine enhanced; haematological toxicity
Metronidazole	Ritonavir	Disulfiram-like reaction
Midazolam	Efavirenz Indinavir Nelfinavir Ritonavir Saquinavir	Midazolam enhanced
Non-steroidal anti-inflammatory drugs (NSAIDs)	Ritonavir Saquinavir Zidovudine	NSAIDs enhanced NSAIDs enhanced; haematological toxicity

^aSee also <http://www.medadvocates.org/drugs/haart/druginteractions.html> and HIV and AIDS Activities at <http://www.fda.gov/ForConsumers/byAudience/ForPatientAdvocates/default.htm> (both accessed 30 September 2013).

interactions can be managed by avoiding anaesthetic agents such as halothane or methoxyflurane that cause hepatic or renal dysfunction. Propofol and NRTIs may both potentially promote mitochondrial toxicity and lactic acidosis, and it may be wise to avoid propofol infusions in patients receiving ARVs. Pharmacokinetic interactions are more complicated and are primarily due to liver enzyme induction or inhibition, particularly the CYP450 3A4 enzyme. PIs and NNRTIs are the most commonly implicated group of ARVs in drug interactions. Enzyme induction or inhibition can affect the action of several classes of anaesthetic drugs, including:

- *opioids*. Fentanyl may be enhanced by ritonavir due to both liver enzyme inhibition and induction. Enzyme inhibition reduces fentanyl clearance and enzyme induction increases metabolism to active metabolites such as normeperidine.
- *benzodiazepines*. Saquinavir may inhibit midazolam metabolism.
- *calcium-channel blockers*. These may have enhanced hypotensive effects due to enzyme inhibition.

- *local anaesthetics*. Agents such as lidocaine may have increased plasma levels due to enzyme inhibition.
- *neuromuscular blockers*. Effects may be prolonged, even by a single dose of vecuronium, for instance.

More information is available at www.hiv-druginteractions.org (accessed 30 September 2013).

Regional anaesthesia

The presence of HIV infection is not an absolute contraindication to regional anaesthesia and there is no evidence that HIV progression is increased by central neuraxial blockade. However, the presence of HIV complications may pose relative contraindications to regional anaesthesia:

- myelopathy
- vertebral or spinal neoplasms
- CNS infections
- coagulopathy.

It is essential to conduct a full preoperative neurological assessment and to document any neurological deficit.

Anaesthetic management plan

Thorough preoperative assessment for status of HIV infection includes:

- history, including risk factors
- physical examination
- laboratory tests
- organ involvement
- drug history and side-effects.

Investigations should include:

- full blood count
- clotting function – to exclude coagulation abnormalities (consideration of use of thromboelastography (TEG)/platelet mapping if available)
- biochemical tests, including glucose, electrolytes, renal and liver function – to exclude possible metabolic, liver or renal disturbances
- viral load and CD4+ count
- chest radiography – screen for opportunistic infections and TB
- cardiac evaluation with electrocardiography and echocardiography (if possible) – to screen for cardiomyopathy.

Perioperative management of ART

Due to increasing problems of drug resistance in the treatment of HIV, it is recommended that ART therapy be continued throughout the perioperative period if at all possible. Naturally, this needs to be compatible with surgery and the patient's gastrointestinal function. Some ARVs are available in liquid form, enabling administration via feeding tube or gastrostomy. Parenteral preparations are limited to zidovudine and enfuvirtide only.

Consider drug interactions between ART and drugs affected by hepatic enzyme inhibition and/or induction.

Employ a strict aseptic technique; HIV-infected patients are immunocompromised and are susceptible to infections.

Periodontal disease in HIV

Bacterial species other than the classical periodontal pathogens may be involved in periodontal diseases since the classical putative periodontal pathogens, *Treponema denticola*, *Porphyromonas gingivalis* and *Tannerella forsythia* may be below the limit of detection. Putative periodontal pathogens are more prevalent in the subgingival microbiota of HIV-seronegative patients with chronic periodontitis, whereas species not usually associated with periodontitis are detected in higher frequency in HIV-seropositive subjects under ART. Species of *Gemella*, *Dialister*, *Streptococcus* and *Veillonella* are predominant. Species or phylotypes most commonly detected are *Bulleidia extructa*, *Dialister*, *Fusobacterium*, *Selenomonas*, *Peptostreptococcus*, *Veillonella* and the phylum TM7.

There is significant prevalence of *Porphyromonas gingivalis* and *Treponema denticola* among HIV-negative patients compared to HIV-positive patients. Odds ratio analysis revealed a statistically significant positive association between 3 of the 28 possible combinations in the HIV-positive group. They included *Prevotella nigrescens*/*Campylobacter rectus*, *P. nigrescens*/*P. gingivalis* and *P. nigrescens*/*T. denticola*. Although the prevalence of periodontal pathogens is similar in both groups, the combination of certain periodontal pathogens may be responsible for chronic periodontitis seen in HIV-infected adults.

Periodontal attachment loss in HIV-infected patients is associated with the major histocompatibility (MHC) complex 8.1 haplotype (HLA-A1,B8,DR3). Periodontal attachment loss is mediated by overproduction of tumour necrosis factor (TNF) and IL-1, and appears to have a genetic component. The 8.1 MHC ancestral haplotype (HLA-A1,B8,TNFA-308(2),DR3) is associated with raised TNF production and predisposes carriers to several autoimmune/immunopathological disorders, including rapid progression of HIV disease, but not early-onset periodontal disease in healthy individuals. Rather a high proportion of subjects with severe periodontal disease carry allele 2 at IL-1A-889 and IL-1B + 3953.

ART may affect the prevalence of some orofacial manifestations (Table 20.14) but may also cause adverse reactions (Table 20.15).

Transmission of HIV to or from health-care professionals

Accidental exposure to blood following a needlestick (sharps) injury is one of the most common occupational accidents in health care. The highest reported risks are after a needlestick incident, especially with:

- devices that are visibly contaminated with blood
- hollow-bore needles that have been in an artery or vein
- deep injuries
- exposure to blood from patients with terminal infection.

Exposure-prone procedures (EPPs) are those where there is a risk that injury to the HCP may result in exposure of the patient's open tissues to the blood of the HCP. These procedures include those where

Table 20.14 Effect of antiretroviral therapy on orofacial manifestations of HIV/AIDS

Declined	Increased
Candidosis	Salivary gland disease
Hairy leukoplakia	Warts and zoster
Kaposi sarcoma	Drug adverse effects

Table 20.15 Management problems related to HIV infection or the adverse effects of antiretroviral therapy, chemotherapy or anti-infective agents

System	Possible lesions	Possible treatment influences
Cardiac	Endocardial, myocardial, pericardial or vascular lesions, or neoplasms	Acute coronary syndrome Dilated cardiomyopathy Endocarditis and valvular lesions Pericardial effusions Pulmonary hypertension Vasculitis
Gastrointestinal	Diarrhoea Hepatobiliary impairment Pancreatitis	Bleeding: electrolyte loss and dehydration Difficulty or pain on swallowing Delayed gastric emptying
Haematological	Anaemia Coagulation abnormalities Haematological malignancies Neutropenia Persistent generalized lymphadenopathy Thrombocytopenia	Bleeding tendency Infections
Metabolic	Hypo- or hyperthyroidism Hyponatraemia from syndrome of inappropriate antidiuretic hormone Hypothalamo-pituitary-adrenal axis disorders Lactic acidosis Lipodystrophy (truncal obesity, buffalo hump) Metabolic syndrome (raised plasma triglycerides, cholesterol) Cushing syndrome and Addison disease	Corticosteroid cover
Neurological	Direct infection, inflammation, demyelination or opportunistic infections, neoplasms or immune deficiency	Autonomic neuropathy Encephalopathy Neurocognitive impairment (with implications for consent) Seizures
Renal	Hypertension Diabetes HIV-associated nephropathy	Drug-induced nephrotoxicity Renal impairment
Respiratory	Both upper and lower airway can be involved with infection, malignancies, opportunistic infections or adverse effects of medication	Obstruction (by Kaposi sarcoma, lymphoma or infections) Atypical infections (commonly tuberculosis, other mycobacteria and fungal infections) Bronchitis Sinusitis Pneumonia Pneumonitis

the worker's gloved hands may be in contact with sharp instruments, needle tips or sharp tissues (spicules of bone or teeth) inside a patient's open body cavity, wound or confined anatomical space, where the hands or fingertips may not be completely visible at all times.

All employers should have an acceptable policy for managing occupational injuries, and could be answerable to the Health and Safety Executive, the General Dental Council or the civil courts.

The risk of HIV transmission from an occupational exposure to HIV-infected blood is dependent upon the titre of HIV in the blood (viral load), the volume of the blood that is transmitted and whether the virus is still infective. The risk of transmission of HIV from an occupational exposure among dental health workers is low; no occupational exposure has as yet resulted in HIV transmission to a member of the dental team. HIV infection of a clinician therefore no longer precludes clinical work in many countries.

Needlestick injuries are most likely in the following situations:

- During needle recapping
- During surgery, especially wound closure
- When an uncapped needle has ended up in linen, etc.
- When taking an unsheathed used needle to the sharps container
- During the cleaning and transporting of waste material
- When using more complex collection and injection techniques
- In accident and emergency departments
- In high-stress interventions.

See also Chapter 31. More information is also available at: <https://www.gov.uk/government/organisations/department-of-health> (search on 'HIV post-exposure prophylaxis'; accessed 30 September 2013).

The risk of transmission of HIV from an infected patient through a needlestick (inoculation) injury is less than 1%: around 1 in 300 – far lower than the nearly 26% of persons who develop HBV infection or the 10% who contract HCV infection after needlestick injuries involving those agents (see Fig. 20.11 and Ch. 31).

The chief occupational risk of acquiring infection is as a result of injury by a sharp instrument, particularly an LA needle, which can contain a significant amount of contaminated fluid. Though needlestick

**Fig. 20.11** Needlestick injury protocol (see also Fig. 31.2).

injuries can transmit the virus, infection among dental health personnel caring for HIV-infected patients is rare, despite reports of many such injuries. In most HCPs who have acquired HIV, the infection has been sexually transmitted. By 2008, there had only been two reports of dental staff contracting HIV as a consequence of occupation, even in endemic areas.

The virus does appear to have been transmitted within health-care facilities on rare occasions. One dentist with HIV infection in Florida, USA, appears to have transmitted it to at least six patients as a consequence of invasive dental procedures. That the dentist was the source of the infection was suggested by the fact that the strain of the virus was the same; the circumstances surrounding transmission remain uncertain, as the dentist has since died. An outbreak of 14 cases of HIV infection was discovered in May 1993 among haemodialysis patients at a university hospital in Bucaramanga, Colombia, and seems most likely to have been transmitted by contaminated dental instruments. Many other studies, however, have shown no evidence of any transmission of HIV from HIV-infected dentists to patients.

TRANSFUSION-RELATED IMMUNOMODULATION (TRIM)

Red blood cell transfusion in any patient may be associated with immunosuppressive or proinflammatory effects that may increase morbidity; older transfused red blood cells are a risk factor for poorer outcomes in certain groups, such as cardiac surgery and trauma patients. Allogeneic blood transfusion (ABT) in an HIV-infected patient can lead to transfusion-related immunomodulation (TRIM), with effects attributable to ABT by immunomodulatory mechanisms (e.g. cancer recurrence, postoperative infection, or virus activation and increased HIV viral loads), plus effects attributable to ABT by pro-inflammatory mechanisms (e.g. multiple-organ failure or mortality). TRIM may be mediated by allogeneic mononuclear cells; white-blood-cell-derived soluble mediators; and/or soluble HLA peptides circulating in allogeneic plasma. Blood should therefore only be transfused where unavoidable to maintain patient safety.

IDIOPATHIC CD4 T-LYMPHOCYTOPENIA (ICL)

Idiopathic CD4 T-lymphocytopenia (ICL) is a rare syndrome that appears to represent a variety of disorders not related to HIV or any known transmissible agent. It causes a generalized immunodeficiency state similar to that seen with HIV infection, with CD4 counts around 300/microlitre, but differs from HIV infection in that all lymphocyte cell lines tend to fall (low CD8 and B cells) and the

lymphopenia is usually transient. In addition, immunoglobulin levels are normal or low.

There is no evidence for transmissibility but ICL has been associated with many infectious entities not related to AIDS and with non-infectious diseases, such as autoimmune disorders, malnutrition, drugs and skin disorders. About 40% of patients with ICL have developed AIDS-defining illnesses, including cryptococcal meningitis, histoplasmosis and MAC. Some persons are healthy but have had idiopathic CD4+ lymphocytopenia diagnosed by the more frequent screening for lymphocyte subsets. Finally, ICL does not progress and may even improve spontaneously.

ANTI-INTERFERON IMMUNODEFICIENCY

Neutralizing anti-IFN γ autoantibodies have been found in 88% of Asian adults with multiple opportunistic infections and associated with a recently reported adult-onset immunodeficiency syndrome akin to that of advanced HIV infection.

OTHER SECONDARY IMMUNODEFICIENCIES

Worldwide, most immune defects are secondary and one of the most common causes is malnutrition. Immunosuppressive and other drugs, other iatrogenic causes and various chronic diseases are increasingly important (Table 20.16). Immunodeficiency can also be caused by hypercatabolism of immunoglobulin or excessive loss of immunoglobulins (nephrosis, severe burns, lymphangiectasia or severe diarrhoea).

AGRANULOCYTOSIS, LEUKOPENIA AND NEUTROPENIA

General aspects

Agranulocytosis is the name given to the clinical syndrome resulting from leukopenia or neutropenia. It is characterized by abnormal susceptibility to infection and oropharyngeal ulceration.

Leukopenia refers to low levels of circulating functional leukocytes, either in absolute numbers or as functionally effective cells. It is a feature of cytotoxic drug therapy and many diseases.

Neutropenia refers to low levels of circulating functional polymorphonuclear leukocytes, either in absolute numbers or as functionally effective cells. It is also a feature of cytotoxic drug therapy and many diseases. Some cases are genetically determined.

These states can develop in isolation or they can be associated with other effects of depressed bone marrow function, notably anaemia and bleeding tendencies, as in acute leukaemia and aplastic anaemia.

Table 20.16 Some causes of white cell defects

Congenital defects	Acquired defects				
	Bone marrow disease	Drugs	Autoimmune disorders	Viral infections	Others
See Appendix 20.1	Leukaemia, other marrow infiltrations and myelofibrosis	Antithyroid drugs Cefalothin Chloramphenicol	Systemic lupus erythematosus Felty syndrome Others	HIV infection Others	Diabetes Crohn disease
	Aplastic anaemia (Ch. 8)	Cytotoxic agents Phenothiazines Phenylbutazone Phenytoin Sulphonamides			

Clinical features

There is often a sudden onset and fever, weakness or prostration, and sore throat are characteristic. Gingival, oral and pharyngeal ulceration with pseudomembrane formation are typical features but ulceration can affect any mucous membrane. Lymphadenopathy and sometimes rashes are also features. Later, haemorrhagic necrosis of mucous membranes and respiratory infection may go on to septicaemia as the terminal event. Purpura and bleeding as a result of thrombocytopenia are also a common early manifestation.

In neutropenia, even a minor infection can quickly become serious. Reasons for special concerns include:

- fever that is 100.4°F (38°C) or higher for more than 1 hour, or a one-time temperature of 101°F or higher
- chills and sweats
- change in cough or new cough
- sore throat or new mouth sore
- shortness of breath
- nasal congestion
- stiff neck
- burning or pain with urination
- unusual vaginal discharge or irritation
- increased urination
- redness, soreness or swelling in any area, including surgical wounds and ports
- diarrhoea
- vomiting
- pain in the abdomen or rectum
- new onset of pain
- changes in skin, urination or mental status.

General management

The diagnosis is confirmed by blood examination and bone marrow biopsy.

Treatment depends on the underlying cause. In the case of drugs, the triggering agent must be stopped and this may sometimes allow bone marrow function to recover. The main measure is to control infections. Septicaemia is a hazard, particularly in neonates and patients treated with cytotoxic chemotherapy.

Gram-negative infections should be treated with antibiotics such as ticarcillin, mecillinam or one of the third-generation cephalosporins, such as ceftazidime or cefotaxime. Complications of septicaemia include acute respiratory distress syndrome, pneumonia or shock, but endocarditis is rare. Mortality rates may be as high as 30%. Patients should therefore be nursed in laminar-airflow rooms and surgical procedures should be carried out under antibiotic cover.

Gram-positive oral microorganisms, such as viridans streptococci – mainly *Streptococcus mitis* and *S. sanguis*, are increasingly frequently implicated and may lead to serious morbidity and mortality. Predisposing factors appear to be mucositis, the use of high doses of cytosine arabinoside, and the failure to use intravenous antibiotics at the time of bacteraemia. Viridans streptococci are sensitive to many antibiotics but there is increasing resistance to penicillin after prolonged exposure. Penicillin, vancomycin and roxithromycin are usually effective in lowering the incidence of viridans streptococcus bacteraemia but co-trimoxazole is not.

If patients develop a fever, samples of blood, urine, sputum and faeces should be taken for culture lest there be septicaemia, and the patient started on systemic antibiotics; initially, piperacillin/tazobactam plus gentamicin is usually given, or ceftazidime if the patient is penicillin-allergic.

Box 20.3 Management modifications for dental care in neutropenias

- Consider delaying treatment until recovery
- Consider colony stimulating factors
- Consider antimicrobial cover
- Strict asepsis

Granulocyte colony-stimulating factors (filgrastim, lenograstim, molgramostim) are now available and may be of benefit.

Dental aspects

Infections and ulcers are the main oral manifestations; periodontal disease may be accelerated and minor oral infections may result in gangrenous stomatitis in severe cases. Oral infections can be painful and a potential source of metastatic infections or septicaemia, sometimes fatal. Oral infections can usually be controlled with topical or systemic antibiotic therapy or sometimes with antiseptics such as chlorhexidine. Mixed infections can often be controlled by a broad-spectrum antibiotic, such as topical tetracycline, but this should be given together with an antifungal drug because of the risk of candidal superinfection. Failure to respond to such treatment indicates that the causative bacteria are not sensitive and bacteriological investigation is required. Clindamycin may be a more suitable choice for anaerobic infections.

Dental surgical procedures should be covered with an antibiotic and particular attention should be paid to the possibility of thrombocytopenia with haemorrhagic tendencies and to the risks associated with corticosteroid treatment (Box 20.3).

CHRONIC DISEASES WITH IMMUNE DEFECTS

Diabetes mellitus is the most common chronic disease associated with immune defects, mainly defective phagocytosis. Cancers of lymphoid or haemopoietic tissues are also linked with immune defects, especially as a consequence of their treatment. Many infections, particularly viral, produce some degree of immune defect.

For dental surgical procedures, particular attention should be paid to the possibility of thrombocytopenia with haemorrhagic tendencies and to the risks associated with corticosteroid treatment.

ASPLENIC PATIENTS

General aspects

The spleen is essential for controlling the quality of erythrocytes in the circulation by sequestering effete erythrocytes. It is also essential for the production of opsonins, thereby having an important function in antibody production and phagocytosis of microorganisms. The opsonins properdin and tuftsin protect against bacteria such as pneumococci.

Asplenia may be caused by splenectomy (e.g. after serious splenic injuries in abdominal trauma, for some haemolytic anaemias, in idiopathic thrombocytopenic purpura and in some lymphomas). The spleen becomes hypofunctional in sickle cell disease and other disorders.

Clinical features

Asplenia predisposes to infections, which usually appear within the first 2 years after splenectomy, though up to one-third may manifest at least 5 years later, and some have developed more than 20 years later. Children are ten times more likely than adults to develop sepsis. Patients may become predisposed to infection with encapsulated bacteria and other microbes. *Streptococcus pneumoniae* (pneumococcus) is

Fig. 20.12 Asplenia.

the most common pathogen and, together with *Haemophilus influenzae* and *Neisseria meningitidis* (meningococcus), accounts for 70–90% of cases. Other infections can include *Capnocytophaga canimorsus* (from dog bites), babesiosis (from tick bites), hepatitis C, tuberculosis and malaria. Infection after splenectomy only rarely emanates from the oral flora.

After splenectomy, patients may also be predisposed to develop malignant neoplasms.

General management

Patients having splenectomy should therefore be immunized 2 weeks beforehand, against pneumococci, *H. influenzae* type b and meningococcus. Post-splenectomy, for at least the first 2 years, and especially for other immunocompromised patients and for children under 16, daily penicillin or erythromycin prophylaxis is advised. Patients are usually advised to carry a warning card (Fig. 20.12).

If patients who have had splenectomy in the past become acutely unwell, they should be given benzyl penicillin promptly.

Dental aspects

There is no indication for antimicrobial prophylaxis before dental procedures unless there are other reasons and, in any event, such prophylaxis might fail.

It is important, however, to consider thrombocytopenia and corticosteroid therapy.

PRIMARY (CONGENITAL) IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases are due to abnormalities of one or more genes that are important in immunity. There are over 100 different immune defects, mostly rare, and most can be categorized according to the main type of immune cell that is defective (Appendix 20.1, Table 20.17 and Fig. 20.13). These are also comprehensively outlined by the International Union of Immunological Societies Expert Committee on Primary Immunodeficiencies (2009).

General aspects

Some primary immune defects are inherited as autosomal recessive traits, some as X-linked recessive traits, and at least one as an autosomal dominant trait. Others are not inherited as single-gene defects. Two of the most common primary immunodeficiency diseases, selective IgA deficiency and common variable immunodeficiency, considered later, are frequently sporadic.

Immune defects are also common in some chromosomal anomalies, including Down syndrome (Ch. 28), Fanconi anaemia and Bloom syndrome, and in various rare hereditary metabolic defects.

Clinical features

Primary immune defects should be suspected if there are recurrent or persistent infections or other features.

The main features suggestive of an immune defect are summarized in Box 20.4 and features of the main primary immune defects in Appendix 20.1.

General management

Antibody deficiency is most frequently encountered and commonly presents with sinopulmonary bacterial infections. If these are the only types of infection under consideration, screening for antibody deficiency is appropriate. Other forms of primary immunodeficiency may present with distinct infectious complications with or without sinopulmonary bacterial disease. Some of these forms of infection are more or less characteristic of specific categories of immunodeficiency.

Some primary immune defects are treated by replacement of defective immunocytes or their products with immunoglobulin or bone marrow transplantation (haematopoietic cell transplantation [HCT] – which has the potential to cure primary immune deficiency syndromes that primarily affect a single lineage, e.g., lymphoid or myeloid lineage), and gene transfer is being developed to correct several defects. Immune system molecules, such as IFN γ , can be injected to improve immune function and control infection.

Infections must be treated by accepted means.

Dental aspects

The more severe congenital immune defects often cause early death, so that they are not relevant to dental care, except in so far as some are treated by bone marrow transplantation.

T-LYMPHOCYTE DEFECTS

CHRONIC MUCOCUTANEOUS CANDIDOSIS

General aspects and clinical features

Chronic mucocutaneous candidosis (CMC or CMCC) is a group of disorders in which candidosis is the main or a prominent feature. Defects of cell-mediated immunity can sometimes be detected, particularly in the more severe cases (Table 20.18).

Early-onset CMC (types 1–3) typically begins in infancy, often as persistent thrush; the candidosis is mainly or entirely oral, and immunological defects are sometimes associated.

Familial candidosis in an adult with chronic oral candidosis can escape diagnosis until middle age. Enquiry should be made as to whether siblings are affected and if there was any parental consanguinity, as the disease appears to be autosomal recessive. In familial candidosis, investigation for iron deficiency should be carried out, and treatment with iron may improve the response to antifungal drugs.

The diffuse type of CMC presents with particularly severe candidosis that can give rise to gross proliferative and disfiguring lesions of the skin (so-called granulomas), as well as widespread oral lesions. Immunological defects are frequently found and there is also susceptibility to bacterial infections of the respiratory tract or elsewhere. Even in this unusually severe form of the disease, candidosis remains superficial and does not progress to candidal septicaemia or other types of disseminated infection.

Candidosis–endocrinopathy syndrome (autoimmune polyendocrinopathy candidosis–ectodermal dystrophy [APECED]) has usually

Table 20.17 Main primary immune defects^a

Main defect	Includes	Manifestations
Severe combined immune deficiencies	Includes mutations in relation to DNA ligase IV and CD3 δ deficiencies	Recurrent serious infections
Predominantly T-cell deficiencies	Chronic mucocutaneous candidiasis DiGeorge anomaly	Usually present as recurrent or persistent fungal infections
Predominantly B-cell deficiencies	Autosomal recessive agammaglobulinaemia X-linked agammaglobulinaemia Common variable immunodeficiency Inducible co-stimulator (ICOS) deficiency Selective antibody deficiency (such as IgA deficiency) Hyper-IgM syndrome – includes activation-induced cytidine deaminase (AID) and uracil-DNA glycosylase (UNG) deficiencies	Usually present as recurrent bacterial infections
Other well-defined immunodeficiency syndromes in which there are non-immunological features	Includes syndromes with defects in DNA repair mechanisms. This group has included Bloom syndrome	The immune defects associated with non-immunological features, such as Wiskott–Aldrich syndrome, DNA repair defects and thymic defects, have traditionally been classified together
Diseases of immune dysregulation	Includes defects of apoptosis resulting in lymphoproliferative or autoimmune syndromes. Autoimmune lymphoproliferative syndrome (ALPS) Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) – a recessive disorder	ALPS presents with lymphadenopathy, autoimmunity and expansion of a normally infrequent population of CD4 ⁺ CD8 ⁺ T cells IPEX presents with protracted diarrhoea, ichthyosiform dermatitis, type 1 diabetes mellitus, thyroiditis and haemolytic anaemia
Defects of phagocytic cell number, function or both	Chédiak–Higashi syndrome Chronic granulomatous disease Hyperimmunoglobulinaemia E (Job) syndrome Leukocyte glucose-6-phosphate dehydrogenase deficiency Myeloperoxidase deficiency Leukocyte adhesion defects – include LAD types 1–3, Rac2 deficiency, β -actin deficiency and localized juvenile periodontitis Papillon–Lefèvre syndrome	Range from defects of wound healing or localized infections or periodontitis, to severe clinical phenotypes requiring bone marrow transplantation
Defects of innate immunity relating to monocyte and dendritic cell functions	Defects in nuclear factor kappa B or other signals	Various
Autoinflammatory disorders	Periodic fever, aphthous stomatitis, pharyngitis, adenitis (PFAPA syndrome) – not inherited Hereditary conditions, including: 1. Familial Mediterranean fever (FMF) 2. Mevalonate kinase deficiencies (including hyperimmunoglobulinaemia D and periodic fever syndrome [HIDS] and mevalonate aciduria) 3. Tumour necrosis factor receptor-associated periodic syndrome (TRAPS) 4. Pyogenic sterile arthritis, pyoderma gangrenosum, acne (PAPA) 5. Chronic recurrent multifocal osteomyelitis (CRMO) 6. Blau syndrome 7. Cryopyrin-associated periodic syndromes (CAPS)	The periodic fevers
Complement deficiencies	Complement component 1 (C1) inhibitor deficiency (hereditary angioedema) C3 deficiency C6 deficiency C7 deficiency C8 deficiency New complement-related deficiencies – mannose-binding protein (MBP) deficiency and MBP-associated serine protease 2 (MASP2) deficiency	Various

^aFor fine detail, see Notarangelo L, et al. 2004.

mild but persistent candidosis as the initial feature; endocrine disorders appear but often not until 10 or 15 years later. Occasionally, this sequence is reversed. There is no evidence that candidosis causes the endocrine disorders or vice versa. Hypoparathyroidism or Addison disease, or both, is the most commonly associated endocrinopathy. The endocrine disorders in candidosis–endocrinopathy syndrome are associated with multiple organ-specific autoantibodies both in patients and

in unaffected relatives. Patients may long appear to be quite well, apart from chronic oral candidosis. If, therefore, a patient, particularly a child or adolescent with chronic oral candidosis, has a family history of any of the associated disorders, and autoantibodies (particularly to glandular tissues) are found, endocrine disease will probably develop in the future.

Candidosis–thymoma syndrome presents with late-onset CMC, when evidence of impaired cell-mediated immunity, particularly to

Fig. 20.13 Primary immune defects.

Box 20.4 Features suggestive of a primary immune defect

- Family history of primary immune deficiency
- Eight or more new ear infections within 1 year
- Failure of an infant to gain weight or grow normally
- Need for intravenous antibiotics to clear infection
- Persistent thrush in the mouth or elsewhere on the skin, after age 1
- Recurrent, deep skin or organ abscesses
- Two or more deep-seated infections, such as sepsis, meningitis or cellulitis
- Two or more months on antibiotics with little effect
- Two or more pneumonias within 1 year
- Two or more serious sinus infections within 1 year

More information is available at: <http://www.piduk.org/> (accessed 30 September 2013).

Table 20.18 Chronic mucocutaneous candidosis syndromes

Type	Clinical features
1. Familial	Persistent oral candidosis Often iron deficiency
2. Diffuse (candida granuloma)	Severe chronic candidosis Susceptibility to bacterial infections
3. Candidosis–endocrinopathy syndrome (polyendocrinopathy syndrome)	Mild chronic oral candidosis Hypoparathyroidism Hypoadrenocorticism
4. Candidosis–thymoma syndrome	Chronic oral candidosis Myasthenia gravis Haematological disorders
5. Chronic mucocutaneous candidosis in HIV disease or hyperimmunoglobulin E syndrome	Recurrent candidosis

Candida albicans, may be found. In such a case, investigation for a thymoma should be carried out, as early excision may improve the prognosis.

General management

Candidosis is persistent and responds poorly to topical treatment with nystatin or amphotericin, but topical antifungal agents, such as miconazole, or systemic ketoconazole, fluconazole, itraconazole or voriconazole, may be helpful.

DIGEORGE ANOMALY

The coincidental association between chronic candidosis and hypoparathyroidism (type I polyendocrinopathy syndrome), also seen in the DiGeorge syndrome (CATCH 22), has given rise to the myth that hypoparathyroidism predisposes to candidosis. However, treatment of hypoparathyroidism has no effect on candidosis, and hypoparathyroidism from any other cause is not associated with candidosis. Branchial arch defects in DiGeorge syndrome affect both thymus (and thymocytes) and parathyroids.

normal B-cell numbers, though some do have low or absent B cells. Abnormalities in T-cell numbers or function are common.

Clinical features

Symptoms are mainly frequent bacterial infections of ears, sinuses, bronchi and lungs. Viral, fungal and parasitic infections, as well as bacterial ones, may be problematic. Pneumonias are common and approximately 50% of patients have autoimmune disease. Gastrointestinal disease, including chronic diarrhoea, affects as many as 30% and there is a high incidence of inflammatory bowel disease, gluten-sensitive enteropathy and nodular lymphoid hyperplasia. *Giardia lamblia* and bacterial overgrowth of the small bowel are the most frequently identified pathogens. Haematological abnormalities may include autoimmune haemolytic anaemia, immune thrombocytopenia, leukopenia and pernicious anaemia. Arthralgia in the knee, ankle, elbow or wrist is common, and rheumatoid arthritis and other collagen vascular diseases are also more common than expected. Splenomegaly and lymphadenopathy may be seen. Patients are usually recognized to be immunodeficient by the second, third or fourth decade of life.

ANTIBODY DEFICIENCY SYNDROMES

Hypogammaglobulinaemia can have several causes and can also be caused by hypercatabolism, or excessive loss, of immunoglobulins (Table 20.19).

COMMON VARIABLE IMMUNODEFICIENCY

General aspects

Also known as adult-onset agammaglobulinaemia, late-onset hypogammaglobulinaemia or acquired agammaglobulinaemia, common variable immunodeficiency (CVID) is relatively common. Serum IgG is low with a marked decrease in IgM or IgA. The serum IgM concentration is normal in about half of the patients. Most patients have

General management

Diagnosis is confirmed by finding low serum IgG, IgA and possibly IgM. B cells still produce antibodies after a common vaccination such as tetanus. Antibody levels can be normalized by intravenous immunoglobulin every 3–4 weeks. Bacterial infections are treated with antibiotics. Physical therapy and daily postural drainage may help clear respiratory infections.

SELECTIVE IgA DEFICIENCY

General aspects

Selective IgA deficiency is the most common congenital immunodeficiency, affecting 1 in 600 in the normal population. IgA is deficient in both serum and secretions.

Table 20.19 Differential diagnosis of hypogammaglobulinaemia

Genetic disorders	Drug-induced	Infections	Malignancy	Immunoglobulin loss or degradation
Ataxia telangiectasia	Antimalarials	Congenital rubella or cytomegalovirus or <i>Toxoplasma gondii</i>	Chronic lymphocytic leukaemia	Lymphangiectasia Nephrosis
Autosomal severe combined immunodeficiency (SCID)	Captopril Carbamazepine Glucocorticoids Fenclofenac	HIV Epstein–Barr virus	Immunodeficiency with thymoma Non-Hodgkin lymphoma B-cell malignancy	Severe burns Severe diarrhoea
Hyper immunoglobulin M (IgM) immunodeficiency	Gold salts Penicillamine Phenytoin Sulfasalazine			
Transcobalamin II deficiency and hypogammaglobulinaemia				
X-linked agammaglobulinaemia				
X-linked lymphoproliferative disorder				
X-linked SCID				
Chromosome 18q– syndrome				
Monosomy 22				
Trisomy 8				
Trisomy 21				

Clinical features

Many individuals with IgA deficiency are asymptomatic if the levels of other classes of immunoglobulin are normal or raised. Others have persistent or recurrent infections and some develop CVID over time. Some have an increased incidence of upper respiratory tract infections, allergies and autoimmune disease but a normal IgG antibody response to vaccination.

Where IgA deficiency is associated with deficiency of IgG2, there is a definite predisposition to recurrent bacterial or viral respiratory infections, and small intestine infections – usually with *Giardia lamblia* (a protozoon causing diarrhoea and malabsorption, although the disease is often unrecognized because the symptoms are chronic and indolent). Atopic disease, coeliac disease, lupus erythematosus, rheumatoid arthritis and Sjögren syndrome are abnormally frequent.

General management

IgA replacement is difficult since autoantibodies frequently form against IgA when blood transfusions or immunoglobulins are given, and can sometimes cause anaphylactic reactions.

Bacterial infections should be treated with antibiotics. Giardiasis needs treatment with metronidazole or quinacrine hydrochloride.

Dental aspects

Despite the fact that IgA is the main salivary antibody, reported effects of IgA deficiency on dental caries and other oral disease are conflicting. Part of the reason for this apparently anomalous situation is that other immunoglobulins may be secreted in saliva. IgA deficiency may be associated occasionally with oral ulcers and herpes labialis.

X-LINKED AGAMMAGLOBULINAEMIA (BRUTON SYNDROME)

Patients with X-linked agammaglobulinaemia (XLA) are male with low CD19+ B cells and low serum IgG, IgM and IgA, no isohaemagglutinins and/or a poor response to vaccines. They develop recurrent bacterial infections in the first 5 years of life, particularly otitis, sinusitis and pneumonia. The most common organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Approximately 20% of patients present with a dramatic, overwhelming infection, often also with neutropenia. Another 10–15% have higher concentrations of serum immunoglobulin than expected or are not recognized to have immunodeficiency until after 5 years of age.

B- AND T-LYMPHOCYTE DEFECTS

ATAXIA TELANGIECTASIA

Ataxia telangiectasia (AT) is progressive cerebellar ataxia with walking difficulty presenting at the end of the first year of life; by the teenage years, most patients are wheelchair-bound. Ocular or facial telangiectasia is usually seen at 4–8 years of life. Serum IgA is low and alpha-fetoprotein high. Many patients have recurrent respiratory infections. Radiation-induced chromosomal breakages may culminate in leukaemia or lymphomas.

SEVERE COMBINED IMMUNODEFICIENCY (SCID)

Patients with SCID have low CD3+ T cells. They usually fail to thrive, and develop persistent diarrhoea, respiratory infections and/or thrush in

the first 7 months of life. *Pneumocystis* pneumonia, significant bacterial infections and disseminated bacille Calmette-Guérin (BCG) infection are common. SCID is fatal in the first 2 years of life, unless the patient is treated with extremely restrictive isolation, haemopoietic stem cell transplant, or therapy that replaces the abnormal gene or gene product. Transplantation in early life offers a survival now approaching 90%.

WISKOTT–ALDRICH SYNDROME

Wiskott–Aldrich syndrome (WAS) presents in males with congenital thrombocytopenia, small platelets and abnormal antibody response to polysaccharide antigens. Many patients have increased IgE and IgA, with low IgM, and T-cell numbers and function decline with age. The main features include eczema, recurrent bacterial or viral infections, autoimmune diseases (vasculitis, haemolytic anaemia and glomerulonephritis) and lymphoma, leukaemia or brain tumour. Otitis and sinusitis, and infections due to herpes simplex virus and EBV are particularly troublesome.

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

Males with X-linked lymphoproliferative syndrome (XLP) are usually asymptomatic until they develop EBV infection, which may cause fulminant hepatitis (60% of patients), particularly in young children. Lymphoma/Hodgkin disease, immunodeficiency, aplastic anaemia or lymphohistiocytic disorders may be fatal in childhood. Less common manifestations include EBV-associated haemophagocytic syndrome and vasculitis.

PHAGOCYTE DEFECTS

CHÉDIAK–HIGASHI SYNDROME

Chédiak–Higashi syndrome (CHS) is caused by impaired polymorphonuclear leukocyte function related to abnormal microtubular assembly. It is a rare autosomal recessive disorder that manifests with: hypopigmentation of skin, eyes and hair; bleeding tendency and easy bruisability; recurrent infections; abnormal natural killer (NK) cell function; and peripheral neuropathy. Most patients who do not undergo bone marrow transplantation die from a lymphoproliferative syndrome.

CHRONIC GRANULOMATOUS DISEASE

Patients with the X-linked form of chronic granulomatous disease (CGD; 60–70%) usually present earlier and with more severe disease than patients with autosomal recessive forms. Abnormal respiratory burst in activated neutrophils characterizes CGD. Clinically, there are deep-seated infections (liver, perirectal or lung abscess; lymphadenitis; or osteomyelitis) due to catalase-positive organisms such as staphylococci, *Serratia marcescens*, *Candida* or *Aspergillus*; diffuse granulomas in the respiratory, gastrointestinal or urogenital tract; failure to thrive; and hepatosplenomegaly or lymphadenopathy.

HYPERIMMUNOGLOBULINAEMIA E SYNDROME (JOB SYNDROME; BUCKLEY SYNDROME)

Patients with hyperimmunoglobulinaemia E syndrome (HIES) appear to have T-cell abnormalities, including a decrease in IFN γ and an increase in IL-4, and an inadequate inflammatory response

that may delay recognition of infections. HIES is characterized by eczema, recurrent skin abscesses, cystic lung infections (primarily *Staphylococcus aureus* and *Candida* species [chronic mucocutaneous candidosis]), eosinophilia and raised IgE. Non-immunological features include multiple bone fractures, joint hyperextensibility and other skeletal abnormalities, coarse facial features, retained primary teeth, palatal keratosis or ridging, and tongue-fissuring.

LEUKOCYTE ADHESION DEFICIENCY (LAD)

Decreased expression of CD18 on neutrophils with mutation in the beta2-integrin gene leads to recurrent or persistent bacterial or fungal infections, leukocytosis, and delayed separation of the umbilical cord and/or defective wound-healing. Infections with *Staphylococcus*, Gram-negative enteric bacteria and fungi are particularly troublesome. Periodontitis is a common finding. In the severe form of LAD, with no CD18 expression on neutrophils, the patient usually succumbs without bone marrow transplantation. In the moderate form, patients can survive to adulthood.

LEUKOCYTE GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Glucose-6-phosphate dehydrogenase (G6PD) is one of the pentose phosphate pathway enzymes, involved in maintaining adequate coenzyme nicotinamide-adenine dinucleotide phosphate (NADPH) in cells. G6PD deficiency can lead to meningitis, septicaemia or osteomyelitis.

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase (MPO) is an enzyme in the neutrophil azurophilic granules and in lysosomes of monocytes, which has a major role in killing some bacteria (*Staphylococcus aureus*, *Serratia* species and *Escherichia coli*), fungi, parasites, protozoa, viruses and tumour cells. Most individuals with partial or total MPO deficiency have no increased frequency of infections but recurrent infections may be seen, especially where there is coexistent diabetes.

COMPLEMENT DEFECTS

Defects in complement components tend to be associated with autoimmune disease, especially lupus erythematosus, and increased susceptibility to meningococcal and gonococcal infections.

HEREDITARY ANGIOEDEMA (C1 ESTERASE INHIBITOR DEFICIENCY)

General aspects

Hereditary angioedema (HANE) is caused by continued complement activation resulting from a mainly genetically determined deficiency of an inhibitor of the enzyme C1 esterase (Fig. 20.14); thus C4 is consumed and its plasma level falls. The level of C3 is usually normal. Complement activation is associated with release of kinin-like substances, such as bradykinin, which are the probable cause of the sudden increase in capillary permeability.

Despite its hereditary nature, usually as an autosomal dominant trait, the disease may not present until later childhood or adolescence, and nearly 20% of cases are caused by spontaneous mutation. Rare cases are acquired.

Fig. 20.14 Hereditary angioedema (HANE).

Clinical features

Blunt injury is the most consistent precipitating event and the trauma of dental treatment is a potent trigger of attacks. Some attacks follow emotional stress.

Hereditary angioedema mimics allergic angioedema, though it causes a more severe reaction. Abdominal pain, nausea or vomiting, diarrhoea, rashes and peripheral oedema sometimes herald an attack. Oedema typically affects the mouth, face and neck region, can persist for up to 4 days and may involve the airway. The extremities and gastrointestinal tract may be involved.

The mortality may be as high as 30% in some families but the disease is compatible with prolonged survival if emergencies are effectively treated.

General management

Initial screening should include a C4 level, which will be depressed during and between attacks. If a C4 level is found to be low or clinical suspicion of hereditary or acquired angioedema is high, testing of C1-inhibitor (INH) level and function is warranted. C4 levels are often low due to improper handling; therefore, repeating a C4 level when further testing is performed is also advisable. In types 1 and 2 HANE, as well as acquired angioedema, the C1 INH level will be low, typically less than 30% of normal (see Table 20.17). A C1q level will differentiate these acquired and hereditary angioedema, as it will only be low in acquired angioedema but not type 1 HANE. In 85% of cases, the C1 esterase levels are low (type 1 HANE); in 15% this inhibitor is present but dysfunctional (type 2 HANE). In both types the C4 level falls. C1 esterase inhibitor concentrates are available for replacement of the missing factor. Type 3 HANE is related to pregnancy and C1 inhibitor levels are usually normal but bradykinin levels high.

Management of HANE may include both short-term and long-term prophylaxis, as well as treatment of acute episodes. Plasma or plasminogen inhibitors, such as tranexamic acid, can mitigate attacks and may be life-saving. The androgenic steroids, danazol and stanozolol, raise plasma C1 esterase inhibitor levels to normal. Stanozolol needs to be given for 5 days to be effective and should not be used during pregnancy. Oligomenorrhoea may be induced in women and there may be acne, hirsutism, hypercalcaemia or headache. Androgens may cause virilization, weight gain and hypertension; antifibrinolytic agents have been reported to cause muscle necrosis, hypotension and menorrhagia. Plasma-derived C1 INH concentrates have good efficacy

and tolerability, adverse effects (headache and fever) are rare, and the primary limitation is cost. Icatibant (a bradykinin antagonist) can be helpful. Ecallantide, a plasma kallikrein inhibitor given subcutaneously, is an efficacious alternative to C1 INH therapy. Adverse effects are mild and similar to C1 INH concentrate but there is a risk of anaphylaxis.

MUCOCILIARY SYNDROMES

Cilia in the respiratory tract normally clear mucus and act as a defence mechanism. If they are impaired, as in some genetic and acquired disorders, this may lead to chronic sinusitis or other respiratory infections. Examples are Kartagener syndrome (mucociliary disease and dextrocardia) and intolerance of NSAIDs in the Fernand–Widal syndrome.

EMERGING IMMUNE DEFECTS

Emerging primary immune defects are increasingly recognised, and these include:

- Herpes simplex encephalitis may arise as a result of impaired intrinsic signalling in neurons and oligodendrocytes from a variety of gene mutations affecting innate immunity (which include; unc-93 homolog B1 (*UNC93B1*), TIR-domain-containing adaptor protein inducing IFN β (*TRIF*), TNF receptor-associated factor 3 (*TRAF3*), TANK-binding kinase 1 (*TBK1*) and Toll-like receptor 3 [*TLR3*]).
- Defects in the innate generation of dendritic cells (DCs), monocytes, neutrophils, B lymphocytes and natural killer (NK) cells, lead to viral, fungal and mycobacterial infections as well as myelodysplasia and are seen in mutations of the GATA-binding protein 2 (*GATA2*) gene.
- The development and immune activation of DCs and other myeloid cells, are impaired by interferon-regulatory factor 8 (*IRF8*) mutations.
- Mutations affecting interleukin-10 (IL-10)-mediated signalling in myeloid cells and other haematopoietic cells seems to be essential to prevent the early onset of colitis.
- Mast cells are susceptible to spontaneous activation and degranulation in cold temperatures where mutations affect phospholipase C γ 2 (PLCG2).
- Mutations in PIK3CD gene lead to PASLI (p110 delta activating mutation causing senescent T cells, lymphadenopathy, and immunodeficiency) with impaired T and B cell immune responses, predisposing patients to chronic respiratory bacterial infections, Epstein-Barr virus infection and lymphoma. mTOR, is excessively activated by p110 delta in PASLI patients.

APPENDIX 20.1 MAIN FEATURES OF MAJOR PRIMARY (GENETICALLY DETERMINED) IMMUNODEFICIENCY DISORDERS

Type or name of syndrome	Immunological phenomena	Clinical effects	Possible orofacial features
<i>Predominantly B-cell defects</i>			
Transient hypogammaglobulinaemia of infancy	Hypogammaglobulinaemia in early childhood only	Eczema, food allergies	NR
X-linked infantile hypogammaglobulinaemia (XLA; Bruton syndrome)	Immunoglobulins of all classes deficient or absent	Recurrent pyogenic infections Infants develop pus-producing infections of the inner ear and lungs Hepatitis, central nervous system (CNS) viral infections	Sinusitis, absent tonsils, cervical lymph node enlargement, ulcers
X-linked hyper-immunoglobulin M (IgM) syndrome	IgA, IgG and IgE low	Recurring upper and lower respiratory infections in first year of life. Enlarged liver and spleen, chronic diarrhoea, and increased risk of unusual or opportunistic infections and non-Hodgkin lymphoma Recurrent bacterial infections in the first 5 years of life <i>Pneumocystis carinii</i> infection in the first year of life Neutropenia <i>Cryptosporidium</i> -related diarrhoea. <i>Cryptosporidium</i> infection may lead to severe bile duct disease and hepatic cancer Sclerosing cholangitis Parvovirus-induced aplastic anaemia	Enlarged tonsils Over 50% of patients have chronic or intermittent neutropenia, often associated with oral ulcers
Non-X-linked hyper-IgM syndrome	IgA and IgE low	Neutropenia, thrombocytopenia, liver disease	Mouth ulcers
Nijmegen breakage syndrome	Serum IgG and IgA more than 2 SD below normal for age	Increased radiation-induced chromosomal breakage on chromosome 8q21 Additional features are café-au-lait spots, vitiligo, and clinodactyly and syndactyly More than 50% develop B- or T-origin lymphomas before 18 y of age Many have recurrent bacterial and viral respiratory infections (56%) associated with antibody deficiencies	Microcephaly Typical facial appearance (receding forehead, prominent midface with long nose and long philtrum and a receding mandible)
WHIM (warts, hypogammaglobulinaemia, infections, myelokathexis) syndrome	Chronic neutropenia (absolute neutrophil count <500/L) Myelokathexis (retention of senescent neutrophils in the bone marrow) Chronic lymphopenia (absolute lymphocyte count <1500/L) Serum IgG at or below the normal range for age Hypogammaglobulinaemia may be present, but the serum immunoglobulin concentrations do not correlate with the number of B cells	Male or female patient Autosomal dominant disorder Most patients present with recurrent infections at less than 3 y of age Warts generally begin to appear after 5 y of age and some patients have hundreds of warts Increased susceptibility to infection from members of the herpesvirus family can be seen Most patients develop a normal neutrophil count during infection	Facial warts

(Continued)

Type or name of syndrome	Immunological phenomena	Clinical effects	Possible orofacial features
Common variable immunodeficiency	Variable deficiency of different immunoglobulins	Respiratory infections starting in childhood	Sinusitis, hyperplastic tonsils, cervical lymph node enlargement, oral ulceration
Wiskott–Aldrich syndrome	Deficiency mainly of IgM and IgA	Recurrent infections, especially by pneumococci, meningococci and <i>Haemophilus influenzae</i> , thrombocytopenia, eczema	Purpura, candidosis, herpetic infections
	IgE may be increased	Severe infections with herpesviruses and <i>Pneumocystis jiroveci</i> (<i>carinii</i>)	
Hypogammaglobulinaemia after intrauterine viral infections (e.g. rubella)	Deficiency usually of only one Ig class (e.g. IgA)	High incidence of malignancies, particularly lymphomas and autoimmune diseases	Enamel hypoplasia
IgA deficiency	Variable. Deficient IgA and sometimes IgE or IgG ₂	Occasionally increased susceptibility to infection	Tonsillar hyperplasia, possibly oral ulceration, herpetic infections
IgG ₂ subclass deficiency	Defective humoral immunity	Recurrent respiratory infections	Sinusitis
<i>T- and B-cell defects</i>			
Congenital thymic aplasia (DiGeorge syndrome)	Deletion of chromosome 22q11.2	Viral and fungal infections starting in infancy	Dysmorphic facies or palatal abnormalities, bifid uvula
	Defective cell-mediated immunity; reduced numbers of CD3+ T cells (<500/mm ³). Ig production also impaired	Cardiovascular defects: conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch or aberrant right subclavian)	Candidosis, herpetic infection
		Hypoparathyroidism with hypocalcaemia of >3 weeks' duration	
		The severity of the T-cell defect varies greatly; in many patients the immunodeficiency resolves in the first few years of life	
		Autoimmune disorders may be seen in older patients	
Major histocompatibility complex (MHC) class II deficiency (base lymphocyte syndrome)	Subtype of severe combined immunodeficiency (SCID)	Seen most often in patients from around the Mediterranean Sea; results in a clinical phenotype similar to SCID with severe infections and protracted diarrhoea in the first 6 months of life	Candidosis
		<i>Pseudomonas</i> , cytomegalovirus and <i>Cryptosporidium</i> infections are common	
		Hepatic abnormalities, particularly sclerosing cholangitis, are frequent	
Severe combined immunodeficiency (SCID)	Defective cell-mediated immunity and hypogammaglobulinaemia	Lack of resistance to all types of infection	Candidosis, herpetic infections
	Two types:		Oral ulceration
	Patients lack adenosine deaminase (ADA)	In the first 3 months of life, babies get serious or life-threatening infections, especially pneumonia, meningitis and sepsis	
	Patients lack the ability to produce the IL-2 receptor gamma chain, a molecule that T cells need to communicate with B cells	Common infections like chickenpox, measles or herpes can overwhelm them	
		Chronic skin infections, candidosis, chronic hepatitis, diarrhoea and blood disorders	
X-linked SCID	Defective cell-mediated immunity and hypogammaglobulinaemia	Onset of failure to thrive before 1 y of age, serum IgG and IgA more than 2 SD below normal for age	Thrush
		Persistent or recurrent diarrhoea, urinary tract infection or thrush	
		Many patients have normal serum IgM	
		Some show signs of graft-versus-host disease	
Deficiencies of MHC class II CD3, ZAP-70 or TAP-2	Decreased CD4 cells, CD8 cells	Recurrent infections	NR
Immunodeficiency with ataxia telangiectasia	Defective cell-mediated immunity	Respiratory infections starting in infancy	Sinusitis, oral ulceration
	Ig production impaired	Ataxia telangiectasia, learning impairment	
Late-onset immunodeficiency	Defective cell-mediated or hypogammaglobulinaemia	Susceptibility to various infections starting late in life	Chronic candidosis

(Continued)

Type or name of syndrome	Immunological phenomena	Clinical effects	Possible orofacial features
<u>Complement deficiencies</u>			
C1, C2 or C4 deficiencies	Defects in complement pathways	Autoimmune disease, especially lupus erythematosus	Possibly oral lesions of lupus erythematosus
C1, C3 or C5 deficiencies	Defects in complement pathways	Increased susceptibility to meningococcal and gonococcal infections	NR
C1 esterase inhibitor deficiency	Abnormal complement activation	Swelling of face and neck Airway obstruction	Swellings
<u>Granulocyte defects</u>			
Interferon-gamma receptor (IFNGR) deficiency	Granulocytes have protein that rejects interferon	Infections with mycobacteria and <i>Salmonella</i>	NR
Cyclical neutropenia	Depression of neutrophil count at 21-day intervals	Periodic infections – especially bacterial	Recurrent oral ulceration Periodontitis
Chronic granulomatous disease	Leukocyte killing defect	Catalase-positive bacterial infections, <i>Escherichia coli</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas</i> , <i>Serratia</i> and <i>Aspergillus</i> Lymph node abscesses	Cervical lymphadenopathy and suppuration Enamel hypoplasia
Myeloperoxidase deficiency	Leukocyte killing defect	Candidosis	Candidosis
Chédiak–Higashi syndrome	Leukocyte defect of chemotaxis and phagocytosis	Albinism, recurrent infections, hepatosplenomegaly, thrombocytopenia	Cervical lymph node enlargement, oral ulceration, periodontitis
Leukocyte adhesion defect (LAD) 1	Adhesion defect (deficiency of beta2-integrin; also called CD18, Mac1 or p150, 95)	Umbilical cord does not detach Severe infections of soft tissue Eroding skin sores without pus Infections of the gastrointestinal tract Wounds that heal slowly and may leave scars Poor prognosis	Periodontitis
LAD 2	Adhesion defect (failure to convert mannose to fucose)	Recurrent infection	Periodontitis
Papillon–Lefèvre syndrome	Chemotactic defect	Recurrent infection	Periodontitis
Job syndrome	HIE with neutrophil defects	Recurrent infection by <i>Staphylococcus aureus</i>	Asymmetry or uneven facial features
Hyperimmunoglobulinaemia E (HIE)	In about half of the cases, linked to chromosome 4. In most, it is autosomal dominant	HIE patients may also have scoliosis (curvature of the spine), weak bones and recurrent bone fractures, strokes or other brain problems, severe itching and inflamed skin	Prominent forehead Deep-set eyes Broad nasal bridge Wide, fleshy nasal tip Protruding lower jaw Periodontitis
Glycogen storage disease b	Leukopenia and defect of chemotaxis	Recurrent infection	Ulcers Periodontitis
Schwachman syndrome (lazy leukocyte syndrome)	Leukocyte defect of chemotaxis	Recurrent infection	Ulcers Periodontitis Ulcers

NR = not recorded; SD = standard deviation.

KEY POINTS

- Increasing population mobility means that a wide range of infections is seen globally
- Infections are especially common in immunodeficient people

An enormous range of infections is recognized; many are prevalent in the tropics and developing countries, and some are fatal. Global travel and global warming increasingly bring contact with these infections to the rest of the world. Concern has been expressed about more than a dozen potentially fatal infections that appear to be increasing in their geographical range (Box 21.1).

Bacteria, viruses and fungi are common in the external and internal environment, however, and most cause problems only if they secrete noxious substances, become invasive or elicit inappropriate host defence responses. Protection against most bacteria involves largely B cells and plasma cell production of antibodies, together with phagocytes (neutrophils and macrophages). Protection against mycobacteria, viruses and fungi is largely via T lymphocytes.

EMERGING INFECTIONS

Emerging infections (see also Appendix 21.1 and Ch. 33) may be:

- a recognized infection spreading to new areas or populations
- a hitherto known disease that is discovered to be caused by infection
- a previously unrecognized infection appearing where the habitat is changing (e.g. deforestation)
- a new infection resulting from change(s) in pre-existing microorganisms
- a known infection re-emerging because it has become resistant to treatment, or because of a breakdown in public health measures.

Box 21.1 Possible fatal diseases increasing with global warming

- Avian flu
- Babesiosis
- Cholera
- Dengue fever
- Ebola fever
- Lyme disease
- Malaria
- Parasitic infections
- Plague
- Red tides
- Rift valley fever
- Sleeping sickness
- Tuberculosis
- West Nile fever
- Yellow fever

INFECTION CONTROL

Guidelines to prevent transmission of infections are found at <http://www.bda.org/dentists/advice/ba/ic.aspx> (accessed 30 September 2013).

DISEASE NOTIFICATION

Notification of a number of specified infectious diseases is required in UK under the Public Health (Infectious Diseases) 1988 Act and the Public Health (Control of Diseases) 1984 Act. New (amended) regulations for clinical notifications came into force on 6 April 2010 (Box 21.2). Registered general *medical* practitioners (GMPs) in England and Wales

Box 21.2 Notifiable diseases

UK

- Acute bacterial meningitis (urgent)
- Acute viral meningitis (not Scotland)
- Acute encephalitis (not Scotland)
- Acute infectious hepatitis (not Scotland, urgent)^a
- Acute poliomyelitis (urgent)
- Anthrax (urgent)
- Botulism (urgent)
- Brucellosis (urgent if UK-acquired)
- Cholera (urgent)
- Diphtheria (urgent)
- Enteric fever (typhoid or paratyphoid, urgent)
- Food poisoning (not Scotland, urgent if clusters or outbreaks)
- Haemolytic uraemic syndrome (urgent)
- Infectious bloody diarrhoea (not Scotland unless caused by *Escherichia coli* O157, urgent)
- Invasive group A streptococcal disease (Scotland any necrotizing fasciitis, urgent)
- Scarlet fever (not Scotland)
- Legionnaires' disease (not Scotland, urgent)
- Leprosy (not Scotland or Northern Ireland)
- Malaria (not Scotland, urgent if UK-acquired)
- Measles (urgent)
- Meningococcal septicaemia (urgent)
- Mumps
- Plague (urgent)
- Rabies (only urgent if seen at time of bite rather than with symptoms)
- Rubella
- Severe acute respiratory syndrome (SARS) (urgent)
- Smallpox (urgent)
- Tetanus (urgent if intravenous drug user)
- Tuberculosis (urgent if health worker, case cluster or multiple drug resistance)
- Typhus
- Viral haemorrhagic fever (urgent)
- Whooping cough (urgent in acute phase)
- Yellow fever (urgent if UK-acquired)

USA

- Anthrax
- Arboviral neuroinvasive and non-neuroinvasive diseases:
 - California serogroup virus disease
 - Eastern equine encephalitis virus disease
 - Powassan virus disease
 - St Louis encephalitis virus disease
 - West Nile virus disease
 - Western equine encephalitis virus disease
- Babesiosis
- Botulism:
 - Botulism, food-borne
 - Botulism, infant
 - Botulism, other (wound and unspecified)
- Brucellosis
- Chancroid
- Chlamydia trachomatis infection
- Cholera
- Coccidioidomycosis
- Cryptosporidiosis
- Cyclosporiasis
- Dengue:
 - Dengue fever
 - Dengue haemorrhagic fever
 - Dengue shock syndrome
- Diphtheria
- Ehrlichiosis/Anaplasmosis:
 - *Ehrlichia chaffeensis*
 - *Ehrlichia ewingii*
 - *Anaplasma phagocytophilum*
 - Undetermined
- Giardiasis
- Gonorrhea
- Haemophilus influenzae, invasive disease
- Hansen disease (leprosy)
- Hantavirus pulmonary syndrome
- Haemolytic uremic syndrome, post-diarrhoeal
- Hepatitis:
 - Hepatitis A, acute
 - Hepatitis B, acute
 - Hepatitis B, chronic
 - Hepatitis B virus, perinatal infection
 - Hepatitis C, acute
 - Hepatitis C, past or present
- HIV infection:
 - HIV infection, adult/adolescent (age ≥ 13 y)
 - HIV infection, child (age ≥ 18 months and < 13 y)
 - HIV infection, paediatric (age < 18 months)
- Influenza-associated paediatric mortality
- Legionellosis
- Listeriosis
- Lyme disease
- Malaria
- Measles
- Meningococcal disease
- Mumps
- Novel influenza A virus infections
- Pertussis
- Plague
- Poliomyelitis, paralytic
- Poliovirus infection, non-paralytic
- Psittacosis
- Q fever:
 - Acute
 - Chronic
- Rabies:
 - Rabies, animal
 - Rabies, human
- Rubella
- Rubella, congenital syndrome
- Salmonellosis
- Severe acute respiratory syndrome-associated coronavirus (SARS-CoV) disease
- Shiga toxin-producing *E. coli* (STEC)
- Shigellosis
- Smallpox
- Spotted fever rickettsiosis
- Streptococcal toxic shock syndrome
- *Streptococcus pneumoniae*, invasive disease
- Syphilis:
 - Primary
 - Secondary
 - Latent
 - Early latent
 - Late latent
 - Latent, unknown duration
 - Neurosyphilis
 - Late, non-neurological
 - Stillbirth
 - Congenital
- Tetanus
- Toxic shock syndrome (other than streptococcal)
- Trichinellosis (trichinosis)
- Tuberculosis
- Tularaemia
- Typhoid fever
- Vancomycin-intermediate *Staphylococcus aureus* (VISA)
- Vancomycin-resistant *Staph. aureus* (VRSA)
- Varicella (morbidity)
- Varicella (deaths only)
- Vibriosis
- Viral haemorrhagic fevers, due to:
 - Ebola virus
 - Marburg virus
 - Crimean–Congo haemorrhagic fever virus
 - Lassa virus
 - Lujo virus
 - New World arenaviruses (Guanarito, Machupo, Junin and Sabia viruses)
- Yellow fever

^aAcute infective hepatitis but not HIV is notifiable in the UK.

have ‘a statutory duty to notify a “proper officer” of the Local Authority of suspected cases of certain infectious diseases’ – usually the consultant in communicable disease control (CCDC). The GMP should fill out a notification certificate immediately on diagnosis without waiting for laboratory confirmation and ensure that it reaches the officer within 3 days (telephone if urgent). The proper officers are required weekly to inform the Health Protection Agency (HPA) Centre for Infections (CFI) of the details of each case of each disease that has been notified.

As well as notifications of the infectious diseases specified below, the 2010 regulations also require GMPs to notify cases of 'other infections or of contamination which they believe present, or could present, a significant risk to human health', e.g. emerging or new infections, or cases of contamination (such as with chemicals or radiation) – particularly if there is a risk of transmission to others. Diagnostic laboratories also have a requirement to notify the HPA of specified causative agents they identify in tests on human samples.

Notification requires completion of the appropriate form, but urgent cases should be notified by telephone as well (certainly within 24 hours of any suspicions arising).

The following details are required:

- Patient's name, date of birth, sex and home address with postcode
- Patient's National Health Service number
- Ethnicity (used to monitor health equalities)
- Occupation, and/or place of work or educational establishment if relevant
- Current residence (if it is not the home address)
- Contact telephone number
- Contact details of a parent (for children)
- The disease or infection, or nature of poisoning/contamination being reported
- Date of onset of symptoms and date of diagnosis
- Any relevant overseas travel history
- If in hospital, also:
hospital address
day admitted
whether the disease was contracted in hospital.

There is no fee payable for notification.

In Scotland, written notification should be undertaken electronically via the Scottish Care Information (SCI) Gateway (<http://www.hps.scot.nhs.uk/publichealthact/NotifiableInfectiousDiseaseData.aspx>; accessed 30 September 2013).

Diseases that are notifiable to the local authorities in the UK and USA are shown in Box 21.2. Incubation times are shown in Appendix 21.2.

Further information may be found at: http://www.hpa.org.uk/infections/topics_az/noids/archive.htm (accessed 30 September 2013).

BACTERIAL INFECTIONS

Bacterial infections and therapy are discussed here and in other chapters (Table 21.1) and in Appendices 21.3, 21.4 and 21.5.

Bacterial infections are common. Most are transient with few untoward sequelae but some can cause serious, recurrent, disseminated or persistent lesions – especially in immunocompromised persons (particularly in neutropenic patients, those with organ transplants, and those with human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS]) – or can be life-threatening immediately (e.g. meningococcal meningitis), less immediately (e.g. diphtheria) or in the longer term (e.g. tuberculosis, syphilis).

Bacterial infections are often diagnosed on clinical grounds, supported by smears, culture, testing for immune responses (serology) and, increasingly, examining for nucleic acids.

Antibacterial drugs can often be effective therapy (see Appendix 21.3) but drainage of pus is often more important. Antibiotic resistance is increasingly a serious problem (e.g. *Staphylococcus aureus*, *Clostridium difficile*, *Mycobacterium tuberculosis*) and is encouraged by unwarranted use of antibiotics. Uncommon bacterial infections

are shown in Appendix 21.6. Immunization against various bacteria is available and should be taken up (Appendix 21.7).

A wide range of bacterial infections are recognized (see Table 21.1). This chapter discusses odontogenic and orofacial bacterial infections; most cause lesions of limited duration but some are life-threatening. Nosocomial infections (health-care associated infections; HCAs), tetanus, puncture wounds and bites, and other infections not discussed elsewhere are then summarized.

OROFACIAL AND ODONTOGENIC BACTERIAL INFECTIONS

PERIODONTAL INFECTIONS

Abscesses

A gingival abscess may arise from infection or a foreign body. A lateral periodontal abscess (parodontal abscess) is seen almost exclusively in patients with chronic periodontitis but may follow impaction of a foreign body or, rarely, can be related to a lateral root canal on a non-vital tooth.

Clinical features

Erythema and swelling are the main features. Lateral periodontal abscesses may be painful and eventually may discharge – either through the pocket or buccally, but more coronally than a periapical abscess.

General management

Drainage is needed, and sometimes antibiotics (Table 21.2).

Acute necrotizing ulcerative gingivitis

Acute necrotizing ulcerative gingivitis (ANUG) is a non-contagious anaerobic infection associated with proliferation of *Borrelia vincentii* and fusiform bacteria. It is typically an infection of young adults, found especially in institutions, the armed forces, etc., and predisposing factors include poor oral hygiene, smoking, viral respiratory infections and immune defects such as in HIV/AIDS.

Clinical features

Characteristic features of ANUG include profuse gingival bleeding, severe soreness from gingival ulceration, halitosis and a bad taste. Malaise, fever and cervical lymph node enlargement are rare.

General management

Diagnosis is usually clinical. Smears show fusospirochaetal bacteria and leukocytes. Occasionally, ANUG may be confused with acute leukaemia or herpetic stomatitis, and a full blood picture may be needed. HIV infection may need to be considered.

Management is by oral debridement, metronidazole (penicillin, if pregnant) and improved oral hygiene.

Noma (cancrum oris; gangrenous stomatitis)

Noma can result from ANUG in malnourished, debilitated or immunocompromised patients, especially in children in developing areas. Anaerobes have been implicated, particularly *Bacteroides* (*Porphyromonas*) species, *Fusobacterium necrophorum* (an animal pathogen), *Prevotella intermedia*, *Actinomyces* and alpha-haemolytic streptococci. In cases following ANUG, *Streptococcus anginosus* and *Abiotrophia* species are the predominant organisms. In early noma, predominant species include *Ochrobactrum anthropi*, *Stenotrophomonas maltophilia*, an uncharacterized species of *Dialister* and an uncultivated phylotype of *Leptotrichia*. A range of species or phylotypes

is found in advanced noma, including *Propionibacterium acnes*, *Staphylococcus* species, *Stenotrophomonas maltophilia*, *Ochrobactrum anthropi*, *Achromobacter* species, *Afiopia* species, *Brevundimonas diminuta*, *Capnocytophaga* species, *Cardiobacterium* species, *Eikenella corrodens*, *Fusobacterium* species, *Gemella haemolysans* and *Neisseria* species. Phylotypes unique to noma infections include those in the genera *Eubacterium*, *Flavobacterium*, *Kocuria*, *Microbacterium* and *Porphyromonas*, and the related *Streptococcus salivarius* and genera *Sphingomonas* and *Treponema*. Spreading necrosis penetrates the buccal mucosa, leading to gangrene, an orocutaneous fistula and scarring.

Diagnosis is clinical; an immune defect should always be excluded. Management includes improving nutrition, systemic antibiotics (clindamycin, penicillin, tetracyclines or metronidazole) and plastic surgery.

Pericoronitis

Acute pericoronitis is inflammation of the operculum over an erupting or impacted tooth, usually a mandibular third molar. It appears in relation to the accumulation of plaque and trauma from the opposing tooth. A mixed flora with *Fusobacterium* and *Bacteroides* is recognized to be important. Immune defects may predispose.

Clinical features

Acute pericoronitis manifests with pain, trismus, swelling and halitosis. The operculum is swollen, red and often ulcerated, and there may be fever and regional lymphadenitis. Pus usually drains from beneath the operculum but, in a migratory abscess of the buccal sulcus, may track anteriorly.

General management

Diagnosis is from clinical features. Radiology is usually indicated to confirm the position and root formation of the underlying partially erupted tooth.

Initial management comprises local debridement and application of antiseptics such as chlorhexidine. Reduction of the occlusal surface (or extraction) of an opposing tooth may be helpful if there is local trauma. Pyrexia, trismus or cervical lymphadenopathy may be indications for use of systemic antibiotics, typically metronidazole. Long-term treatment may include extraction of the associated impacted tooth, particularly when this is a lower third molar.

Dental abscess (periapical abscess, odontogenic abscess)

General aspects

A dental abscess is often a sequel of pulpitis caused by dental caries, but may arise in relation to any non-vital tooth. A mixed bacterial flora, especially anaerobes such as *Fusobacterium* and *Bacteroides* (*Porphyromonas*), is implicated.

Clinical features

The causal tooth is non-vital but tender to palpation. Most dental abscesses produce an intraoral swelling, typically on the labial or buccal gingival; those on maxillary lateral incisors and those from palatal roots of the first molar tend to present palatally. Occasionally, abscesses track or discharge elsewhere; for example, lower incisors or molars may discharge extraorally, and maxillary premolars and molars may discharge into the maxillary sinus (Fig. 21.1). Pain and

Table 21.2 Antimicrobials for odontogenic and antral infections^a

Condition	In non-allergic individuals, antimicrobial for >3 days or until symptoms resolve	Comments
Acute necrotizing gingivitis	Metronidazole or amoxicillin	Only if systemic involvement
Bites	Co-amoxiclav	Ch. 24
Cellulitis	Benzyl penicillin plus flucloxacillin	–
Periapical abscess	Amoxicillin or metronidazole for 5 days	Only if systemic involvement or cellulitis
Pericoronitis	Metronidazole or amoxicillin	Only if systemic involvement or trismus
Periodontal abscess	Amoxicillin or metronidazole for 5 days	Only if systemic involvement or cellulitis
Periodontitis	Metronidazole or doxycycline	Only for severe disease
Sinusitis	Amoxicillin or doxycycline or erythromycin for 7 days	Only for symptoms >7 days

^aAfter British National Formulary 2009.

facial swelling are characteristic but, once the abscess discharges, the acute inflammation, pain and swelling resolve and a chronic abscess develops discharging from a sinus – usually buccally and intraorally. Acute periapical suppuration may track through the cortical plate and may be limited by fascial planes within anatomical spaces or spread beyond them, as in the case of Ludwig’s angina. Spread may also be lymphatics to regional lymph nodes, or haematogenously leading to thrombophlebitis, bacteraemia or even septicaemia.

General management

Diagnosis is from clinical features plus imaging. Extraction or endodontic therapy of the affected tooth removes the source of infection. Analgesics may be indicated. Antimicrobials are required only in the circumstances outlined below.

ODONTOGENIC INFECTIONS

Odontogenic infections are mainly a consequence of pulpitis that leads initially to periapical infection and a dental abscess. Most odontogenic (and many orofacial) infections arise from the commensal oral mixed flora, with a substantial proportion of anaerobes. Most odontogenic and orofacial infections respond to drainage, by either endodontic treatment, incision or tooth extraction. A drain usually needs to stay in place for 24–48 hours until most/all of the pus has discharged. Analgesics also may be required. Antimicrobials may be indicated in a number of circumstances (Table 21.3).

Fig. 21.1 Odontogenic infection.

Table 21.3 Indications for antimicrobial therapy

Patient status	Infections
Any patient with:	Fascial space infections in the neck Necrotizing fasciitis Osteomyelitis; removal of affected tissue is mandatory
Ill or immunocompromised persons with:	Serious or life-threatening infections Acute sinusitis Acute ulcerative gingivitis Dental abscess Dry socket Oral surgery Pericoronitis

Most odontogenic infections respond well to penicillin or metronidazole, but increasing rates of resistance due to production of beta-lactamase (an enzyme that degrades penicillins) have lowered the usefulness of many penicillins. Amoxycillin (± metronidazole) is a common first choice: second choices include cefuroxime, erythromycin, or clindamycin. Co-amoxiclav plus clindamycin are increasingly used first-line because of their broad spectrum of activity and resistance to beta-lactamase.

Anaerobic infections

Most head and neck infections are endogenous and mixed, with anaerobes, two-thirds containing more than one anaerobic species. Predominant anaerobes include *Prevotella*, *Fusobacterium* species, *Actinomyces* species (about 50% are *Actinomyces odontolyticus*), anaerobic cocci and *Eubacterium* species. *Prevotella intermedia*, *Fusobacterium nucleatum*, *Prevotella melaninogenica* and the *Bacteroides fragilis* group are the most common Gram-negative anaerobic species. Microaerophilic streptococci are often associated with anaerobes. Gram-positive anaerobic cocci (GPAC) are detected in about 15% of specimens – *Finegoldia magna* accounting for about one-third. Among aerobic/facultative isolates are Gram-positive cocci, Gram-negative bacteria and *Candida* species.

Treatment involves surgical procedures and antibacterial agents, which should cover both aerobes and anaerobes. Resistance rates to some agents (such as ampicillin/sulbactam and clindamycin) have increased.

Group A streptococcus (GAS) infections

People may carry group A streptococci in the throat or on the skin without symptoms of illness. Streptococcal oral or head and neck infections are shown in Table 21.4 (see also Fig. 21.2). Most streptococci are highly susceptible to penicillin. Some pneumococci (mostly imported) are increasingly resistant. Few people who come in contact with GAS will develop invasive GAS disease, but people with chronic illnesses like cancer, diabetes and chronic heart or lung disease, and those on

Table 21.4 Streptococcal infections in the head and neck

Bacteria	Found in/on	May cause
<i>Streptococcus viridans</i>	Normal oral flora	Caries and, rarely, infective endocarditis
<i>Strep. pyogenes</i>	Skin and pharynx	Cellulitis, impetigo (Fig. 21.2), necrotizing fasciitis, pharyngitis, scarlet fever or erysipelas, rheumatic fever and carditis
<i>Strep. pneumoniae</i> (pneumococci)	Upper respiratory tract	Acute glomerulonephritis, meningitis, sinusitis, otitis media, bronchitis and pneumonia

Fig. 21.2 Impetigo can mimic herpes simplex infections.

immunosuppressive medications such as steroids, have a higher risk. Persons with skin lesions (such as cuts, chickenpox or surgical wounds), the elderly, and adults with a history of alcohol abuse or injection drug use also have a higher risk for disease. Infection with GAS can result in a range of symptoms ranging from mild illness (streptococcal throat or a skin infection such as impetigo) to severe disease (necrotizing fasciitis, streptococcal toxic shock syndrome [STSS]). About 25% of those with necrotizing fasciitis and more than 35% with STSS die (see below).

Staphylococcal infections

Staphylococcal oral or head and neck infections may be caused by *Staphylococcus aureus*; most are minor (such as furuncles and boils) and most can be treated without antibiotics, but *S. aureus* can also cause serious infections such as surgical wound infections, sinusitis, tonsillitis, otitis externa or media, tracheitis, cellulitis, necrotizing fasciitis and toxic shock syndrome (caused by a staphylococcal-produced toxin that has resulted from nasal packing, and by tampon use). Infection is characterized by fever, hypotension, flushing of the skin followed by desquamation, shock and sometimes death.

Up to 80% of the *S. aureus* isolates in the West are resistant to penicillin, primarily due to production of beta-lactamase, but these will usually respond to lactamase-stable antibiotics such as flucloxacillin and meticillin. Meticillin-resistant *S. aureus* (MRSA) is resistant to these, however, and often to other antibiotics. Culture is essential to guide treatment of MRSA infections.

SERIOUS SEQUELAE OF ODONTOGENIC OR OROFACIAL INFECTIONS

Fatal dental or orofacial infections are rare unless there is an immune defect, but may include progression to mediastinitis, infective endocarditis, necrotizing fasciitis, brain abscess and disseminated intravascular coagulation. Patients with advanced infections need urgent admission for intravenous antibiotics and urgent surgery to remove the cause as well as for incision and drainage of tissue spaces involved. ICU may be needed until the airway is assured. Fiberoptic endotracheal intubation or occasionally emergency surgery (cricothyrotomy or tracheostomy) may be indicated.

Cellulitis

Cellulitis is usually an acute streptococcal or staphylococcal skin infection. It normally resolves on treatment with benzyl penicillin plus flucloxacillin or, if the patient is penicillin-allergic, clarithromycin, erythromycin, clindamycin or vancomycin/teicoplanin. Cellulitis can spread locally or systemically.

Buccal cellulitis is usually caused by *Haemophilus influenzae* type B, spread by bacteraemia, by lymphatics from, for example, otitis media, or more probably from direct invasion through the oral mucosa. It is an uncommon but distinctive infection, characterized by swelling, tenderness, induration and warmth of the cheek soft tissues in the absence of an adjacent oral or skin lesion; it almost invariably affects children under the age of 5 years. A minority develop meningitis. Blood and cerebrospinal fluid cultures should be taken and treatment with intravenous cefuroxime started.

Lymphangitis

Lymphangitis (inflammation of the lymphatics with pain and systemic symptoms) is commonly secondary to an acute streptococcal or staphylococcal cellulitis, or to an abscess in the skin or soft tissues. Lymphangitis may be confused with thrombophlebitis and suggests

that an infection is progressing, and may lead to bacteraemia, septicaemia and life-threatening infection.

Fascial space infections

Fascial space infections of the neck are dangerous, since they can embarrass the airway, erode the carotid vessels, cause toxicity, or spread to the mediastinum or intracranially. They usually arise from the oral flora and are polymicrobial, involving predominantly anaerobes, including Gram-positive cocci and bacilli, as well as Gram-negative bacilli.

Patients with fascial space infections must be admitted for hospital care, which may involve drainage and usually high-dose antibiotics.

Necrotizing fasciitis (Fournier gangrene, Meleney ulcer, postoperative progressive bacterial synergistic gangrene, flesh-eating bacteria, Cullen ulcer)

More information about necrotizing fasciitis is available at: <http://www.nnff.org/> (accessed 30 September 2013).

General aspects

Necrotizing fasciitis is a dangerous, rapidly progressive, and spreading infection in the deep fascia, with secondary necrosis of subcutaneous tissues, which destroys muscles, fat and skin. The speed of spread along the deep fascial plane is directly proportional to the thickness of the subcutaneous layer. Most patients are middle-aged or older but, though the condition has become more frequent because of an increase in immunocompromised patients with diabetes, cancer, alcoholism, vascular insufficiencies, transplants, neutropenia or HIV, few have such detectable underlying predisposing factors.

Group A haemolytic streptococci and *S. aureus*, alone or in synergism, are often the initiating causal bacteria, but other aerobic and anaerobic pathogens, such as *Bacteroides* (*Porphyromonas*), *Clostridium*, *Peptostreptococcus*, Enterobacteriaceae, coliforms, *Proteus*, *Prevotella*, *Pseudomonas*, *Klebsiella*, *Bacteroides fragilis*, *Fusobacterium necrophorum* and *Escherichia coli* may be present.

Some men who have sex with men (MSM) have suffered outbreaks of necrotizing fasciitis caused by community-associated MRSA – distinct from health-care-associated strains. Anaerobic streptococci, occasionally seen in drug users, cause many forms of non-clostridial myonecrosis. Necrotizing fasciitis can also be caused by *Vibrio vulnificus*, often following the consumption of raw seafood – especially in patients with chronic liver disease. There may also be a relationship between the use of non-steroidal anti-inflammatory drugs (NSAIDs) and the development of necrotizing fasciitis during varicella infections.

Clinical features

There is often a history of trauma or recent surgery to the area. Features of necrotizing fasciitis include the following:

- **Early** (usually within 24 hours):
Usually a minor trauma or other skin opening (the wound does not necessarily appear infected)
Pain in the general area of the injury, not necessarily at the site of the injury but in the same region or limb of the body; it is usually disproportionate to the injury and may start as something akin to a muscle pull, but becomes more and more painful
‘Flu-like’ symptoms, such as diarrhoea, nausea, fever, confusion, dizziness, weakness and malaise

Intense thirst

- **Advanced** (usually within 3–4 days):
Swelling of the limb or area of body experiencing pain, possibly accompanied by a purplish rash
Large, dark marks on the limb, which will become blisters filled with blackish fluid
Necrotic appearance of the wound, with a bluish, white or dark, mottled, flaky surface
- **Critical** (usually within 4–5 days):
Severe drop in blood pressure
Signs that the body is entering toxic shock
Unconsciousness.

The lesion begins with an area of thrombosis and skin necrosis, which is initially red, painful and oedematous. Erythema quickly spreads over hours to days, and rapidly turns purplish, dusky and then black, with gas and exudate, and pain disproportionate to the clinical appearance. The margins of the infection move into surrounding skin without being raised or sharply demarcated. Over the next several hours to days, despite severe pain, there may be cutaneous anaesthesia – an unusual combination, as the cutaneous nerves are damaged by the infection (hence anaesthesia) but the proximal stump is irritated (hence the pain). Multiple patches develop to produce a large area of gangrenous skin.

Early on, the patient may look deceptively well but, within 24–48 hours, fever appears with rapidly spreading tissue necrosis, so that the patient usually appears moderately to severely toxic.

General management

Necrotizing fasciitis is uncommon but potentially fatal; if from a dental source, it can also spread and may threaten the airway. The mortality can sometimes reach 30%.

The gas-forming organisms may release subcutaneous gas that may be seen on radiography. Absence of gadolinium contrast enhancement in magnetic resonance imaging (MRI) T1 images reliably detects fascial necrosis. Thoracic computed tomography (CT) may be required to detect mediastinal spread.

Necrotizing fasciitis requires early aggressive treatment. The patient should be admitted to hospital and intubated; the affected area is opened to drain, and necrotic tissue excised. High doses of penicillin or clindamycin are given, plus metronidazole or a cephalosporin, or gentamicin, combined with clindamycin or chloramphenicol. Hyperbaric oxygen, if available, should be given.

Streptococcal toxic shock syndrome (STSS) results in acute hypotension and organ (e.g. kidney, liver, lungs) failure. STSS is not the 'toxic shock syndrome', which is due to *S. aureus* associated with tampon usage.

Recommended therapy for necrotizing fasciitis and STSS is early aggressive surgery plus high-dose antimicrobials (penicillin plus clindamycin). Supportive care in an intensive care unit may also be needed.

Lemierre syndrome (post-anginal septicaemia)

Lemierre syndrome is a rare, potentially fatal, acute anaerobic oropharyngeal infection, the classical presentation of human necrobacillosis. The main pathogen is *Fusobacterium necrophorum*, an obligate anaerobic, pleomorphic, Gram-negative rod.

The primary infection is in the head in a young, previously healthy person, who subsequently develops persistent high fever and disseminated metastatic abscesses, frequently including septic thrombophlebitis of the internal jugular vein. Lemierre syndrome is often complicated by septic pulmonary emboli and distant metastatic infections.

Surgical drainage and intravenous antibiotics are indicated. *F. necrophorum* is typically susceptible to penicillin, cephalosporins, metronidazole,

clindamycin, tetracyclines and chloramphenicol. Some beta-lactamase-producing strains of *F. necrophorum* have been reported.

Septicaemia

Septicaemia can arise from odontogenic or orofacial infections, but more commonly from infections of the urinary tract, gallbladder or chest. Immunosuppressed patients are particularly susceptible and oral bacteria are sometimes responsible.

Blood, urine and sputum should be cultured and the patient started on ceftriaxone (a once-daily dose), or cefuroxime plus metronidazole if anaerobic sepsis is suspected.

Actinomycosis (lumpy jaw)

Actinomycosis is a rare chronic infection, usually of the face and neck. It is caused by *Actinomyces israelii*, a Gram-positive, non-contagious anaerobic bacillus with filamentous growth and mycelia-like colonies bearing a striking resemblance to fungi; it is primarily a commensal found in normal oral cavities, tonsillar crypts, dental plaque and carious teeth. There are three main presentations.

Cervicofacial actinomycosis is the most common and typically causes a red or purplish, somewhat indurated, subcutaneous mass of abscesses and open draining sinuses, usually in the submandibular area near the angle of the mandible, arising a few weeks after an antecedent local lesion (dental or periodontal infection or tooth extraction). Tenderness is slight or absent. Microscopic examination of drained fluid shows 'sulphur granules' and *Actinomyces*, and culture of the fluid or tissue shows *Actinomyces* species.

Pulmonary actinomycosis causes fever and general malaise, cough and purulent sputum. Cutaneous sinuses may form.

Abdominal actinomycosis may cause pain and a palpable mass in the abdomen.

Treatment of actinomycosis is at least 1–2 months of penicillin or tetracycline. Surgical drainage may be indicated.

Osteomyelitis

See Chapter 16.

ANTIMICROBIAL PROPHYLAXIS

Antimicrobial cover may be required for bites; for contact with certain infections (e.g. open tuberculosis, meningitis, *Haemophilus influenzae* B infections or group A streptococci); and for oral-health-care invasive procedures in people with sickle cell anaemia or asplenia (usually phenoxymethyl penicillin or erythromycin – plus relevant vaccinations). It is sometimes suggested for various procedures or in various other conditions, but otherwise is infrequently indicated (Box 21.3).

Box 21.3 Conditions in which antibiotic prophylaxis for oral health care is not usually considered essential

- Augmentation procedures (e.g. lips, breasts)
- Cardiac surgery
- Immunocompromising states unless severe
- Indwelling intraperitoneal catheters
- Intraocular lenses
- Pacemakers and other cardiac devices
- Penile prostheses
- Prosthetic joint implants
- Ventrículo-peritoneal shunts

HEALTH-CARE-ASSOCIATED (NOSOCOMIAL) INFECTIONS (HCAIs)

HCAIs are an increasing problem across the world (Box 21.4). Box 21.5 shows precautions against them. A number of microorganisms can be involved in HCAIs, usually bacteria, and many are antimicrobial-resistant ('super-bugs'). HCAIs may affect wounds (surgical site infections), the skin, the respiratory tract, the gastrointestinal tract, the urinary tract, catheters, ventilators or any implanted device. Central line-associated bloodstream infections, catheter-associated urinary tract infections and ventilator-associated pneumonia account for about two-thirds of all HCAIs that are not in surgical sites.

WOUND INFECTIONS (SURGICAL SITE INFECTIONS)

General aspects

Infections (surgical wound infections; surgical site infections, SSIs) can be a problem in terms of morbidity and mortality. Postoperative bacterial infection rates vary from 3% to 21%, with SSIs accounting for up to 34% of the total (probably underestimated since most wound infections start after the patient is discharged). SSIs have significant morbidity and mortality, accounting for approximately 77% of deaths of general surgical patients.

Surgical wounds have been classified as clean, clean-contaminated, contaminated and dirty-infected (Table 21.5). Most head and neck surgery involves class I or II wounds.

Most SSIs arise from the patient's own flora, from health-care workers and articles brought into the operative field, and from the operating room air. The usual pathogens on skin surfaces are Gram-positive aerobic cocci (mainly staphylococci), but anaerobes and Gram-negative aerobes may be involved. The normal oral flora is 90% anaerobes and 10% Gram-positive aerobic cocci. Gram-negative aerobes may be a problem in patients who have been hospitalized or treated with radiotherapy. Factors promoting wound infection include preoperative removal of hair, especially when there is skin abrasion, inadequate skin preparation with bactericidal solution, poor surgical technique, lengthy operation (over 2 hours), intraoperative contamination, prolonged stay in hospital,

Box 21.4 Main health-care-acquired infections (HCAIs)

- *Acinetobacter*
- *Burkholderia cepacia*
- *Clostridium difficile*
- *Clostridium sordellii*
- Enterobacteriaceae (carbapenem-resistant)
- *Escherichia coli*
- Glycopeptide-resistant enterococci (GRE)
- Hepatitis
- Human immunodeficiency virus (HIV)
- Influenza
- *Klebsiella*
- Meticillin-resistant *Staphylococcus aureus* (MRSA)
- *Mycobacterium abscessus*
- Norovirus
- Pencillin-resistant *Streptococcus pneumoniae* (PRSP)
- *Staphylococcus aureus*
- Tuberculosis
- Vancomycin-intermediate *Staphylococcus aureus* and vancomycin-resistant *Staphylococcus aureus*
- Vancomycin-resistant enterococci (VRE)

Box 21.5 Prevention of health-care-associated infection transmission

- Follow good hygiene and standard infection control procedures
- Avoid contact with wounds or material contaminated from wounds
- Use alcohol-based waterless antiseptic agents for routinely decontaminating hands, when hands are not visibly soiled
- Wash hands thoroughly with a non-antimicrobial soap and water, or an antimicrobial soap and water, when hands are visibly dirty or contaminated with proteinaceous material such as blood
- Keep cuts and abrasions clean and covered with a proper dressing until healed, when hands are cut or abraded
- Use a moisturizer to prevent skin cracking

Table 21.5 Surgical wound classification and subsequent risk of infection (no antibiotics used)

Classification	Oral or perioral example	Description	Infective risk (%)
Clean (Class I)	Excision of a facial skin lesion	Uninfected operative wound No acute inflammation Closed primarily Respiratory, gastrointestinal, biliary and urinary tracts not entered No break in aseptic technique Closed drainage used if necessary	<2
Clean-contaminated (Class II)	Parotid surgery	Elective entry into respiratory, biliary, gastrointestinal or urinary tracts and with minimal spillage No evidence of infection or major break in aseptic technique	<10
Contaminated (Class III)	Third molar surgical removal	Non-purulent inflammation present Spillage from gastrointestinal tract Penetrating traumatic wounds <4h Major break in aseptic technique	About 20
Dirty-infected (Class IV)	Incision and drainage of a submandibular abscess	Purulent inflammation present Preoperative perforation of viscera Penetrating traumatic wounds >4h	About 40

hypothermia, trauma, non-viable tissue in the wound, haematoma, foreign material (including drains and sutures), dead space, pre-existing sepsis (local or distant), immunocompromised or malnourished host, hypovolaemia, poor tissue perfusion or obesity, and delayed prophylaxis with, or incorrect choice of, antibiotics.

Prophylaxis

Prophylactic antibiotics are indicated for clean-contaminated and contaminated trauma, for clean procedures in which prosthetic devices are inserted and, more controversially, for clean procedures such as orthognathic surgery.

The concentration of prophylactic antibiotic should be at therapeutic levels by the time of incision, during the surgical procedure and for a few hours postoperatively, and this is achieved by intravenous administration of the antibiotic 30 minutes before incision (but not more than 2 hours before surgery). For head and neck surgery, *S. aureus*, streptococci, anaerobes and streptococci can be present in an oropharyngeal approach; examples of antibiotics shown to be effective in class II head and neck wound prophylaxis include cefazolin 1–2 g alone or in combination with metronidazole, or clindamycin alone or with gentamicin or amikacin, amoxicillin/clavulanate, ampicillin/sulbactam and ticarcillin/clavulanate.

Clinical features

SSI is suggested by features such as pus draining from the wound, the wound becoming excessively tender, progressive swelling starting about 48 hours after surgery, increasing redness around the wound (cellulitis), a red streak from the wound toward the heart (lymphangitis), lymphadenitis or fever. The wound may fail to heal within 10 days after the injury, the scab increases in size, and a pimple or yellow crust may form on the wound (impetigo).

General management

Treatment of SSI often involves antibiotics after opening the wound, evacuating pus and cleansing the wound – inspecting deeper tissues for integrity and for deep space infection or source. Dressing changes allow the tissues to granulate, and the wound heals by secondary intention over several weeks.

The antibiotic choice depends on the known or probable infecting microorganism, and factors such as severity of SSI, patient's age, hepatic and renal function, allergies and other medication(s). First choices are flucloxacillin in the absence of allergy if staphylococci or streptococci are implicated; metronidazole or clindamycin for anaerobic infections; cefuroxime for Gram-negative organisms; and amoxicillin or co-amoxiclav for enterococcal infection. For pain relief, paracetamol (acetaminophen), ibuprofen or an opioid is indicated.

CENTRAL LINE-ASSOCIATED BLOODSTREAM INFECTION (CLABSI)

CLABSI is a serious infection that may present with fever, skin erythema and soreness around the central line entry point. CLABSIs must be prevented in the following manner:

- Follow recommended central line insertion practices:
 - Hand hygiene
 - Skin antiseptic
 - Barrier precautions: sterile gloves, sterile gown, cap, mask, sterile drape.

- Once the central line is in place, wash hands with soap and water or an alcohol-based handrub before and after touching the line.
- Remove a central line as soon as it is no longer needed.

More than 50% of all *S. aureus* CLABSI isolates are MRSA but the incidence is decreasing. In contrast, *Klebsiella pneumoniae* and *E. coli* resistance to third-generation cephalosporins has increased significantly, as has imipenem and ceftazidime resistance in *Pseudomonas aeruginosa*, and *Candida* spp. are increasingly fluconazole-resistant.

Guidelines for the prevention of intravascular catheter-related infections are available at: <http://www.cdc.gov/hicpac/BSI/BSI-guidelines-2011.html> (accessed 30 September 2013).

ANTIBIOTIC-RESISTANT INFECTIONS

The main antibiotic-resistant infections are meticillin-resistant *S. aureus* (MRSA) and clindamycin-resistant *Clostridium difficile*, but there are several others; many of these arise as HCAs and the most important are discussed here, alphabetically. Six of these bacteria have been dubbed ESKAPE (*Enterococcus faecium*, *S. aureus*; *Klebsiella* species, *Acinetobacter baumannii*, *Pseudomonas aeruginosa* and *Enterobacter* species). Some of these infections are with multidrug-resistant organisms (MDROs); see http://www.cdc.gov/hicpac/mdro/mdro_toc.html (accessed 30 September 2013).

ACINETOBACTER

Acinetobacter are commonly found in soil and water. *Acinetobacter* infections in the community are rare and most strains are sensitive to antibiotics. Infections are usually HCAs and are typically found in intensive care units, in very ill patients and with resistant organisms. *A. baumannii* accounts for about 80% of reported infections and these include pneumonia, bacteraemia (bloodstream infection), wound infections and urinary tract infections. They are often resistant to antibiotics and are increasingly difficult to treat. *A. baumannii* wound infections have been found in US military personnel deployed to Iraq and Afghanistan. Of the beta-lactamase inhibitors, sulbactam possesses the greatest intrinsic bactericidal activity against *A. baumannii*. Carbapenems (imipenem, meropenem or doripenem) are the most important other options for serious infections caused by multidrug-resistant *A. baumannii*. Amikacin and tobramycin are aminoglycosides that appear to retain activity against *A. baumannii*. Other possibilities include polymyxin E, polymyxin B, colistin, minocycline and doxycycline. Tigecycline may be used, as may extended-infusion β -lactams, cefepime and piperacillin–tazobactam.

BURKHOLDERIA CEPACIA

Burkholderia cepacia is a group of bacteria found in soil and water; they are often resistant to common antibiotics but pose little risk to healthy people. However, *B. cepacia* can cause infections in people with immune defects or chronic lung disease (particularly cystic fibrosis/bronchiectasis). Treatment typically involves multiple antibiotics and may include ceftazidime, doxycycline, piperacillin, meropenem, chloramphenicol or co-trimoxazole.

CLOSTRIDIUM DIFFICILE

Clostridium difficile (also called *C. diff*) is the major organism linked with antibiotic-associated diarrhoea and colitis, usually caused by expanded-spectrum and broad-spectrum cephalosporins and clindamycin, though the role of fluoroquinolones is less clear. An HCAI that

mostly affects older patients with other underlying disorders in hospital environments, the disease usually develops after cross-infection from another patient, either through direct contact, or via health-care staff or via a contaminated environment. Community-acquired *C. difficile* infection (CDI) has also emerged.

Diagnosis is from the presence of *C. difficile* toxins in a faecal sample. The emergence and epidemic spread of a novel strain, known as PCR ribotype 027 (BI/NAP1/027), resistant to clindamycin, is an issue. Type 027 produces many more of the toxins than most other types.

Prevention and control of *C. difficile* is by reduction of the use of broad-spectrum antibiotics, isolation of patients with *C. difficile* diarrhoea, good infection control nursing (alcohol gel does not destroy the spores), and enhanced environmental cleaning using a chlorine-containing disinfectant. Metronidazole and vancomycin are the treatments of choice but some strains are now resistant. More information on epidemiology can be found by searching on *C. difficile* at <http://cmr.asm.org> (accessed September 2013).

CLOSTRIDIUM SORDELLII

Clostridium sordellii is a rare bacterial cause of pneumonia, endocarditis, arthritis, peritonitis and myonecrosis. *Cl. sordellii* bacteraemia and sepsis are usually seen in people with other health conditions – mostly after trauma, childbirth and gynaecological procedures – but they have recently been associated with medically induced abortions and injection drug use. Mortality is very high; *Cl. sordellii* is typically susceptible to beta-lactams, clindamycin, tetracycline and chloramphenicol but resistant to aminoglycosides and sulphonamides. Further details may be found at: <http://www.cdc.gov/hai/organisms/csordellii.html> (accessed September 2013).

EXTENDED-SPECTRUM BETA-LACTAMASE (ESBL) PRODUCERS

Gram-negative enteric bacilli (Enterobacteriaceae) are producers of enzymes that destroy beta-lactam antibiotics and mediate resistance to extended-spectrum (third-generation) cephalosporins (e.g. ceftazidime, cefotaxime and ceftriaxone) and oxyimino-monobactams (e.g. aztreonam) but do not affect cephamycins (e.g. cefoxitin and cefotetan) or carbapenems (e.g. meropenem or imipenem). ESBL enzymes are most commonly produced by *E. coli* and *K. pneumoniae*, but other bacteria that may do so include *Enterobacter cloacae*, *Citrobacter freundii*, *Serratia marcescens*, *Pseudomonas aeruginosa*, *Salmonella* species and *Proteus mirabilis*. *K. pneumoniae* most commonly produce *K. pneumoniae* carbapenemase (KPC). Resistance of *Enterobacter* species to third-generation cephalosporins is most typically caused by overproduction of AmpC beta-lactamases. Some *E. cloacae* strains are now ESBL- and AmpC-producers, conferring resistance to both third- and fourth-generation cephalosporins.

Quinolone resistance in Enterobacteriaceae is usually the result of chromosomal mutations leading to alterations in target enzymes or drug accumulation. More recently, however, plasmid-mediated quinolone resistance has been reported in *K. pneumoniae* and *E. coli*, associated with acquisition of the *qnr* gene. The vast majority of Enterobacteriaceae, including ESBL-producers, remain susceptible to carbapenems, which are considered the preferred empirical therapy for serious infections.

ESBL infection may stem from infected chicken meat and outbreaks have originated in hospitals and nursing homes, and increasingly in the community, typically with urinary tract infections and bacteraemia. Persistent oral carriage may be seen in immunocompromised persons, in

advanced age and in dry mouth. Until recently, the numbers of patients affected remained small and the problem showed little sign of growing. However, a new class of ESBL (CTX-M enzymes) has emerged and has been widely detected among hospital *E. coli* but also found in the community. These ESBL-*E. coli* are found most often in urinary tract infections and are resistant to penicillins and cephalosporins. Carbapenems, such as meropenem, are usually the effective treatment for ESBL. However, carbapenem-resistant Enterobacteriaceae (CRE; glycopeptide-resistant enterococci [GRE]) may arise in *Klebsiella* species and *E. coli*. CRE infections are most common in patients receiving treatment involving devices such as catheters or ventilators, and those who are on long antibiotic courses. New Delhi metallo-beta-lactamase (NDM-1), an enzyme that inactivates carbapenems, is most widespread in *Klebsiella* in the Indian subcontinent but has spread to the UK and elsewhere, often via patients previously treated in the subcontinent. Verona integron-encoded metallo-beta-lactamase (VIM) and imipenemase (IMP) metallo-beta-lactamases may also be seen.

CRE have been associated with high mortality rates (up to 40–50% in some studies). In addition to beta-lactam/carbapenem resistance, CRE often have high levels of resistance to many other antimicrobials. More information is available at: <http://www.cdc.gov/hai/organisms/cre/index.html> (accessed September 2013).

Most bacteria with NDM-1 remain susceptible to colistin and tigecycline. ‘Pan-resistant’ KPC-producing strains have been reported.

METICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS (MRSA)

Meticillin-resistant *Staphylococcus aureus* (MRSA) is resistant to beta-lactam antibiotics (meticcillin and other more common antibiotics, such as oxacillin, flucloxacillin, penicillin and amoxicillin). Most severe or potentially life-threatening MRSA infections occur among patients in health-care settings. The most common clones are E(pidemic)-MRSA 15 and E-MRSA16. Strains of *S. aureus* producing Panton–Valentine leukocidin (PVL) are especially virulent. About 1 in 3 people carry *S. aureus* on the skin surface or in the nose; if this enters the body through a break in the skin, it can cause infections such as abscesses or impetigo. MRSA is no more infectious than other types of *S. aureus* but infections are more difficult to treat, owing to their antibiotic resistance, and mortality is increased. The infection may simply require a much higher dose over a much longer period, or the use of an agent to which MRSA is not resistant.

MRSA is usually spread through person-to-person contact with someone who has an MRSA infection or who is colonized. It can also spread through contact with towels, sheets, clothes, dressings or other objects that have been used by someone with MRSA. *S. aureus* can also survive on objects or surfaces such as door handles, sinks, floors and cleaning equipment. MRSA infections are far more common in people who are in hospital; risk factors are shown in Box 21.6.

Box 21.6 Risk factors for MRSA infection

- Immune incompetence (e.g. elderly, newborn babies, patients with diabetes, cancer or HIV/AIDS)
- Open wound, catheter or intravenous tube
- Severe skin condition (e.g. burn or cut, ulcer or psoriasis)
- Recent surgery
- Frequent courses of antibiotics
- Prolonged hospital stay
- Asymptomatic MRSA nasal carriage

Community-associated MRSA infections typically involve the skin, and are usually transmitted from people with active MRSA skin infections. The strains causing these infections, designated community-associated MRSA (CA-MRSA), are distinct from health-care-associated strains (HA-MRSA). Infection with multidrug-resistant USA300 MRSA has emerged among MSM. Infection most often involves the buttocks, genitals or perineum. The risk is independent of HIV infection but the infection might be sexually transmitted in this population.

Community-associated MRSA spreads especially to:

- intravenous drug users
- children in day care
- athletes
- military personnel
- prison inmates.

Clinical features

Symptoms depend on the type of infection. Most *S. aureus* infections involve the skin, and include boils, abscesses, styes, carbuncles, cellulitis and impetigo, but infections are also able to enter the bloodstream (bacteraemia); these can cause septicaemia, septic shock, septic arthritis, osteomyelitis, abscesses, meningitis, pneumonia and endocarditis, and can be fatal. *S. aureus* can also cause scalded skin syndrome and, very occasionally, toxic shock syndrome.

General management

Many hospitals now test all people being admitted to see if they are colonized; swabs from the skin and nose, and urine and blood samples may be tested. It can take 3–5 days for the results to become available. People colonized with MRSA may still be admitted to hospital but treated to reduce or remove it by using antibiotic cream applied to the skin or the inside of the nose, and washing skin and hair with antiseptic shampoo and lotion. Health-care workers should use fast-acting, special alcohol rubs or gels, and wear disposable gloves when there will be physical contact with open wounds: for example, when changing dressings, handling needles or inserting intravenous lines.

MRSA infections are diagnosed by testing blood, urine or a tissue sample for the presence of the organism. Patients who are only colonized with MRSA usually do not need treatment. Infections often require hospital treatment in isolation for several weeks. Frank MRSA infections can sometimes be treated without antibiotics by draining and, in reality, most are resistant to multiple antibiotics as well as to meticillin.

Agents used to treat MRSA infections include vancomycin, or quinupristin combined with dalbavipristin or linezolid, but resistance has been reported. Linezolid can also cause cytopenias, including pancytopenia, and optic neuropathy, and acts as a monoamine oxidase inhibitor. Teicoplanin, rifampicin and streptogramin may be effective.

People more at risk of MRSA are best advised not to visit an infected person and all visitors must wash their hands thoroughly before and after visiting. Mandatory MRSA bacteraemia surveillance and better infection control practices, such as universal hand hygiene, contact precautions and admission screening, have seen a dramatic reduction in MRSA infection. The intensive care unit (ICU), an important reservoir for seeding MRSA, has been at the forefront of MRSA control programmes. Decolonization with agents such as chlorhexidine and mupirocin has an important role in reducing transmission. Chlorhexidine particularly is being recommended in the ICU

for an increasing number of indications, including decolonization, universal patient bathing, oropharyngeal antiseptics in ventilated patients and antiseptics at vascular catheter insertion sites.

MRSA has rarely been transmitted to dental patients but oral infections have now been reported.

PENICILLIN-RESISTANT *STREPTOCOCCUS PNEUMONIAE* (PRSP)

Streptococcus pneumoniae (pneumococcus) is the major pathogen causing community-acquired infections such as acute otitis media, pneumonia, bacteraemia and meningitis. Penicillin resistance is seen in over 80%. The penicillin-resistant *S. pneumoniae* are usually also resistant to macrolides, tetracyclines, co-trimoxazole, chloramphenicol and clindamycin, and increasingly to fluoroquinolone. Treatment is generally with a third-generation cephalosporin, or vancomycin together with rifampicin for a serious infection such as meningitis.

STAPHYLOCOCCUS AUREUS

S. aureus is found on the skin and in the nose of about 30% of healthy individuals. Coagulase-positive (*S. aureus*) and coagulase-negative staphylococci are Gram-positive cocci – important causes of infection, primarily of the skin, bloodstream, native and prosthetic cardiac valves, and other implanted devices. Their progressively reduced susceptibility to penicillin, meticillin and glycopeptides makes treatment of staphylococcal infections difficult. Although the use of chlorhexidine-impregnated catheters has reduced catheter-related infections, chlorhexidine-resistant *S. aureus* has emerged. MRSA strains carrying the antiseptic resistance genes *qacA/B* can be clinically resistant to chlorhexidine.

The two most commonly used decolonization agents are mupirocin for nasal carriage and chlorhexidine for skin carriage, the latter applied either as a daily bath after dilution in water, where there is potential for variability in the applied concentration, or as disposable cloths saturated in 2% chlorhexidine. Triclosan, octenidine dihydrochloride and tea tree oil are alternatives to chlorhexidine.

Chlorhexidine is used for skin antiseptics prior to blood culture collection and the insertion of vascular catheters; applied to the catheter exit site in the form of impregnated sponges; impregnated into vascular catheters to prevent bloodstream infections; and for oropharyngeal antiseptics to prevent ventilator-associated pneumonias. Mupirocin resistance is well known, but chlorhexidine resistance is an emerging threat and of additional concern.

STENOTROPHOMONAS MALTOPHILIA ('STENO')

Stenotrophomonas (Pseudomonas) maltophilia is an aerobic, non-fermentative, Gram-negative bacterium of low virulence found in aquatic environments. It frequently colonizes fluids used in hospitals (e.g. irrigation solutions, intravenous fluids) and is found in patient secretions (e.g. secretions, urine, exudates).

S. maltophilia rarely causes disease in healthy hosts, unless invasive medical devices are present. Antimicrobial treatment is usually unnecessary and may be potentially harmful. Infections are, in any event, difficult to treat, but *S. maltophilia* is susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), meropenem, minocycline, quinolones and colistin/polymyxin B.

TUBERCULOSIS

See Chapter 15.

VANCOMYCIN-RESISTANT BACTERIA

Vancomycin-resistant enterococci (VRE)

Vancomycin-resistant enterococci (VRE) are often present in the normal intestinal flora and in the female genital tract, as well as in the environment. Some of the other antibiotics that fail include some types of penicillin, cephalosporins, clindamycin, aminoglycosides, macrolides (such as erythromycin), tetracycline, quinolones and others.

Most VRE infections occur in hospitals and are often acquired from other people or from contaminated food or water. Up to 66% carry enterococci in the mouth, especially patients undergoing endodontic treatment. VRE may be associated with endodontic failures. It can cause diarrhoea, wound infection, bacteraemia or urinary tract infections, mainly in immunocompromised and medically ill patients. It may also give rise to endocarditis. Most VRE infections can be treated with antibiotics other than vancomycin.

Vancomycin-intermediate *Staphylococcus aureus* and vancomycin-resistant *Staphylococcus aureus*

Vancomycin-resistant (VRSA) and reduced susceptibility (vancomycin-intermediate) *S. aureus* (VISA) infections are usually seen in people with underlying health conditions (e.g. diabetes, chronic kidney disease), devices (e.g. catheters), previous infections with MRSA, and recent exposure to vancomycin and other antimicrobials.

Quinupristin–dalfopristin, linezolid, tetracycline, trimethoprim–sulfamethoxazole (TMP–SMX), tigecycline and daptomycin have been used for treatment of VISA infections.

TETANUS, PUNCTURE WOUNDS AND BITES

TETANUS

General aspects

Tetanus is a non-communicable infection caused by wound contamination with *Clostridium tetani* spores; it has a mortality of up to 60%. The spores are ubiquitous in soil or dust, particularly where there is faecal contamination, as on agricultural land. Tetanus is most likely to follow contaminated deep wounds, such as puncture wounds, especially if there is tissue necrosis, but it may also follow trivial wounds, or even bites or burns. The elderly, particularly women, are at greatest risk. Neonates may develop tetanus from contamination of the umbilical stump, a condition only found in the developing world.

Clinical features

The incubation period is between 4 and 21 days, commonly about 10 days.

C. tetani produces a neurotoxin (tetanospasmin) that is responsible for violent muscular spasms; trismus (lockjaw) due to masseteric spasm is the single most common early sign. Facial spasm produces a so-called sardonic smile (risus sardonicus), in which the eyebrows are raised with eyes closed and the lips are drawn back over clenched teeth. Spinal muscle spasm produces arching of the back (opisthotonos), while laryngeal spasm can lead to asphyxiation. Autonomic dysfunction can cause cardiac arrhythmias and fluctuations in blood pressure. Death may follow within 10 days of the onset of tetanus, usually from asphyxia, autonomic dysfunction or bronchopneumonia.

General management

Patients who have contaminated wounds, such as those associated with maxillofacial injuries caused by road traffic or riding accidents, are at greatest risk from tetanus. Situations that are considered tetanus-prone include any wound or burn sustained more than 6 hours before surgical treatment of the injury, or that shows a significant degree of devitalized tissue; a puncture wound; contact with manure or soil; or clinical sepsis.

Management of wounds where tetanus is likely includes active immunization with tetanus toxoid but it is *not* good practice to give toxoid after every *minor* injury, as severe allergic reactions can occasionally follow (Table 21.6).

The diagnosis of tetanus is clinical. There are no immediate tests that will help the diagnosis. Patients with tetanus should be admitted to an ICU for protection of the airway (tracheostomy should be carried out if the airway is endangered) and to facilitate artificial respiration, should it become necessary. They should be given anti-tetanus immunoglobulin (early, as it is ineffective after the toxin has become bound to nervous tissue) – human anti-tetanus immunoglobulin (ATG; Humotet, 500 units or more); if this is not available, animal anti-tetanus serum (ATS) should be used, after testing for hypersensitivity and with adrenaline (epinephrine) and corticosteroids available in case a severe reaction develops. Control of muscle spasms should be achieved by heavy sedation or, in severe cases, using general anaesthesia, muscle relaxants and mechanical ventilation; wound debridement should also be carried out, the purpose being to remove the source of toxin, as antibiotics alone are ineffective. Metronidazole is usually given.

Survivors suffer no after-effects but should have active immunization with toxoid.

Prophylaxis

Prophylaxis is active immunization in childhood, given as a triple vaccine (diphtheria, pertussis and tetanus antigens) starting at the age of 12 weeks, followed by further injections 6–8 weeks later and then after a further 4–6 months. Booster immunization (diphtheria, tetanus, pertussis and polio) is given at 3 years 4 months, and tetanus, diphtheria and polio at around 14 years old. The duration of immunity after such an immunization schedule is not known but current practice is to boost it every 10 years. Groups at highest risk (e.g. farm workers) should be given boosters every 5 years. Most cases of tetanus in developed countries are now seen in those who were never immunized, or in those whose immunity has declined – hence the risk in the elderly.

Table 21.6 Management of wounded patients at risk from tetanus

Wound type	Immune status	Course of action ^a
Superficial wound or abrasion	Immune ^b	–
	Not known to be immune	Active immunization with toxoid. Full three-dose course or, if partially immune, a reinforcing dose
Deep wounds, puncture wounds, or bites or burns	Immune	Give toxoid booster ^c
	Not known to be immune	Give antibiotics (metronidazole or penicillin) and start immunization with toxoid and: (1) if seen after 4h, give 250–500 units HTIG i.m.; (2) if seen after 24h, give 500 units HTIG i.m.

^aWound debridement in all.

^bLast of three-dose course or reinforcing dose within past 10 y.

^cHuman tetanus immunoglobulin (HTIG; 250–500 units i.m.) should also be given if the wound is highly contaminated or there is any doubt about immune status.

Dental aspects

Trismus is usually caused by local irritation, such as pericoronitis or temporomandibular pain–dysfunction syndrome, but in the absence of a local cause, tetanus must always be considered. Such patients should therefore be asked whether they have had any recent wounds, particularly if they are farm workers or gardeners.

Dyskinesias due to phenothiazines include facial grimacing but rarely trismus – the mouth is usually opened forcefully.

PUNCTURE WOUNDS

A puncture wound is caused by an object *piercing* the skin and creating a small hole. Some punctures can be very deep, do not often result in obvious excessive bleeding and tend to close fairly quickly spontaneously. A puncture wound from a cause such as stepping on a nail can become infected. Treatment may be necessary to prevent tetanus or other infections. Most healthy people without signs of infection do not require antibiotics, but these may be given to people with diabetes, peripheral vascular disease, contaminated wounds or deep wounds to the foot.

BITES

Dogs and cats cause most animal bites. Dog bites may cause severe tissue injury, as well as infections. Cat bites are more frequently (approximately 50%) infected. Animal bite infections are usually bacterial – typically polymicrobial (staphylococci and anaerobes). Tetanus is rarely transmitted.

Bites from non-immunized domestic animals and wild animals may carry the risk of rabies, which is more common in raccoons, skunks, bats and foxes than in cats and dogs. Rabbits, squirrels and other rodents rarely carry rabies.

Human bites are discussed in Chapter 24. Bites from humans may carry the risk of blood-borne virus infections (e.g. hepatitis B or C, or HIV). Consideration of post-exposure prophylaxis is important.

Treatment of bites may include debridement; antimicrobial coverage for staphylococci (co-amoxiclav) and anaerobes; and consideration of the possibilities of tetanus, rabies and blood-borne viruses.

Cat scratch disease (CSD) is caused by a bacterium, *Bartonella henselae*, usually transmitted when a person is bitten or scratched by a cat. About 40% of cats carry *B. henselae* at some time in their lives but show no signs. Patients develop lymphadenopathy, especially around the head, neck and axilla, and may develop fever, headache, fatigue and anorexia. Immunocompromised people are more likely to have complications – bacillary angiomatosis and Parinaud oculoglandular syndrome.

FOOD POISONING

Food poisoning is common, especially where hygiene is lacking and in warmer climates. Prevention is by:

- washing hands thoroughly before preparing or eating food, particularly after using the bathroom, changing nappies or having contact with animals or their environments
- cooking meat, poultry and fish thoroughly, preferably using a thermometer
- preventing cross-contamination in food preparation areas by washing hands, working tops, cutting boards and utensils thoroughly – particularly after preparing raw meat
- avoiding unpasteurized dairy products and juices
- avoiding swallowing water when swimming or playing in lakes, ponds, streams, rivers or swimming pools.

CAMPYLOBACTER

Campylobacter is the commonest reported bacterial intestinal disease in the UK. Most infections are with *C. jejuni* or *C. coli*, which are found in the gastrointestinal tract of birds (particularly poultry), cattle and domestic pets. Raw or undercooked meat (especially poultry), unpasteurized milk, bird-pecked milk on doorsteps, untreated water, and domestic pets with diarrhoea are the usual sources. Occupational exposure when processing poultry in abattoirs has been implicated in some cases. However, most infections remain unexplained by recognized risk factors.

Clinical features and general management

After an incubation period of 1–11 days (usually 2–5 days), there is abdominal pain, profuse diarrhoea and malaise, but vomiting is uncommon.

Disease may be passed from person to person if personal hygiene is poor. The illness is contagious, and children must be kept at home until they have been clear of symptoms for at least 2 days. Treatment is with azithromycin.

ESCHERICHIA COLI

E. coli are bacteria that normally live in the intestines of humans and animals without causing problems. Some strains can cause food poisoning, however, and one (*E. coli* O157:H7) can cause severe food poisoning, releasing a verotoxin (verocytotoxic *E. coli* [VTEC]; enterohaemorrhagic *E. coli* [EHEC]; or ‘Shiga toxin-producing’ *E. coli* [STEC]) that binds to receptors on human kidney, brain and gut cells, damaging them.

STEC live in the guts of ruminant animals, including cattle, goats, sheep, deer and elk. The major source of human illnesses is cattle. STEC that cause human illness generally do not make animals sick. Other kinds of animals, including pigs and birds, sometimes pick up STEC from the environment and may spread it. Foods implicated can include unpasteurized (raw) milk, unpasteurized apple cider, and soft cheeses made from raw milk. Sometimes the contact is obvious (e.g. working with cows or changing nappies) but sometimes it is not (e.g. eating undercooked hamburger or contaminated lettuce). People have been infected by swallowing water while swimming, touching the environment in zoos, and eating food prepared by people who did not wash their hands well.

The strain of STEC O104:H4 that caused a large outbreak in Europe in 2011 was referred to as EHEC. The most common STEC in North America is *E. coli* O157:H7 (*E. coli* O157 or simply ‘O157’).

Other *E. coli* serogroups in the STEC group, including *E. coli* O145, are sometimes called ‘non-O157 STECs’. Some types of STEC frequently cause severe disease, including bloody diarrhoea and haemolytic uraemic syndrome (HUS).

Clinical features

After an incubation period of 3–4 days (1–10 days), abdominal pain or non-bloody diarrhoea appears and worsens over several days. While people can become infected at any age, very young children and older people are more likely to develop severe illness and HUS. The symptoms of STEC infections vary but often include severe stomach cramps, diarrhoea (often bloody) and vomiting. If there is fever, it usually is not very high (less than 38.5°C). Most people recover within 5–7 days.

Around 5–10% of those who are diagnosed with STEC infection develop HUS and manifest decreased frequency of urination, malaise and anorexia. HUS, if it occurs, develops an average 7 days after the first symptoms, when the diarrhoea is improving. Persons with HUS should be hospitalized because renal failure is possible.

General management

STEC infections are usually diagnosed through laboratory testing of faecal specimens. Non-specific supportive therapy, including hydration, is important. There is no evidence that treatment with antibiotics is helpful, and taking antibiotics may increase the risk of HUS. Antidiarrheal agents may also increase that risk.

STEC typically disappear from the faeces by the time the illness is clinically resolved but may be shed for several weeks, even after symptoms go away. Young children tend to carry STEC longer than adults. A few people keep shedding these bacteria for several months.

INVASIVE MENINGOCOCCAL DISEASE

Meningococcal infection is typically caused by *Neisseria meningitidis*. Of the 13 *N. meningitidis* serotypes, only A, B, C, W135 and Y are clinically important. *N. meningitidis* serogroups A, B and C account for up to 90% of disease worldwide. W135 has emerged in recent years in Africa and the Middle East. Serogroups B and C are responsible for most cases in Europe and the Americas, serogroups A and C in Asia and Africa. Worldwide, the highest rates of infection occur in the meningitis belt of sub-Saharan Africa – from Senegal in the west, to Ethiopia in the east.

High-risk groups for invasive meningococcal disease include:

- people living in dormitories
- microbiologists who are routinely exposed to isolates of *N. meningitidis*
- people visiting countries where *N. meningitidis* is hyperendemic or epidemic (e.g. for Hajj), particularly if contact with the local population is prolonged
- people who have terminal complement component deficiencies
- people who have asplenia.

The reservoir for *N. meningitidis* is exclusively human, the bacteria being carried in the nasopharynx. Transmission is via the respiratory route, from coughing and sneezing, during close contact with a carrier. Epidemics are seen during the winter–spring period in temperate areas and during the dry season in tropical areas.

Clinical features

Infection risk is highest in the first 7 days after exposure to an infected person and falls rapidly during the following week. The incubation period is 2–10 days. Meningococcal infection can cause mainly:

- meningitis (49% of cases)
- septicaemia (33%)
- pneumonia (9%).

Infection can have an abrupt onset, with a rapid disease course and a case fatality rate of up to 15%; up to 20% of survivors suffer serious sequelae, including deafness, neurological deficit or limb loss. Meningococcal meningitis usually presents with sudden onset of fever, intense headache, nausea and vomiting. Neck stiffness from meningeal irritation is characteristic. A non-blanching petechial or purpuric rash usually occurs with septicaemia. Delirium, coma and shock can ensue.

General management

Suspected meningococcal infection is a medical emergency. On admission to hospital, parenteral antibiotics should be commenced

immediately. Intensive care, monitoring and supportive treatment are necessary.

For practical purposes, a 7-day period is considered sufficient to identify close contacts for prophylaxis. The ideal protection is provided by simultaneous administration of an antimicrobial drug and quadrivalent meningococcal vaccine. This approach is particularly suitable for outbreaks because of prolonged risk of transmission.

Antibiotic prophylaxis should be given as soon as possible after diagnosis of the index case. The drug of choice is rifampicin 600 mg b.i.d. for 2 days, but a single dose of ciprofloxacin 500 mg or an intramuscular injection of ceftriaxone 250 mg may also be used. The protection lasts for several days to a few weeks. The risk for contacts is still significant after 2 weeks and may persist for 6 months or even longer. Therefore immunization should be considered.

There is no vaccine to protect against all forms of meningitis and associated diseases, including the most common in the UK – meningococcal group B and streptococcal group B. Routine UK immunization programme protects against *Haemophilus influenzae* b, meningitis C and, most recently, pneumococcal meningitis.

Quadrivalent A/C/W135/Y and bivalent A/C meningococcal vaccines are available in the UK. ACWY is needed for Hajj/Umrah pilgrims (http://www.nathnac.org/pro/factsheets/Hajj_Umrah.htm; accessed 30 September 2013). There are two quadrivalent vaccines available in the UK: ACWY Vax[®] and Menveo[®]. See also Chapter 33.

Information for health professionals is available at: <http://www.nathnac.org/pro/factsheets/index.htm> (accessed 30 September 2013).

OTHER BACTERIAL INFECTIONS

Many other infections are seen, especially in the developing world (see Appendix 21.5).

VIRAL INFECTIONS

Viral infections are often transmitted readily in saliva and other body fluids; where general hygiene is low and there is close contact with other persons or their secretions, infections are common. They thus mainly affect young children, who often thereby acquire immunity. In developed countries, children may not contract these infections and thus are non-immune, and may have a primary infection as adolescents and adults.

Rashes (exanthemata) are common in some viral infections (Table 21.7).

Most viral infections are transient with few untoward sequelae, though many cause malaise, fever and depression of the immune system. Some viral infections can be immediately life-threatening (e.g. severe acute respiratory syndrome; SARS), others can result in tumours (e.g. hepatitis C and B and liver cancer), and others can seriously damage the immune system (e.g. HIV/AIDS; Ch. 20). Many viral infections can cause severe, recurrent, disseminated or persistent lesions in immunocompromised persons, such as those with organ transplants or HIV/AIDS.

Viral infections are often diagnosed on clinical grounds, supported by testing for immune responses (serology) and, increasingly, by examining for viral nucleic acids.

Antiherpetic and antiretroviral drugs can be effective (see the Appendices in Ch. 21) but relatively few other effective antiviral agents are available. Immunization against various viruses is available and should be taken up.

A wide range of infections is recognized (Table 21.8). This chapter discusses the important common viral infections, alphabetically; see

Table 21.7 Common childhood infections with rashes (exanthemata)

	Name	Alternative term
First disease	Measles	Rubeola
Second disease	Scarlet fever	Streptococci
Third disease	German measles	Rubella
Fourth disease	Filatov–Dukes disease	Doubt exists over the existence of this
Fifth disease	Erythema infectiosum ('slapped cheek syndrome')	Parvovirus
Sixth disease	Herpesvirus 6 infection ('exanthem subitum')	Roseola infantum

Appendices 21.8 and 21.9 for serious life-threatening but fortunately uncommon viral infections.

CHIKUNGUNYA

This is a togavirus (RNA) transmitted by the Asian Tiger mosquito (*Aedes albopictus*), found mainly in areas in, and bordering, the Indian Ocean. Similar to dengue and O'nyong'nyong, the incubation is 2–4 days, and clinical features may include;

- Oral ulceration
- Rash; central maculopapular
- Headache, malaise
- Arthralgia
- Fever to 39 degrees.

There are neither cures nor antiviral drug treatments.

ENTEROVIRUSES

Enteroviruses multiply in the gut mucosa and are transmitted from person to person by the faecal–oral route. Most infections are in childhood, often as small epidemics. Enterovirus infections are usually

Fig. 21.3 Hand, foot and mouth disease.

transient but produce lifelong immunity to the strain. Clinical syndromes are generally mild but occasional infections may cause serious disease, such as paralytic poliomyelitis, meningitis or myocarditis. Enterovirus diseases relevant to dentistry include hepatitis A (Ch. 9), poliomyelitis (Ch. 13), herpangina, and hand, foot and mouth disease.

HERPANGINA

Coxsackie viruses, usually A7 or B1, or echoviruses 9 or 17 cause infections, often subclinically. After an incubation of 2–9 days, clinical features may include mouth ulcers affecting the posterior mouth alone (soft palate and uvula) and causing sore throat, cervical lymphadenitis, fever, malaise, irritability, anorexia and sometimes vomiting. Diagnosis is from the clinical features. Management is symptomatic (see Herpes simplex).

HAND, FOOT AND MOUTH DISEASE

Picornaviruses (Coxsackie A and enterovirus [EV] 71) are responsible for most hand, foot and mouth disease (HFMD). Coxsackie (usually A16; rarely, A5 or 10) virus infections are often subclinical. However, the World Health Organization reported one outbreak in 2008 in China involving a total of 1884 cases, including 20 deaths, due to enterovirus EV-71. Clinical features, after an incubation of 2–6 days, include mouth ulcers, resembling herpetic stomatitis, mild fever, malaise, anorexia and a rash. Red papules that evolve to superficial vesicles in a few days form mainly on the palms and soles (Fig. 21.3). Diagnosis is from the clinical features. Management is symptomatic (see Herpes simplex).

HERPESVIRUSES

The herpesviruses are DNA viruses, transmitted mainly in saliva and other body fluids (Table 21.9). They typically cause a short-lived primary clinical, or more often subclinical, infection, and remain latent thereafter. Reactivation is often because of immunosuppression and recrudescence can lead to protracted illness. Some herpesviruses can be oncogenic.

HERPES SIMPLEX VIRUS (HSV; HUMAN HERPESVIRUS TYPES 1 AND 2) INFECTIONS

General aspects

Type 1 herpes simplex virus (HSV) typically causes primary oral infection with acute gingivostomatitis but may cause primary pharyngeal or anogenital infection. Type 2 HSV typically causes anogenital

Table 21.9 The herpesviruses

Herpesvirus type	Standard nomenclature	Abbreviation
1	Herpes simplex type 1	HSV-1
2	Herpes simplex type 2	HSV-2
3	Herpes varicella zoster	VZV
4	Epstein–Barr virus	EBV
5	Cytomegalovirus	CMV
6	Human herpesvirus type 6	HHV-6
7	Human herpesvirus type 7	HHV-7
8	Human herpesvirus type 8 (Kaposi sarcoma herpesvirus)	HHV-8 (KSHV)

Fig. 21.4 Herpes simplex recurrent infection.

Fig. 21.5 Recurrent herpes labialis.

infections but may cause oral or oropharyngeal infections. HSV thereafter remains latent in the sensory ganglia but if reactivated may cause lesions. Recurrent infections typically affect the mucocutaneous junctions and are often precipitated by factors such as exposure to systemic infections, sunlight, trauma, stress, menstruation or immune incompetence (Figs 21.4 and 21.5).

Clinical features

Primary oral infection with HSV, usually type 1, typically causes acute gingivostomatitis, ulcers, fever, cervical lymph node enlargement and irritability. It is common in young children and sometimes misdiagnosed as 'teething', or may be subclinical. Primary herpetic gingivostomatitis is limited to the mouth and resolves within about 10 days but, in immunosuppressed patients or in those with eczema, disseminated infection may result.

Thereafter HSV remains latent, often in the trigeminal ganglia, but reactivates from time to time; it appears in the saliva and may cause

Fig. 21.6 Herpetic whitlow.

Table 21.10 Antiviral therapy considerations in common herpesvirus infections

Virus	Disease	Otherwise healthy patient	Immunocompromised patient
Herpes simplex	Primary	Consider oral aciclovir ^a 100–200 mg, five times daily as suspension (200 mg/5 mL) or tablets	Aciclovir 250 mg/m ² i.v. every 8 h
	Recurrent herpetic ulcers	Consider oral aciclovir ^a 100–200 mg, five times daily as suspension (200 mg/5 mL) or tablets	Consider aciclovir 250 mg/m ² i.v. every 8 h
	Recurrent herpes labialis	Penciclovir 1% cream or aciclovir 5% cream every 2 h	Consider aciclovir 250 mg/m ² i.v. every 8 h
Herpes varicella	Chickenpox	–	Aciclovir 500 mg/m ² (5 mg/kg) i.v. every 8 h
	Zoster (shingles)	3% aciclovir ophthalmic ointment for shingles of ophthalmic division of trigeminal	Aciclovir 500 mg/m ² (5 mg/kg) i.v. every 8 h or famciclovir 250 mg three times daily, or 750 mg daily

Aciclovir: systemic preparations, caution in renal disease and pregnancy, occasional rise in liver enzymes and urea, rashes, CNS effects. Famciclovir: caution in renal disease and pregnancy. Occasional nausea and headache.

^aIn neonate, treat as if immunocompromised.

lesions. The virus can be spread by saliva and occasionally causes painful whitlows in dental staff not previously exposed to it (Fig. 21.6). A growing number of oral or oropharyngeal infections appear to be caused by HSV-2, which otherwise causes genital infections. Diagnosis is typically clinical.

Aciclovir is effective against HSV but many patients present with disease that is too far advanced for there to be any real benefit. Aciclovir, famciclovir and other antivirals are essential to control infection in immunocompromised patients (Table 21.10). Treatment is supplemented with supportive care, such as adequate fluid intake, antipyretics and analgesics (usually paracetamol [acetaminophen]), and good oral hygiene by mouth cleansing and use of aqueous chlorhexidine mouthwashes.

Recurrent infections appear in up to 30% of patients, typically at the mucocutaneous junction of the lip (herpes labialis; cold sores) or nose, and are often precipitated by exposure to systemic infections, sunlight, trauma, stress or menstruation. These factors stimulate HSV to reactivate by more than one mechanism. One way is by direct induction of viral genes such as *ICP4* and *VP16*. Heat can induce these viral genes either directly or via the by-products of heat. The activated viral gene products then overcome the effects of latent (LAT) RNAs. Another mechanism is an indirect one involving immunosuppression. Ultraviolet light is immunosuppressive and also induces cytokines that can trigger inflammation. These cytokines may affect dendrites that communicate the signal back to the neuron where the viral DNA is residing; *ICP4* and *VP16* are viral genes critical for reactivation.

Diagnosis is clinical. Recurrent labial infections respond well to penciclovir or aciclovir cream applied early. A patch with hydrocolloid particles and zinc sulphate is an alternative.

Intraoral recurrences appear as ulcers and seem to be more likely after trauma, such as in the palate, or in immunocompromised patients (e.g. leukaemia or HIV/AIDS). Aciclovir may be indicated but HSV is now showing starting to show resistance. Famciclovir, valaciclovir or even foscarnet may then be required.

Genital herpes

A person almost always contracts HSV-2 infection by sexual contact. HSV-1 infection of the genitals is almost always caused by oral–genital contact with a person who has oral HSV-1 infection. One out of five of the total adolescent and adult population in the USA are infected with HSV-2; the prevalence is rising but few have signs or symptoms. When signs of genital herpes do appear, they are typically as blisters on or around the genitals or rectum. The blisters break, leaving tender ulcers that may take 2–4 weeks to heal. It is important that women avoid contracting HSV-2 during pregnancy because a first episode during pregnancy causes a greater risk of transmission to the newborn. HSV-2 can cause potentially fatal infections in infants if the mother is shedding virus at the time of delivery. If a woman has active genital herpes at delivery, a Caesarean delivery is therefore usually performed.

Antiviral medications, such as aciclovir or famciclovir, can shorten and prevent outbreaks during the period the medication is being taken.

VARICELLA ZOSTER VIRUS (VZV; HUMAN HERPESVIRUS 3)

Chickenpox

General aspects

Varicella (chickenpox) is a highly contagious disease caused by the varicella zoster virus (VZV), spread readily by droplets. VZV is an exclusively human pathogen. The primary infection typically occurs during childhood and causes varicella. Patients are infectious from 1–2 days before the rash, until the rash scabs and dries.

During viraemia, VZV enters epidermal cells, causing the typical varicella rash; it then enters sensory nerves in mucocutaneous sites and travels through retrograde axonal transport to the sensory dorsal root ganglia adjacent to the spinal cord, where the virus establishes permanent latency in neuronal cell bodies. VZV then remains latent within dorsal root ganglia and, if reactivated, as can happen in older or immunocompromised people, can lead to shingles (zoster) – a painful unilateral rash.

More information on varicella and other infectious diseases may be found at: <http://www.hpa.org.uk/Topics/InfectiousDiseases/InfectionsAZ/> (accessed September 2013).

Clinical features

Varicella is most common in children below the age of 10 years. There is fever, malaise and a centripetal rash (mainly on trunk and face), which passes through macular, papular, vesicular and pustular stages before scabbing. There are about 3–5 crops of lesions. There may be mouth ulcers.

Infants, adolescents, adults and immunocompromised persons are at higher risk for complications, such as disseminated or haemorrhagic varicella. Adults, especially those who are pregnant or who smoke, are at risk from fulminating varicella pneumonia. There is also a risk to the fetus and neonate if the mother contracts chickenpox. In the first 20 weeks of pregnancy, a congenital varicella syndrome with microcephaly, cataracts, growth retardation and limb hypoplasia may result, and the mortality rate is high. Later in pregnancy, chickenpox may result in zoster in an otherwise healthy infant. Chickenpox around the time of delivery may cause severe and even fatal infection of the neonate.

General management

Diagnosis is clinical. Varicella zoster immunoglobulin, or aciclovir, valaciclovir or famciclovir, may be indicated for non-immune persons who are pregnant or immunocompromised. Varicella vaccine is effective in preventing illness or modifying varicella severity if used within 3 days, and possibly up to 5 days of exposure.

Zoster

General aspects

VZV remains latent within dorsal root ganglia and may be reactivated, especially in the elderly or immunocompromised, leading to shingles (zoster). In about 8–10%, zoster may reflect an underlying immunodeficiency state, sometimes as a result of HIV/AIDS or a neoplasm, particularly a lymphoma.

Latent VZV infects approximately 98% of the adult population and is non-infectious but it can reactivate to migrate to the skin through axons, spread from cell to cell, and penetrate the epidermis, causing pain; this is followed by a vesicular rash distributed across closely overlapping dermatomes of the involved sensory nerve roots. VZV reactivation triggers are unclear but cell-mediated immunity (CMI) is important in controlling the development of zoster. The CMI components are partially or substantially maintained by periodic ‘endogenous boosting’ in response to subclinical reactivation or to ‘exogenous boosting’ in response to VZV circulating in the population as chickenpox.

Age is the most important risk factor for development of zoster. Approximately 50% of persons who live to the age of 85 years will have experienced zoster.

The incidence of zoster is increased substantially in persons with haematological malignancies and solid tumours. Patients with Hodgkin’s disease are at particularly high risk for zoster. Zoster is common following haemopoietic stem cell transplantation (HSCT) and following solid organ transplants (renal, cardiac, liver and lung; 5–17%). Incidence is highest during the months immediately following the procedure, and the majority of zoster cases occur within a year of transplantation. The risk for zoster and its recurrence is elevated in persons infected with HIV.

The risk for zoster also appears to be higher in persons with inflammatory diseases. Zoster has been associated with systemic lupus erythematosus (SLE), rheumatoid arthritis, granulomatosis with polyangiitis (formerly called Wegener granulomatosis), Crohn disease and ulcerative colitis, and possibly diabetes mellitus and multiple sclerosis.

Fig. 21.7 Thoracic zoster.

Fig. 21.8 Ophthalmic zoster.

Zoster lesions contain high concentrations of VZV that can be spread, presumably by the airborne route, and cause primary varicella in exposed susceptible persons. Zoster is contagious after the rash erupts and until the lesions crust. It is less contagious than varicella, though transmission has been documented between patients or from patients to health-care personnel, but transmission from health-care personnel to patients has not been documented.

Clinical features

Zoster involves one or more contiguous sensory dermatomes, usually of the face or the chest, and causes severe pain and a rash similar to chickenpox but localized to the dermatome (Fig. 21.7). Trigeminal ophthalmic zoster may cause facial rash and pain, and ulcerate the cornea (Fig. 21.8). Zoster of the maxillary or mandibular divisions of the trigeminal nerve may cause facial rash and pain (sometimes simulating toothache) and oral ulceration – unilateral and in the nerve distribution.

Zoster is usually more severe in older adults, typically with a prodrome of headache, photophobia and malaise (Fig. 21.9). Abnormal skin sensations and aching, burning, stabbing or shock-like pain of varying severity are common and can precede the rash by days to weeks; rarely, they might constitute the only clinical manifestation (termed zoster sine herpette).

Zoster rash is typically unilateral and does not cross the midline, erupting in one or two adjacent dermatomes. Thoracic, cervical and ophthalmic involvement are most common. The rash is initially erythematous and maculopapular but progresses to coalescing clusters of clear vesicles over several days and then evolves through pustular, ulcer and crust stages over 7–10 days, with complete healing within 2–4 weeks.

A common consequence of zoster is post-herpetic neuralgia (PHN), a persistent pain after resolution of the rash. The duration of pain after

Fig. 21.9 Zoster in cervical nerves.

rash resolution, used to define PHN, ranges from at least 30 days to 6 months or more after rash onset. PHN can last for weeks or months and occasionally for many years, and varies from mild to excruciating in severity; it may be constant, intermittent, or triggered by trivial stimuli.

Zoster may be associated with other complications too: 10–25% have eye involvement, called herpes zoster ophthalmicus (HZO). Keratitis occurs in approximately two-thirds of patients with HZO, often causing corneal ulceration. Other sequelae include conjunctivitis, uveitis, episcleritis and scleritis, retinitis, choroiditis, optic neuritis, lid retraction, ptosis and glaucoma. Extraocular muscle palsies also occur. Ramsay Hunt syndrome is an uncommon complication, in which there is a peripheral facial nerve palsy accompanied by reactivation of VZV in the geniculate ganglion of the facial nerve with zoster vesicles on the ear, hard palate or tongue. Occasionally, zoster can cause motor weakness in non-cranial nerve distributions, called zoster paresis; this develops abruptly within 2–3 weeks of the rash and can involve upper or lower extremities. Diaphragmatic paralysis has also been described. Zoster can also result in autonomic dysfunction, causing urinary retention and colon pseudo-obstruction. Rarely, patients will experience acute focal neurological deficits weeks to months after resolution of the rash, with myelitis, aseptic meningitis, meningoencephalitis or Guillain-Barré syndrome.

In immunocompromised persons, the rash tends to be more severe and its duration prolonged; there may be dissemination and it is a marker for VZV viraemia that can seed the lungs, liver, gut and brain, and cause pneumonia, hepatitis, encephalitis and disseminated intravascular coagulopathy. Neurological zoster complications are increased in immunocompromised persons and can be aggressive and even fatal; they include myelitis, chronic encephalitis, ventriculitis, meningoencephalitis and cranial palsies.

General management

Diagnosis is clinical and might not be possible in the absence of a rash. VZV obtained from lesions can be identified using tissue culture, but this can take several days and false negative results occur because

viable virus is difficult to recover from cutaneous lesions. Direct fluorescent antibody (DFA) staining of VZV-infected cells in a scraping of cells from the base of the lesion is rapid and sensitive. DFA and other antigen-detection methods can also be used on biopsy material, and eosinophilic nuclear inclusions (Cowdry type A) are observed on histopathology. Polymerase chain reaction (PCR) techniques can be used to detect VZV DNA rapidly and sensitively.

Treatment of zoster is with aciclovir, valaciclovir or famciclovir by mouth, given within 3 days of the appearance of the rash. Intravenous administration is needed in immunodeficient patients, particularly in those with HIV/AIDS, for whom it can be a life-threatening disease.

An urgent ophthalmological opinion should be sought for patients with ophthalmic zoster. Aciclovir, famciclovir and valaciclovir are approved by the US Food and Drug Administration (FDA) for treatment of zoster; they reduce the duration of viral shedding and lesion formation, and decrease the time to rash healing, the severity and duration of acute pain from zoster, and the risk for progression to PHN. Even with antiviral treatment, fatality from dissemination is 5–15%, with most deaths attributable to pneumonia.

The pain of herpetic neuralgia may not respond well to analgesics but tricyclic antidepressants, carbamazepine or capsaicin may be of value. Other treatments for postherpetic pain include skin stimulation of the painful area by prolonged rubbing with a soft cloth; firm pressure with the flat of the hand or the ball of the thumb; massage; acupuncture; local heat; a cold spray; or transcutaneous electric nerve stimulation (TENS).

Immunization of children against VZV reduces the risk of zoster at a later age. However, if immunity wanes with age, there may be epidemics of chickenpox in the middle-aged, and if the middle-aged who have had chickenpox do not receive occasional boosts of their immunity by exposure to chickenpox (which has been prevented in children by vaccination), the incidence of shingles may rise. In immunocompromised patients who are exposed to VZV, it may be desirable to give zoster immunoglobulin or vaccine.

If a person susceptible to varicella infection has close exposure to a person with zoster, postexposure prophylaxis with varicella vaccine or VARIZIG™ should be considered. Zoster vaccine may be offered to older patients and is now offered in UK to those over 70.

EPSTEIN–BARR VIRUS (EBV; HUMAN HERPESVIRUS 4)

General aspects

Epstein–Barr virus (EBV) causes infectious mononucleosis (IM; classic glandular fever). EBV also has epidemiological associations with Burkitt and some other lymphomas, and with nasopharyngeal carcinoma. EBV may also cause sialadenitis (see later) and, in immunocompromised patients, may be associated with hairy leukoplakia (Ch. 20) or lymphomas.

Clinical features

EBV is found in saliva during IM and for several months thereafter. It is also often in the saliva of immunocompromised persons. Though infectivity is low, EBV appears to be spread by close oral contact, such as kissing.

Infection is common among young adults but is often subclinical or unrecognized, especially in children. IM mainly causes lymphadenopathy, sore throat and fever but is protean in its manifestations (glandular fever). Glandular fever is a syndrome in which fever, malaise and lymph node enlargement are the main features; though typically

Box 21.7 Causes of glandular fever syndromes

- Cytomegalovirus infection
- Epstein–Barr virus infection (infectious mononucleosis)
- HIV infection
- Human herpesvirus 6 infection
- Infectious lymphocytosis (babesiosis; *Bordetella pertussis*; brucellosis; cat scratch disease; Coxsackie, hepatitis, influenza, mumps, rubella, syphilis, TB; varicella)
- Toxoplasmosis
- Rarely: acute leukaemia; drug-induced hypersensitivity syndrome (DIHS; drug reaction with eosinophilia and systemic symptoms [DRESS] syndrome)

Fig. 21.10 Infectious mononucleosis.

caused by EBV, other infectious agents are occasionally responsible (Box 21.7).

IM can appear in many forms:

- *Febrile type IM* – high fever with rubelliform rashes and occasionally jaundice
- *Anginose type IM* – sore throat with soft palate petechiae and a whitish exudate confined to the tonsils, and pharyngeal oedema that may threaten the airway (to be distinguished from diphtheria) and petechiae on the palate. The latter are occasionally seen in other viral infections, such as rubella and HIV. Occasionally, there is mouth ulceration
- *Glandular type IM* – generalized, especially cervical lymph node enlargement and splenomegaly. IM is an important cause of enlarged cervical lymph nodes. Unfortunately, the lymph node histopathological changes closely resemble those in lymphomas and an expert opinion is needed.

Complications of IM include persistent fatigue, mild liver dysfunction, ECG changes, depression, neurological syndromes and, rarely, nephritis, pancreatitis or lung infiltration. Ampicillin and amoxicillin frequently cause a maculopapular rash (which is not an allergy), affecting the extensor surfaces of limbs (Fig. 21.10).

General management

Characteristic blood changes of IM are an excess of atypical lymphocytes (mononucleosis); these may cause confusion with leukaemia – but

for the absence of anaemia. Occasionally, there is also mild neutropenia or thrombocytopenia.

Serological tests for IM include heterophile antibodies and EBV antibodies. Heterophile antibodies are immunoglobulin M (IgM) antibodies that agglutinate sheep and horse red blood cells. The Paul–Bunnell heterophile antibody test uses sheep erythrocytes, but a more rapid method identifies heterophile antibodies (to horse red blood cells) by detecting agglutination on a glass slide (Monospot test). Heterophile antibodies usually develop during the first or second week of the illness (60% of patients), and by 4 weeks up to 90% of patients have a titre before absorption of 224, which then declines and disappears over 3–6 months.

EBV-specific laboratory tests on a single acute-phase serum sample can help determine whether a person is susceptible to EBV, has had recent infection, has had past infection, or has reactivated EBV infection (Table 21.11).

When the Monospot (Paul–Bunnell) test is negative, the best testing combination is of:

- IgM and IgG to viral capsid antigen (VCA): IgM appears early in infection and disappears within 4–6 weeks. IgG to VCA appears in the acute phase, peaking at 2–4 weeks after onset, declining slightly and then persisting for life
- IgM to early antigen (EA), and IgG to EA: these appear in the acute phase and generally fall to undetectable levels after 3–6 months
- antibody to EBV nuclear antigen (EBNA): this slowly appears 2–4 months after onset and persists for life. Some EBNA enzyme immunoassays can detect antibody sooner.

However, even when EBV antibody tests suggest that reactivated infection is present, this does not necessarily indicate that the current illness is caused by EBV infection, since a number of healthy people continue to have antibodies to EBV EA for years. There may be a false positive Wassermann reaction.

Infection with EBV is usually acute and self-limiting, and no reliably effective specific treatment is available. As malaise and fatigue are frequent accompaniments, however, the patient may benefit from bed rest. Systemic corticosteroids are required if there is severe pharyngeal oedema that poses a hazard to the airway. Nearly 20% of patients have concurrent beta-haemolytic streptococcal pharyngeal infection, for which penicillin may be given. Tinidazole may improve the sore throat.

Burkitt lymphoma

Burkitt lymphoma, found predominantly in Africa in children below 12 years of age, presents with massive swellings that affect the mandible in particular; there is pain, paraesthesia and bone destruction, causing tooth mobility, jaw radiolucencies and destruction of the lamina dura. It appears to be related to EBV in association with malaria.

Burkitt lymphoma may also be seen outside of Africa and can be a complication of HIV/AIDS. Chemotherapy is remarkably effective but relapse is common.

Hairy leukoplakia in HIV/AIDS

See Chapter 20.

Lymphomas

See Chapter 8.

Nasopharyngeal carcinoma

See Chapters 14 and 22.

CYTOMEGALOVIRUS (CMV; HUMAN HERPESVIRUS 5)

Cytomegalovirus (CMV) is a ubiquitous herpesvirus found in large quantities in the saliva and urine of infected persons.

Primary infections are mostly asymptomatic but some cause a glandular fever-like illness. Thereafter CMV remains latent in oropharyngeal and other epithelial cells, and may be reactivated by immunosuppression and other factors. Under these circumstances, disseminated infection can cause CMV retinitis in particular, often leading to blindness. CMV infection is a particular problem in HIV/AIDS (Ch. 20).

The other main problem identified in relation to CMV is its potential to cause fetal damage. A range of infections of the pregnant mother, especially in the first trimester, can cause fetal damage, that can sometimes be fatal. These include *toxoplasmosis*, *rubella*, *cytomegalovirus* and *herpes simplex virus* (TORCH syndrome). When less severe, they may cause mild hearing loss; alternatively, they may result in learning disability, pneumonitis, cardiac malformations, microphthalmia, microcephaly, jaundice and low birth weight. CMV is thereafter excreted by the neonate in urine and saliva for many months.

Antiviral therapy for CMV includes ganciclovir or foscarnet.

HUMAN HERPESVIRUS 6

Human herpesvirus 6 (HHV-6) is a T-cell lymphotropic herpesvirus that is almost invariably contracted via oropharyngeal secretions within the first 2 years of life.

HHV-6 causes a febrile illness, sometimes with a macular or papular rash on the face and/or trunk (exanthema subitum; roseola infantum; sixth disease), mild diarrhoea, cough, oedematous eyelids and occasionally sialadenitis, hepatitis, meningitis or meningo-encephalitis or blood dyscrasias (particularly granulocytopenia). Erythematous papules (Nagayama spots) may appear on the soft palate and uvula and pharynx. Cervical lymphadenopathy is detectable in about one-third of patients. HHV-6 infection in later life may produce a glandular fever syndrome, persistent lymphadenopathy, chronic fatigue syndrome or hepatitis.

Thereafter, HHV-6 remains latent. Immunocompromised patients may suffer reactivation of HHV-6 with pneumonitis, retinitis, encephalitis or bone marrow failure, and it may have a cofactorial role in HIV infection. There are suggested but certainly unproven associations with multiple sclerosis and various neoplasms.

HHV-6 is inhibited by ganciclovir, foscarnet (phosphonoformate, PFA) and phosphonoacetic acid (PAA) but is relatively resistant to aciclovir.

HUMAN HERPESVIRUS 7

Human herpesvirus 7 (HHV-7) is T-lymphotropic; it is not known to be related to any human disease but might be a cofactor in HHV-6-related syndromes and may cause rashes.

Table 21.11 Diagnosis in Epstein–Barr virus (EBV) infection

EBV nuclear antigen (EBNA) antibody	Other EBV antibodies	Interpretation
Absent	Viral capsid antigen (VCA) antibodies absent	Susceptible
Absent	VCA immunoglobulin M (IgM) antibody present	Primary infection
	VCA IgG antibody rising or high	
Present	VCA antibodies present	Past infection
Present	Early antigen (EA) antibodies present	Reactivation

HUMAN HERPESVIRUS 8

Human herpesvirus 8 (HHV-8; Kaposi sarcoma herpesvirus, KSHV) is a B-lymphotropic DNA virus, transmitted mainly by sexual contact. It is strongly associated with Kaposi sarcoma and body cavity-based lymphomas. It is present in saliva but there are as yet no documented cases of nosocomial transmission to health-care workers. There is no specific effective treatment but ART (Ch. 20) may play an indirect role in clearing HHV-8 from HIV-infected patients.

HUMAN IMMUNODEFICIENCY VIRUSES

See Chapter 20.

MEASLES

Measles is an acute infection with the measles virus, transmitted by droplet infection, with an incubation period of about 10–14 days. Whitish spots in the buccal mucosa (Koplik spots) herald the onset. The illness consists of fever, coryza, conjunctivitis and a maculopapular rash. Complications include bronchitis, pneumonia, otitis media, convulsions and encephalitis (which has a mortality of 15% – highest in infants – and leaves a neurological deficit in up to 40%). Subacute sclerosing panencephalitis (SSPE) is a late complication.

Immunization is indicated in early childhood (Appendix 21.7) and had almost abolished measles, until the recent decline over concerns about immunization.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a viral infection that spreads easily among children; in adults, it may be sexually transmitted and is common in HIV/AIDS. Characteristic umbilicated papules may be seen on the face and elsewhere. Local application of trichloroacetic acid effectively burns the lesions off.

MUMPS

Mumps was a common infection, usually caused by the mumps virus and spread by droplet infection; it is now mostly eliminated by vaccination. Of 101 specimens in a recent study on mumps, 38 were positive for a single virus: Epstein-Barr virus (in 23), human herpesvirus (HHV)-6B (10), human parainfluenza virus (HPIV)-2 (3), HPIV-3 (1), and human bocavirus (1). Mumps virus itself, enteroviruses (including human parechovirus), HHV-6A, HPIV-1, and adenoviruses were not detected. Mumps-like illnesses are occasionally caused by adenoviruses or echoviruses.

The incubation period is 14–21 days and mumps is transmissible from 2 or 3 days before parotitis appears until several days afterwards. Mumps causes swellings involving particularly the major salivary glands, usually the parotids (Fig. 21.11). One or both parotids become enlarged and tender (parotitis) with trismus, and oedema and erythema of the orifice of the parotid duct (papillitis). The other major salivary glands may also be affected but rarely in the absence of parotitis. Mumps should always be considered in the differential diagnosis of acute swellings of salivary glands, particularly in the young. Complications of mumps are uncommon but include deafness, pancreatitis, meningo-encephalitis, orchitis and oophoritis in particular. The latter conditions rarely cause sterility, even if bilateral.

Fig. 21.11 Mumps.

Fig. 21.12 Human papillomavirus infection: common warts.

There is no antiviral agent available for use against mumps. Mumps immunization is carried out in childhood.

PAPILLOMAVIRUSES (HUMAN PAPILLOMAVIRUSES; HPVS)

Human papillomaviruses (HPVs) are ubiquitous DNA viruses. Over 100 HPV types are recognized; they are transmissible and mostly cause benign warts and other epithelial lesions affecting skin and mucosae, including mouth and genitals. Skin warts (verruca vulgaris) are common (Figs 21.12 and 21.13), especially in children, and spread mainly from close contact or in wet environments such as changing rooms. Genital warts (condylomata acuminata) are caused by HPV and may be found on the penis, vulva or vagina or perianally, or may be unseen in the urethral meatus or cervix. Around one-third of young American women have genital HPV infection. About 65% of sexual contacts of patients with genital warts develop warts after an incubation period that may exceed 2 years.

Some HPVs cause oral warts (verruca vulgaris) and papillomas. Heck disease (focal epithelial hyperplasia) is an unusual oral condition caused by specific HPV (types 13 and 32), mainly in ethnic groups such as Inuits and American Indians.

Some HPVs are closely associated with malignant disease; for example, HPV-16, 18 and 33 appear to be associated with cervical carcinoma. HPVs may also be associated with some oropharyngeal carcinomas.

Fig. 21.13 Human papillomavirus infections.

Local surgery or podophyllum resin has been the usual treatments for non-malignant HPV-related lesions. Immune stimulators such as interferon-alpha and imiquimod are now available.

HPV vaccines protect against the types of HPV that cause most cervical cancers. There are two vaccines, both of which are safe and are usually given as a three-shot series:

- Cervarix: recommended for females from 10 to 25 years of age, and protects against HPV 16 and 18.
- Gardasil: recommended for 11–26-year-old females and also for 9- to 26-year-old males to protect against some genital warts. This vaccine protects against HPV 6, 11, 16 and 18.

There is no statistically significant increased risk for stroke, thromboembolism, appendicitis, seizures, syncope, allergic reactions, Guillain-Barré syndrome and anaphylaxis but the most common adverse events reported from vaccination have been:

- syncope – common, especially in pre-teens and teens
- local pain and redness at the site of immunization
- dizziness
- nausea
- headache
- venous thromboembolism – 90% had a known other risk factor, such as smoking, obesity or hormonal contraceptives.

PARVOVIRUSES

Parvoviruses are among the smallest, simplest DNA viruses and cause infections in a variety of birds and mammals. The only known human parvovirus is B19, which is transmitted by droplets, touch and occasionally in blood, and usually has an incubation period of 4–14 days. Parvoviruses tend to infect rapidly dividing tissues, most commonly the fetus, the intestinal epithelium or the haemopoietic system. A total of 70–90% of most adult populations is seropositive for B19.

Parvovirus commonly causes fifth disease (erythema infectiosum; slapped cheek syndrome), a mild illness with a lace-like rash on the face, trunk and extremities, usually in children. In approximately 80% of patients, there is also arthropathy – temporary arthritis-like joint involvement (particularly in adults). Since the vaccination-induced disappearance of rubella, parvovirus is the commonest cause of infection-related transitory arthritis, particularly if it affects the hands.

B19 also causes acute depression of red blood cell production, a transient event of little clinical significance, except in patients with other haematological diseases, particularly sickle cell disease, when haemolytic crises may be precipitated. B19 infection in pregnancy is associated with early fetal loss, although the probability of this appears to be low (less than 10%). There is no specific therapy for parvoviruses.

RUBELLA (GERMAN MEASLES)

ACQUIRED RUBELLA

Rubella, caused by rubella virus, is a highly infectious but usually mild disease, spread by droplet infection, with an incubation period of about 14–21 days.

In children, rubella causes a minor macular rash, starting on the face and behind the ears, mild fever, sore throat and enlarged lymph nodes (including the posterior auricular and suboccipital posterior cervical nodes). In adults, rubella may cause arthritis or arthralgia.

No antiviral treatment is available for rubella. Immunization is available and indicated for health-care workers. After rubella immunization, immunity is long-lasting.

CONGENITAL RUBELLA

Rubella infection during the first trimester of pregnancy can damage the fetus, causing problems ranging from deafness to death. If the fetus survives, learning disability, retinopathy and cataracts, cardiac malformations and deafness may result (major rubella syndrome). The infant may also have liver damage, bone defects and thrombocytopenic purpura. The virus is excreted, particularly in the urine, for months after birth (see TORCH syndrome). Pregnant females should thus consider whether or not they are immune to rubella. Rashes resembling rubella (rubelliform rashes) are also common in enterovirus and other infections, and thus a *clinical* diagnosis of rubella may not always be accurate unless confirmed serologically. Females who believe they have had rubella (and thus think they are immune) may in fact be non-immune and they and any fetus may be at risk. Antibody titres should be assayed to determine their actual immune status.

Rubella immunization of non-immune pre-pubertal females is the most effective prophylaxis and should be given to female health-care staff who are not known to be immune, who are seronegative, and who

Table 21.12 Confirmation of diagnosis of rubella

Suspected rubella infection of patient	Suspected rubella contact
1. Test acute serum for haemagglutination inhibition (HAI) antibody to rubella	1. Test acute serum for HAI antibody to rubella
2. If HAI-positive in acute serum, reassure. If HAI continues negative, reassure	2. Test serum of the contact for rubella. If HAI-negative, reassure
3. If HAI-negative but then rises, offer termination or rubella immunoglobulin	3. If pregnant woman has rubella antibodies already, reassure
	4. If pregnant woman has no immunity and contact is, or is suspected of being, rubella-positive, retest patient's sera for HAI. If HAI continues negative, reassure. If HAI becomes positive, offer termination or rubella immunoglobulin

are not pregnant and are unlikely to become pregnant within the following 2 months. Rubella immunization should also be given to males who, as health-care workers, may come into contact with pregnant women.

Because of the danger to the fetus, pregnant patients exposed to, or developing, rubella or a similar rash should have serological investigation. The haemagglutination inhibition (HAI) test for rubella antibodies is rapid and reliable; antibody titre rises within 48 hours of illness or immunization, persists for years, and is useful for differentiating past infection from acute illness. Serum should be obtained within 2 days of the onset of the illness or within 2 weeks of exposure to the virus. If this acute serum is not available, complement fixation tests or assay of rubella-specific IgM antibody is required (Table 21.12).

OTHER VIRAL INFECTIONS

See Appendix 21.9.

MYCOSES (FUNGAL INFECTIONS)

Fungi are widespread and sometimes commensals, but infections may occur where general hygiene is low, where suitable local conditions (humid sites) are present and where people are immunocompromised, such as those with organ transplants or HIV/AIDS.

Fungal infections (Table 21.13) are often diagnosed on clinical grounds, supported by culture. Antifungal drugs can be effective therapy but resistance may arise, especially in long-term use or HIV/AIDS (Appendix 21.10). Most fungal infections have few untoward sequelae in otherwise healthy people but some can cause severe, recurrent, disseminated or persistent lesions in immunocompromised persons (Appendix 21.11).

SUPERFICIAL MYCOSES

The common superficial mycoses are candidosis and tinea.

CANDIDOSIS

Candidosis (candidiasis) is infection with *Candida* species, usually *Candida albicans*. Candidosis can produce a variety of clinical pictures but thrush is the best-known type. Thrush was aptly described in the nineteenth century as a ‘disease of the diseased’, and candidosis can

undoubtedly be a reflection of impaired immune responses. This has become particularly evident since HIV/AIDS was first recognized. *Candida* is one of many other fungi that can cause severe, recurrent, disseminated or persistent lesions in immunocompromised persons, such as those with AIDS (Figs 21.14 and 21.15).

Candida species other than *C. albicans* can cause candidosis (Table 21.14), particularly in immunocompromised individuals, and some, especially *C. krusei*, are resistant to conventional antifungal agents. Correction of any underlying local cause, and use of antifungals, is the usual treatment for candidosis. Topical gentian violet is now rarely used as an antifungal. Topical nystatin or an azole such as miconazole or fluconazole are the usual treatments. Nystatin is available as a suspension, miconazole as a gel or gingival muco-adhesive tablet.

Thrush

General aspects and clinical features

Thrush produces a highly characteristic picture of soft, creamy-coloured, slightly raised patches that *can be wiped off the mucosa*, leaving red areas. These lesions may form isolated flecks or large confluent areas. Typical sites are the vagina or mouth.

Thrush is common in the newborn, in whom it does not usually indicate any immunodeficiency and may resolve spontaneously or in response to topical antifungal treatment. In adults, unless they are known to be having immunosuppressive treatment, thrush is rare and should prompt investigation for an underlying cause. Thrush in a young or middle-aged adult must be regarded as a possible sign of HIV infection until proved otherwise. The other main predisposing factors are antibiotic treatment, anaemia, diabetes mellitus or an immunological defect, as shown in Table 21.15.

General management

The diagnosis is usually clinical but can be readily confirmed by taking a Gram-stained smear, which shows long tangled masses of candidal hyphae.

Superficial fungal infections often respond readily to topical treatment but deep-seated infections often require protracted systemic therapy. In addition to treatment of any underlying disorder, localized thrush should be manageable with topical antifungal drugs such as nystatin or amphotericin. Alternatively, a nystatin suspension or systemic fluconazole or suspension may be indicated.

Erythematous candidosis

General aspects and clinical features

Erythematous candidosis appears as mucosal erythema, in the mouth due to coverage of the mucosa with a denture (denture-related stomatitis; denture sore mouth), antibiotic treatment, xerostomia or immunodeficiency. Denture-related stomatitis (denture-associated stomatitis) is a common infection secondary to long-standing occlusion of part of the oral mucosa by a denture. Denture-related stomatitis typically develops beneath a well-fitting upper denture, which effectively cuts off the mucous membrane from the normal oral defence mechanisms. It is not seen under a lower denture, in spite of the fact that the latter is a common cause of trauma. The characteristic feature is uniform bright erythema of the whole of the upper denture-bearing area, limited by the denture margin. Occasionally, the erythema is patchy or there may be flecks of thrush. Symptoms are typically absent but occasionally there is soreness. Angular stomatitis is frequently associated. The vast majority of patients are healthy, as local factors alone determine the pathogenesis. Occasionally, patients may be anaemic but less frequently than might be expected from the fact that angular stomatitis is often regarded as a typical sign of iron deficiency. Other occasional contributory factors are dry mouth, diabetes mellitus or immune defects. It is, however, unjustifiable to screen all patients with denture-related stomatitis but investigation should be considered if the patient has any other complaints suggestive of such disorders or if the infection is particularly severe or intractable. Treatment includes leaving dentures out of the mouth at night and storing them in hypochlorite to clear the fungus from the denture surface. Topical antifungals should also be used, as suggested above, or the fitting surface of the denture can be coated with miconazole.

Antibiotic stomatitis occasionally follows the use of broad-spectrum antibiotics, particularly tetracycline used topically in the mouth. The whole of the oral mucosa is then typically red, oedematous and sore. One or two flecks of thrush may be found in protected situations, such as the posterior upper buccal sulcus. A similar picture of generalized redness and soreness of the oral mucosa is the typical manifestation of candidosis related to xerostomia. As with any other type of candidosis, angular stomatitis may be associated.

Xerostomia may also underlie erythematous candidosis. In HIV infection a patch of erythematous candidosis is sometimes seen on the palate or tongue.

General management

The treatment of erythematous candidosis is to deal with the underlying problem, if feasible, and to give antifungal drugs as described earlier.

Angular stomatitis

General and clinical aspects

Angular stomatitis (angular cheilitis; cheilosis) is most frequently seen as a complication of denture-related stomatitis but can be associated with any type of intraoral candidosis; in addition, it is a 'classic' sign of a deficiency anaemia.

General management

It is important to consider the possibility of underlying systemic disease, and treat it where possible.

Clearance of intraoral candidosis with adequate antifungal treatment typically leads to healing of the lesions at the angles of the mouth without any local treatment, but miconazole cream applied to

the lesion may be useful. Occasionally, bacteriological examination may be necessary, as the cause may be staphylococcal, but imidazoles such as miconazole or clotrimazole also have antibacterial activity and may be effective.

Candidal leukoplakia

General aspects and clinical features

Candidal leukoplakia (chronic hyperplastic candidosis) appears as white plaques clinically indistinguishable from other types of keratotic lesion, though they may be speckled, tough and firmly adherent; they are seen mainly in men of middle age or over, many of whom are heavy smokers. Typical sites are the buccal mucosa just within the commissures, or the dorsum or edges of the tongue. Long-standing angular stomatitis and occasionally also denture-related stomatitis may be associated. Patients are usually otherwise well.

Candidal leukoplakia may account for up to 10% of leukoplakias and several reports of malignant transformation have appeared. However, the prevalence of candidal leukoplakia and its potentialities remain uncertain.

General management

Diagnosis depends on biopsy, showing *C. albicans* hyphae and a characteristic inflammatory reaction in the superficial epithelial plaque. Investigations should include a family history and haematological examination. Investigations for cell-mediated responses to *C. albicans* may be needed to exclude one of the rare mucocutaneous candidosis syndromes that show similar oral lesions, as described below, but in most cases no abnormality is detectable.

Treatment is difficult, since the response to topical antifungal drugs such as nystatin or amphotericin is poor, and excision is also followed by recurrence. Antifungals like miconazole topically or ketoconazole or fluconazole systemically appear to be more effective.

Persistent candidosis

General aspects and clinical features

Persistent candidosis is a well-recognized complication of defective cell-mediated immunity (Box 21.8).

Both thrush and herpetic infection may be present together and produce confluent lesions.

General management

Candidal infection usually responds eventually to antifungal drugs but sometimes immunosuppressive treatment has to be moderated for a time. Patients on long-term corticosteroid treatment for any of the immunologically mediated diseases are also susceptible to oral candidosis but not often as a serious complication.

Box 21.8 Causes of persistent candidosis

- HIV infection
- Primary immunodeficiencies, especially severe combined (Swiss) type or DiGeorge syndrome
- Chronic mucocutaneous candidosis (CMCC)
- Intense immunosuppression, particularly for organ grafts
- Resistant *Candida* species

Chronic mucocutaneous candidosis (CMC or CMCC)

See Chapter 20.

‘Chronic candidiasis syndrome’

Many normal persons, around half the population, harbour *C. albicans* as part of their normal microflora. This finding has been exploited as a supposed explanation of such symptoms as headaches, fatigue and lassitude, rashes and gastrointestinal symptoms, but this so-called syndrome has absolutely no scientific basis, and there is no evidence that antifungal treatment is warranted. A controlled trial has shown that it has no effect on the symptoms.

TINEA

General aspects and clinical features

Tinea is a term for a range of common skin infections seen worldwide; they are caused by dermatophytes, usually *Trichophyton* (Table 21.16; Figs 21.16 and 21.17). Dermatophytes, specifically *Trichophyton*, *Epidermophyton* and *Microsporum* species, are responsible for most superficial fungal infections. Fungal transmission occurs through direct contact with infected persons, animals, soil or fomites.

General management

Treatment of tinea is with topical clotrimazole, miconazole or terbinafine, or oral fluconazole, itraconazole or terbinafine.

Dental aspects

Terbinafine may disturb taste. Azoles may enhance the effects of warfarin (Ch. 8).

Table 21.16 Forms of tinea

Tinea	Features	Organisms
Barbae	Beard area	<i>Trichophyton verrucosum</i>
Capitis ('ringworm')	Head; itchy, red areas, leaving bald patches	<i>Trichophyton tonsurans</i> <i>Microsporum andouinii</i> <i>Microsporum canis</i>
Corporis	Red spots growing into large rings on arms, legs or chest	<i>Trichophyton rubrum</i> <i>M. canis</i> <i>T. tonsurans</i> <i>T. verrucosum</i>
Cruris	Itchy erythema in moist, warm areas, e.g. the groin ('jock itch') or beneath the breasts (Fig. 21.16). Second most common tinea	<i>T. rubrum</i> <i>Epidermophyton floccosum</i>
Pedis (athlete's foot)	Most common tinea. Itchy and red moist skin between toes (Fig. 21.17), with a white, wet surface. Infection may spread to the toenails (tinea unguium – from Latin for nail). Toenails become thick and crumbly	<i>T. rubrum</i> <i>Trichophyton mentagrophytes</i> var. <i>interdigitale</i> <i>E. floccosum</i>
Versicolor	Patchy skin discolouration. Areas of infected face, for example, may appear lighter in colour (hypopigmented). Seen primarily in young adults	<i>Malassezia furfur</i>

Fig. 21.16 Tinea cruris.

Fig. 21.17 Tinea pedis.

SYSTEMIC MYCOSES (DEEP MYCOSES)

Healthy individuals in endemic areas (often in the developing world) are often infected with fungi, typically involving the lungs but often asymptomatic. In otherwise healthy persons, even acute pulmonary and primary mucocutaneous symptomatic mycotic lesions may resolve spontaneously. Chronic pulmonary infections tend to progress and disseminated infections can be fatal. Immunocompromised persons are at particular risk from clinical disease. Equally, clinical infection with mycoses may be an indication of an underlying immune defect. Severe, recurrent, disseminated or persistent lesions appear in immunocompromised persons, particularly those with HIV/AIDS, organ transplants, leukaemia, leukopenia, solid tumours or burns, and in premature infants.

The proliferation of mycoses in immunocompromised persons includes 'new' opportunists such as new *Candida* species, *Torulopsis glabrata*, *Fusarium* and *Trichosporon beigelii*.

Orofacial lesions caused by the main systemic mycoses may occasionally be seen in isolation but they are typically associated with lesions elsewhere, often in the respiratory tract. The diagnosis may be suggested by a tumour-like nodule or mass, chronic oral ulceration, chronic sinus infection or bizarre mouth lesions, especially in immunocompromised patients or in those who have been in endemic areas, or where there is granuloma formation found on biopsy. Investigations

include smear, biopsy, culture, sometimes serology, physical examination and chest radiography. Tissue forms of the fungus may be visible but special stains are often required.

Patients should be managed in consultation with a physician with appropriate expertise, usually with systemic antimycotics. Most systemic mycoses can be treated with systemic amphotericin given orally, liposomally or slowly intravenously, or with azoles. Adverse effects from intravenous amphotericin include thrombophlebitis, nephrotoxicity, chills, nausea, anaemia and hypokalaemia. The azoles are less toxic but the cost is prohibitive where they are most needed – in the developing world. Given orally, the adverse effects of ketoconazole include nausea, gynaecomastia and liver damage. The main adverse effects of miconazole include thrombophlebitis and ventricular tachycardia. Fluconazole and itraconazole are therefore now being used but fluconazole resistance can be a significant problem.

SYSTEMIC CANDIDOSIS

Candidosis is typically a superficial mycosis but, nevertheless, increasingly often causes invasion of deep organs, particularly in immunocompromised persons. Many *Candida* species are now responsible; some are resistant to fluconazole but voriconazole or caspofungin may be effective.

PNEUMOCYSTIS JIROVECI (CARINII)

General aspects and clinical features

Pneumocystis jiroveci (*carinii*) is now recognized to be a fungus rather than a protozoan. Some of the first patients recognized in the HIV epidemic were revealed because of *Pneumocystis* pneumonia (PCP); it is a common infection in AIDS and other severely immunocompromised patients.

General management

Treatment is with co-trimoxazole, inhaled pentamidine isetionate or atovaquone.

ASPERGILLOSIS

General aspects and clinical features

Aspergillus species are the most common environmental fungi and are prolific saprophytes in soil and decaying vegetation.

Aspergillosis is found worldwide; it is increasing in frequency and is the most prevalent mycosis after candidosis. Inhalation of *Aspergillus* spores and colonization of the respiratory tract are common but disease is rare. Types of aspergillosis include the following:

- *Allergic bronchopulmonary aspergillosis* – the most common disease
- *Invasive aspergillosis* – a rare lung infection that may spread to brain, bone or endocardium. Invasive sinus aspergillosis affects mainly immunocompromised hosts, though it is also seen in some apparently healthy individuals in subtropical countries, such as Sudan, Saudi Arabia or India
- *Aspergillus fumigatus* – the usual cause of invasive sinus aspergillosis, although *A. flavus* appears to predominate in immunocompromised patients. There is destruction of the antral wall and often antral pain, swelling or sequelae from orbital invasion (impaired ocular motility, exophthalmos or impaired vision) or intracranial extension (headaches, meningism)

- *Aspergillomas* – fungus balls that grow in pre-existing cavities, such as tuberculous lung cavities. Aspergilloma of the maxillary antrum is uncommon, typically appearing in a healthy host as a hyphal ball in a chronically obstructed sinus
- *Chronic sinus aspergillosis* – an uncommon cause of a diffusely radio-opaque antrum, sometimes with dense punctate radio-opacities. It is unresponsive to treatment used for bacterial sinusitis. Occasional cases of sinus aspergillosis are a result of metastasis from pulmonary aspergillosis or are iatrogenic, following dental procedures such as extractions
- *Allergic fungal sinusitis* – an uncommon problem, usually due to fungi other than *Aspergillus*.

General management

Diagnosis of antral aspergillosis is supported by MRI and CT (which are more sensitive than conventional radiography in detecting bone erosion) and confirmed by smear and lesional microscopy, staining with periodic acid–Schiff (PAS) or Gomori methenamine silver. Immunostains may help definitive diagnosis.

Prolonged conservative therapy may worsen the prognosis. Topical ketoconazole or clotrimazole may clear superficial infections. If there is no resolution in 72 hours, a course of systemic amphotericin should be tried. Miconazole is not active and ketoconazole is not particularly active against *Aspergillus*, but itraconazole may have a place in treatment. Fluconazole is under trial.

Non-invasive antral forms usually need treatment by antral debridement and drainage. Corticosteroids may also be indicated in allergic sinusitis.

Invasive aspergillosis should be treated by surgical debridement supplemented with amphotericin and, possibly, hyperbaric oxygen.

BLASTOMYCOSES

General aspects and clinical features

Blastomyces dermatitidis causes North American blastomycosis, seen predominantly in the USA and Canada. *Paracoccidioides brasiliensis* causes the South American form, seen especially in Brazil. Inhalation of spores, found in soil, leads to subclinical infection in up to 90% of the population in endemic areas. Outdoor workers are particularly affected.

Clinical illness is typically pulmonary. HIV infection and other immunocompromising states predispose to pulmonary and disseminated disease.

General management

Diagnosis is based on biopsy, smear or culture. Amphotericin, ketoconazole, miconazole, itraconazole and voriconazole can be effective.

COCCIDIOIDOMYCOSIS

General aspects and clinical features

Coccidioidomycosis is seen mainly in hot dry areas of the south-west USA, Mexico, Central America and parts of South America. Inhalation of spores of *Coccidioides immitis*, found in soil, produces subclinical infection in up to 90% of the population. Clinical illness is typically acute pulmonary disease and fever (San Joaquin valley fever). Chronic pulmonary disease is less common but pregnant women, blacks, Filipinos, Mexicans and immunocompromised persons are susceptible.

General management

Diagnosis is mainly by history and examination, supported by histology and the spherulin or coccidioidin skin tests. Management is with systemic amphotericin, sometimes supplemented with ketoconazole, itraconazole, fluconazole or voriconazole.

CRYPTOCOCCOSIS

General aspects and clinical features

Cryptococcosis is seen worldwide. Aspiration of spores of *Cryptococcus neoformans*, a yeast found especially in pigeon faeces and soil, may lead to infection. In healthy persons, infection is typically pulmonary and subclinical. Immunocompromised persons are liable to dissemination of infection to meninges, heart, spleen, pancreas, adrenals, ovaries, muscles, bones, liver and gastrointestinal tract. Most patients with disseminated cryptococcosis have meningoencephalitis and, untreated, this is fatal in over 70%.

Cryptococcosis is the most common systemic mycosis in AIDS.

General management

Diagnosis is confirmed by microscopy, culture and assay of serum or cerebrospinal fluid for capsular antigen and antibody. Systemic amphotericin is effective, best supplemented with flucytosine. Ketoconazole and itraconazole may be effective.

HISTOPLASMOSIS

General aspects and clinical features

Histoplasmosis is found worldwide and is the most frequent systemic mycosis in the USA. *Histoplasma capsulatum* is present especially in bird and bat faeces and is a soil saprophyte found particularly in the Ohio and Mississippi valleys, Latin America, India, the Far East and Australia. In endemic areas, over 70% of adults are infected, typically subclinically, by inhaling spores. Clinical histoplasmosis includes acute and chronic pulmonary and cutaneous forms. Disseminated and potentially fatal histoplasmosis, which can affect the reticuloendothelial system, lungs, kidneys and gastrointestinal tract, is rare and seen typically in immunocompromised patients, especially in HIV/AIDS.

General management

Diagnosis is confirmed by microscopy, culture and serotests. Amphotericin is the first line for treatment, followed by ketoconazole, fluconazole, itraconazole or voriconazole.

MUCORMYCOSIS (ZYGOMYCOSIS; PHYCOMYCOSIS)

General aspects and clinical features

Mucorales are responsible for most mucormycosis. *Mucor*, *Rhizopus* and many other species of the class Zygomycetes can be responsible and therefore the condition is probably better termed zygomycosis. These fungi are ubiquitous worldwide in soil, manure and decaying organic matter, and can commonly be cultured from the nose, throat, mouth and faeces of healthy individuals.

Immunocompromising conditions underlie most zygomycosis; diabetes mellitus and leukaemia are the most important underlying causes but

cases are now appearing in HIV/AIDS and malnutrition. Rhinocerebral and pulmonary zygomycoses are the most common forms.

Rhinocerebral zygomycosis is usually caused by *Rhizopus oryzae*; it typically starts in the nasal cavity or paranasal sinuses with pain and nasal discharge, accompanied by fever, and may then invade the palate, orbit or skull. Orbital invasion may cause orbital cellulitis, impaired ocular movements, proptosis and ptosis. Intracranial invasion follows penetration of ophthalmic vessels or the cribriform plate.

General management

Zygomycosis used to be almost uniformly fatal and still has a mortality approaching 20%. Radiography or MRI typically shows thickening of the antral mucosa with patchy destruction of the walls, and may define the extent of the lesion.

Diagnosis is confirmed by smears and histological demonstration of tissue invasion by hyphae. Control of underlying disease is essential, if at all possible, together with systemic amphotericin and surgical debridement.

RHINOSPORIDIOSIS

Rhinosporidium seeberi can infect the nasal and other mucosae. It is particularly common in India and Sri Lanka, but also found in Latin America, Africa and South-East Asia. Mouth lesions are usually proliferative lumps on the palate. Diagnosis is by biopsy. Surgery is required for treatment.

SPOROTRICHOSIS

Sporothrix schenckii is found throughout the world, mainly as a saprophyte on plants and shrubs. Disease is seen almost exclusively in visitors to tropical and subtropical countries. Infection follows an injury to the epithelium resulting in a primary lesion – a sporotrichotic chancre. Lesions may then spread by the lymphatics. Pulmonary and disseminated sporotrichoses are rare and of uncertain origin.

Diagnosis is confirmed by histology and culture. Potassium iodide is effective treatment for superficial sporotrichosis, itraconazole or amphotericin for other forms.

CRYPTOSPORIDIOSIS ('CRYPTO')

Cryptosporidiosis is a diarrhoeal disease spread in animal and human faeces; it is one of the most frequent causes of water-borne disease among humans and can be spread by drinking and recreational water. *Cryptosporidium* is a parasite found throughout the world in soil, food, water or surfaces that have been contaminated with faeces from infected humans or animals. *Cryptosporidium* survives outside the body for long periods of time, and is resistant to chlorine disinfection. It is not spread by contact with blood but exposure to human faeces through sexual contact may transmit infection. People who are most likely to become infected with *Cryptosporidium* include:

- children who attend day-care centres
- child-care workers
- people who take care of others with cryptosporidiosis
- international travellers
- backpackers, hikers and campers who drink unfiltered, untreated water

- people who drink from untreated shallow, unprotected wells
- people, including swimmers, who swallow water from contaminated sources
- people who handle infected cattle
- people exposed to human faeces through sexual contact.

Although cryptosporidiosis can infect anyone, young children, pregnant women and the immunocompromised are likely to develop more serious illness.

Clinical features

The incubation period is 2–10 days (average 7 days). Some people with cryptosporidiosis have no symptoms but the most common symptom is watery diarrhoea. Other features include:

- abdominal pain
- nausea
- vomiting
- dehydration
- fever
- weight loss.

General management

Treatment for cryptosporidiosis is nitazoxanide.

INFESTATIONS

Parasitic infestations are endemic in the tropics and developing world, and are seen increasingly frequently in developed countries, in travellers or immigrants; infection is usually acquired from animals (zoonotic parasites), water or improperly prepared food. Common parasitic infestations include fleas, lice, mites and ticks, all transmitted between humans, particularly in conditions of poor hygiene and close-living and in war areas; sometimes disease can be fatal. Serious parasitic infections are shown in Box 21.9 and Appendix 21.12.

Since the appearance of the HIV/AIDS pandemic, parasitic infestations, especially toxoplasmosis and leishmaniasis, are now being recognized in HIV-infected patients.

Many parasitic infestations can be prevented by avoidance of insect bites (avoiding areas of high prevalence, maintaining good hand and food hygiene, and using protective clothing and insect repellents), especially at high-risk times (dusk is the worst time for many mosquitoes, though dengue is transmitted by mosquitoes that bite during the day). Many parasitic infestations are difficult to diagnose unless there is a high index of suspicion. Clinicians and pathologists should therefore

Box 21.9 Main parasitic infestations

- Amoebiasis – common in the developing world; causes gastrointestinal disease
- Giardiasis – common worldwide; causes gastrointestinal disease
- Leishmaniasis – common in the tropics and around the Mediterranean; may cause skin lesions
- Malaria – one of the more serious infestations worldwide; common in the tropics, where anopheline mosquitoes survive; causes haemolysis
- Toxoplasmosis – one of the more serious infestations worldwide; endemic in the developing world, relatively common in the developed world; causes eye and CNS disease
- Worms, fleas, lice, ticks, mites and maggots (Ch. 33)

be vigilant, especially when examining lesions in travellers or immigrants. Treatments include a range of medications, and patients should be managed in consultation with a specialist physician.

AMOEBIASIS

General aspects and clinical features

Entamoeba histolytica can cause amoebic dysentery or amoebic liver abscesses.

General management

Metronidazole is used. Diloxanide furoate clears cysts from symptomless patients.

GIARDIASIS

General aspects and clinical features

Giardia lamblia is a protozoon, cysts of which may be found in unfiltered drinking and recreational waters contaminated by faeces of humans or animals in many parts of the world. Features include anorexia, chronic diarrhoea, abdominal cramps, bloating, frequent loose greasy stools, fatigue and weight loss.

General management

Treatment is with metronidazole, tinidazole or mepacrine.

LEISHMANIASIS

General aspects and clinical features

A blood-sucking sandfly is the intermediate host; humans or other vertebrates, including dogs and cats, are the definitive hosts. The developmental stage is the amastigote in the vertebrate host and promastigote in the arthropod host. After inoculation into the skin, leishmanias multiply within histiocytes. Leishmaniasis is one of the most common HIV/AIDS-associated opportunistic infections in Spain. Human *Leishmania* species, although similar in morphology and life cycle to one another, produce different types of infection.

Mucocutaneous leishmaniasis usually has an incubation period of 2–8 weeks but it can be as long as 3 years. An itching papule at the site of the sandfly bite (usually on the face) becomes surrounded by gradually spreading erythema and induration. In a few days, the surface crusts, then breaks down to form a slowly extending ulcer that discharges fluid. Healing usually begins in 3–12 months, leaving a scar. Secondary lesions develop at the mucocutaneous junctions many years after the primary infection and are destructive. The nose is the site of predilection.

Visceral leishmaniasis causes fever, splenomegaly, anaemia, wasting, cough and diarrhea, and is potentially fatal.

General management

Clinical and serological tests are useful diagnostically but the demonstration of the parasite in biopsies or smears is definitive. A leishmanin skin test is also available. Mucocutaneous leishmaniasis may heal spontaneously but, since there can be extensive destruction of tissue, chemotherapy is indicated.

Pentavalent antimony as sodium stibogluconate or meglumine antimonate is usually effective. Alternatives are amphotericin or pentamidine isetionate. Miltefosine is the only available oral treatment for visceral, cutaneous, and mucosal leishmaniasis.

MALARIA

General aspects and clinical features

Malaria is the most serious and common parasitic infection worldwide; it still infects over 100 million persons, mainly in tropical areas of Africa, Latin America and Asia. It is transmitted by mosquito bites and is potentially fatal.

There are four main species of the protozoon, usually *Plasmodium falciparum* or *P. vivax*, sometimes *P. ovale* or *P. malariae*. In highly endemic areas, the patient may become infected with one, two or even more species of the malarial parasite. In India, 4–8% of cases are due to mixed infection. The plasmodium infects erythrocytes and damages them, causing haemolysis, as well as fever, myalgia, headaches and, in some cases, cerebral involvement. Infection with *P. falciparum* is the most dangerous (Table 21.17) and often fatal (malignant malaria) due to haemolysis and sludging in intracerebral vessels. Infection with *P. vivax*, *P. ovale* or *P. malariae* is usually benign.

Typical features of malaria are incapacitating episodes of hyperrexia, rigors and chills, sometimes recurring for years.

Table 21.17 Malaria

Plasmodium	Comments	Chloroquine resistance
falciparum	Widespread. Results in the most severe infections and responsible for nearly all malaria-related deaths. 'Severe' and 'complicated' are the terms used more frequently than 'malignant' to describe this type of malaria	Chloroquine-resistant strains found in South America, Central America east of the Panama Canal, the Western Pacific, East Asia and sub-Saharan Africa. Resistance to combination of pyrimethamine and sulfadoxine in South-East Asia, Amazon Basin and sub-Saharan Africa. Variable degrees of resistance to quinine and quinidine in South-East Asia and Oceania, and in sub-Saharan Africa
malariae	Restricted distribution in India and responsible for less than 1% of infections	No chloroquine resistance
ovale	A rare parasite of humans; mostly confined to tropical Africa	No chloroquine resistance
vivax	The widest geographical distribution throughout the world. Causes much debilitating but relatively mild disease, which is seldom fatal. Also called benign or uncomplicated malaria	High levels of chloroquine resistance in Indonesia and Papua New Guinea, also Solomon Islands, Myanmar, Brazil, Colombia. Resistance to pyrimethamine and sulfadoxine, particularly in South-East Asia

General management

Diagnosis is made from the history of travel to a malarial area and from clinical features, confirmed by demonstrating the parasite in a blood smear. Repeated smears may be required.

Treatment of *P. malariae* disease is usually chloroquine; that of *P. ovale* and *P. vivax* malaria is usually chloroquine followed by primaquine; and that of *P. falciparum* infections (which are often drug-resistant, particularly in Asia and Latin America) is currently with quinine, mefloquine or artesunate or artemether or artemether with lumefantrine.

Prophylaxis

Specialist advice should always be sought before travel to the tropics. Disease is transmitted by the bite of an infected mosquito, and clothing, insect repellents and nets reduce the risk. Prophylactic chemotherapy does not guarantee total protection but may be life-saving. It may be with chloroquine and/or proguanil, but mefloquine or doxycycline or proguanil plus atovaquone is recommended where the malaria risk is high and chloroquine resistance likely; it should commence well before entering the malarial area and continue for 6 weeks after leaving.

TOXOPLASMOSIS

General aspects and clinical features

Toxoplasma gondii is a common intestinal parasite of many animals, particularly cats. Infection is contracted mainly from the ingestion of cysts, either from animal faeces or in inadequately cooked food (up to 10% of lamb and pork contains cysts). *Toxoplasma* may also be transmitted occasionally in infected blood or blood products.

T. gondii may cause a glandular fever-type of illness with fever and cervical lymphadenopathy, sometimes with rash, hepatosplenomegaly, myalgia and other minor features. Some patients may develop chorioretinitis, which threatens sight, severe pneumonia, necrotizing encephalitis or myocarditis, but such untoward sequelae are seen mainly if the patient is immunocompromised. Central nervous system (CNS) involvement is common, and can cause changes in mental status, headache, neurological defects and epilepsy. CT or MRI scans may demonstrate the lesions.

Toxoplasmosis in pregnancy may lead to chorioretinitis, or transplacental spread and fetal infection, with resultant congenital defects and blindness (TORCH syndrome; Fig. 21.18).

Fig. 21.18 Congenital toxoplasmosis causing learning impairment with visual and hearing defects.

General management

Toxoplasmosis is confirmed serologically by the Sabin–Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test or indirect haemagglutination test. The organism may be demonstrable in tissue sections or smears. Treatment is *not* usually required for asymptomatic healthy infected persons who are not pregnant. For immunocompromised patients with toxoplasmosis, treatment is a combination of pyrimethamine and sulfadiazine, together with folic acid (pyrimethamine is a folate antagonist), continued for at least 1 month after clinical resolution. Weekly full blood counts are essential.

For pregnant patients with toxoplasmosis, sulfadiazine alone is used since pyrimethamine may be teratogenic. Clindamycin, clarithromycin and azithromycin are alternatives.

WORMS

A range of helminths can occasionally infect humans (Table 21.18).

CYSTICERCOSIS

Cysticercus cellulosae (encysted larva of *Taenia solium*) can cause cysticercosis, which prevails in regions of poverty and where hygiene is insufficient, particularly Africa, the Far East, India, Latin America, Eastern Europe and the Iberian peninsula. It is rare in Jews and Muslims since they avoid pork.

General aspects and clinical features

The adult *T. solium* lives in the intestine of humans, the only definitive host. The stools release eggs, which, if they contaminate the ground,

Table 21.18 Worms (helminths)

Usual helminth	Geographical distribution	Therapy
Cestodes		
<i>Cysticercus cellulosae</i> (<i>Taenia solium</i> larvae)	Worldwide	Niclosamide Praziquantel
<i>Echinococcus granulosus</i>	Middle East, North and East Africa, Asia, Latin America, Australasia	Albendazole
Nematodes		
<i>Ancylostoma duodenale</i>	Mediterranean littoral, Middle East, China, India, South America	Mebendazole
<i>Ascaris lumbricoides</i>	Worldwide	Mebendazole Levamisole
<i>Filariae</i>	South-East Asia, India, East Africa, South America	Diethylcarbamazine Ivermectin
<i>Gnathostoma spinigerum</i>	South-East Asia	Albendazole Ivermectin
<i>Gongylonema pulchrum</i>	Former USSR, China, Sri Lanka	Albendazole
<i>Onchocerca volvulus</i>	Africa, Central America	Ivermectin Diethylcarbamazine
<i>Schistosoma mansoni</i> , <i>S. haematobium</i> or <i>S. japonicum</i>	Middle and Far East, Latin America, sub-Saharan Africa	Praziquantel
<i>Trichinella spiralis</i>	Worldwide	Mebendazole
<i>Trichuris trichiura</i>	South-East Asia	Mebendazole

can be swallowed by pigs. The eggs hatch in the pig's intestine, releasing oncospheres that enter the bloodstream and become encysted as cysticerci in muscle. Pork is then the intermediate host. The life cycle is completed when humans ingest inadequately cooked pork containing cysticerci (measly pork), which, upon reaching the human intestine, release the oncospheres. Oncospheres also penetrate the gut mucosa and are distributed to various tissues and organs, particularly muscles; here they develop into cysticerci, most commonly in the brain and eye, striated muscles in the tongue, neck and trunk, and skin and subcutaneous tissues.

General management

Prevention relies on thorough cooking of pork meat and good hygiene.

Diagnosis usually relies upon identification of the parasite. The appearance of the translucent membrane, with its central milky spot, is characteristic.

Praziquantel plus prednisolone (prednisone), or albendazole, or niclosamide can be curative. Single or even multiple parasites may be excised from tissues and organs.

ECHINOCOCCOSIS (ECHINOCOCCIASIS)

Echinococcosis (hydatid disease) is caused most often by larvae (cestodes) of the tapeworm *Echinococcus granulosus*. Echinococcosis has been a serious problem in many sheep-raising regions, most prevalently in Australia, New Zealand, South, East and North Africa, Mediterranean countries and parts of the Russian Federation, Middle East and Americas.

General aspects and clinical features

The adult tapeworm *E. granulosus* lives in the small intestine of sheep mainly, though many mammals can serve as intermediate hosts. The eggs hatch in the sheep's intestine, releasing oncospheres that penetrate the intestinal mucosa, enter the bloodstream and develop into hydatid cysts in various organs, particularly the liver and the lungs. Daughter cysts pass in the faeces. Dogs and wolves are infected by eating the discarded offal of sheep and deposit eggs in their faeces. Humans are an accidental intermediate host, usually infected by ingestion of eggs from the faeces of dogs, typically from improper hand-washing and, less often, by ingestion of contaminated water or food such as lamb or mutton containing cysts or eggs. The incubation is from 10 to 30 years. Only the larval stage, the hydatid cyst, develops in humans and there are no specific clinical signs until a cyst becomes large enough to act as a space-occupying lesion, causing compression of adjacent structures. Typically, the liver and sometimes the lungs, bone or brain are affected.

General management

A skin test (Casoni test) is available but not specific. Serology may be helpful. Eosinophilia is merely suggestive of a parasitic disease and not specific. The hydatid cyst can sometimes be demonstrated radiographically or by MRI or ultrasound, but a definitive diagnosis is often made only by identifying it at operation.

Prevention relies on protecting definitive hosts (dogs), as well as intermediate hosts (sheep), from contamination. Thorough hand-washing, washing of vegetables and wild berries located close to the ground, and elimination of contact with potentially contaminated dogs are the best measures. High doses of albendazole, mebendazole or flubendazole interfere with larval growth but are not curative. Only surgery is curative.

FILARIASIS

General aspects and clinical features

Filariae are helminths transmitted by the bite of blood-sucking insects, usually mosquitoes or black flies, whose adult and larval forms are found in humans. The main filariasis is onchocerciasis, seen mainly in tropical Africa but also in Saudi Arabia, Yemen and Latin America. It may involve the face, and eye lesions remain a major problem in Africa (river blindness). The diagnosis is made by identifying the worm in biopsies. Treatment is with ivermectin.

Lymphatic filariasis is infestation, particularly by *Wuchereria bancrofti* or *Brugia malayi*, transmitted by blood-sucking mosquitoes and most common in India, South-East Asia, the South Pacific, Latin America, East Africa and Egypt. The lymphatics are affected, causing obstructive oedema or elephantiasis. Diagnosis is from blood examination for filariae. Diethylcarbamazine is the treatment of choice.

GNATHOSTOMIASIS

Gnathostomiasis is a rare benign infestation, seen mainly in South and South-East Asia; it is caused by larvae of the nematode *Gnathostoma spinigerum*, harboured in chicken, snails or fish. The worm may cause swellings in the skin or mouth, or occasionally bleeding. Skin tests and serology help the diagnosis. Metronidazole, albendazole or ivermectin may be of some benefit or the worm can be excised.

LARVA MIGRANS

General aspects and clinical features

Adult hookworms live mainly in animal intestines and release ova into the faeces, which are then found in sand or soil contaminated by the animals. The ova hatch into infective larvae, which can infect human skin; here they fail to develop fully but may wander in the tissues, causing 'larva migrans'. Larva migrans is common in tropical climates, along the US coast from southern New Jersey to Florida, around the Caribbean and around the Mediterranean. It is seen especially in those working or playing in warm, moist, shaded sandy places.

There are two types of larva migrans:

- *Visceral larva migrans* is synonymous with toxocariasis – infection by larvae from roundworms of dogs, cats or wild carnivores
- *Cutaneous larva migrans* (creeping eruption) is caused by hookworms of dogs, cats and other mammals and characterized by itching serpiginous tracks, mainly on the feet, hands or buttocks.

Larva migrans is self-limiting but nearly 50% of patients can develop transient migratory pulmonary infiltrates with eosinophilia (Loeffler syndrome).

General management

Larva migrans can be prevented by stopping dogs, cats and other animals contaminating play areas. Treatments include thiabendazole, albendazole, ivermectin or mebendazole. Local application of 10% thiabendazole, ethyl chloride, chloroform, electrocoagulation and cryotherapy have been tried for cutaneous lesions.

THREADWORMS

General aspects and clinical features

Threadworms (*Enterobius vermicularis*; pinworms) are common infestations worldwide. The ova are swallowed and worms develop when

exposed to digestive juices of the upper gastrointestinal tract. Female worms lay ova on the anal skin, which cause intense peri-anal itching.

General management

Treatment must involve the whole family and includes mebendazole (or piperazine) and improved hygiene.

TRICHINOSIS

General aspects

Trichinosis is the most frequent roundworm infestation to affect muscles.

Trichinella spiralis is a nematode acquired through the ingestion of contaminated meat, usually pork products. Trichinosis is more prevalent in Central Europe and North America, where pork is widely consumed, than in Islamic or Jewish cultures or tropical countries. Both larval and adult forms of *T. spiralis* can parasitize humans as the definitive host but later they become the intermediate host when the larvae are established in the muscles. The same host sustains the adult worm temporarily, but the larvae for a long period of time. After ingestion of infected meat, the larvae mature to adult forms in the intestine in approximately 1 week. Adult female nematodes then deposit larvae in the gastrointestinal mucosa. The larvae penetrate and subsequently enter the bloodstream and pass to muscles such as the tongue, masseter, gastrocnemius, deltoid and diaphragm, where they grow and develop, and become encapsulated. Many infestations are subclinical but they can calcify and appear as radio-opaque nodules.

Clinical features

In mild infections, symptoms are often vague and transient. Acute trichinosis is characterized by myalgia, facial and palpebral oedema, and fever with eosinophilia. Myocarditis is present in up to 20% and there may be involvement of lungs, kidneys, pancreas and CNS.

General management

The diagnosis is clinical, supported by a history of ingestion of poorly cooked meat and by investigations. There is eosinophilic leukocytosis, serodiagnosis is feasible after the third week, and serum levels of muscle enzymes (such as creatine phosphokinase) are also raised. However, definitive diagnosis relies on biopsies from affected muscle or blind biopsies from the deltoid or gastrocnemius muscles.

Treatment is mebendazole or thiabendazole. Prevention requires meat to be cooked throughout at a temperature above 65°C.

TRICHURIASIS

General aspects and clinical features

Trichuriasis, infestation of the large intestine by the whipworm *Trichuris trichiura*, is common in the Caribbean and South-East Asia, especially in children, who contract the condition by ingesting eggs from contaminated soil.

General management

Trichuriasis is diagnosed by faecal examination for the worms. Treatment is mebendazole or albendazole.

MITES

General aspects and clinical features

Scabies is a common infestation with the mite *Sarcoptes scabiei*, which is transmitted by close contact, particularly in bed. The mite burrows into the superficial skin and lays eggs, which excite an inflammatory response and an itchy rash, typically interdigitally and on the wrists.

General management

Patient and family/partners need improved hygiene and treatment with malathion or permethrin.

MAGGOTS

General aspects and clinical features

Myiasis is the condition when fly maggots invade living tissue, most commonly the nose, or when they are harboured in the intestine or any part of the body and feed on the host's organs. Human myiasis is most common in the tropics.

Various flies can cause human myiasis; most troublesome in the New World is *Cochliomyia hominivorax* (screwworm). *Chrysomya bezziana* is seen in Africa, Asia, the Pacific Islands and the Old World.

Larvae burrow through tissue and may produce a type of larva migrans creeping eruption (see earlier); when they mature, they migrate out of the host in an effort to reach soil to pupate, and may then be visible.

General management

A few drops of turpentine or 15% chloroform in light vegetable oil should be instilled in the lesion and larvae should be removed with blunt tweezers.

APPENDIX 21.1 EMERGING INFECTIONS

Infection	Comments	Distributions
Acquired immunodeficiency syndrome (AIDS); human immunodeficiency virus (HIV)	Recognized in 1980s	Worldwide
Bovine spongiform encephalopathy (BSE; 'mad cow disease').	Prion disease first recognized in mid-1980s	UK mainly
Cholera new strain: 0139	Appeared in 1992 in south-eastern India	India, into western China, Thailand and other parts of South-East Asia
Cryptosporidiosis	Came to prominence in AIDs epidemic	Worldwide
Diphtheria	Epidemics since 1980s following lax vaccinations	Russian Federation and other former republics of the USSR
Ebola	Recorded in Zaire and Sudan in 1976; struck in Côte d'Ivoire in 1994 and 1995, Liberia in 1995, and again in Zaire in 1995	Africa, Asia, USA and Latin America
Enterococci strains	Outbreaks resistant to the main groups of antibiotics, such as the beta-lactams and the aminoglycosides	USA and other countries
<i>Escherichia coli</i> O157:H7 strain	Appeared in 1982	
Hantavirus pulmonary syndrome	First recognized in USA in 1993	Hantavirus infection has been detected in more than 20 US states, and has also surfaced in Argentina and Brazil. Other hantaviruses have been recognized for many years in Asia
Influenza pandemics	–	Worldwide
Resistant tuberculosis, malaria, cholera, dysentery, pneumonia, staphylococci, streptococci	–	Worldwide
<i>Salmonella typhi</i> , resistance to antibiotics	–	Resistance to multiple drugs is common in South-East Asia
<i>Salmonella typhimurium</i> isolated from cattle is paralleled by increasing resistance among strains of human origin	–	India and Pakistan in recent years
<i>Shigella dysenteriae</i>	–	Thailand
		Central and southern Africa

APPENDIX 21.2 SOME INFECTIOUS DISEASES: INCUBATION TIMES AND PERIOD OF INFECTIVITY

Incubation period	Disease	Incubation period	Period of infectivity
<1 week	Diphtheria	2–5 days	Until treated ^a
	Gonorrhoea	2–5 days	Until treated ^a
	Influenza	1–2 days	Until fever gone
	Scarlet fever	1–3 days	3 weeks after onset of rash
	Hand, foot and mouth	3–6 days	Until rash gone
1–2 weeks	Herpes	2–12 days	Until lesions gone ^a
	Measles	7–14 days	4 days after onset of rash
	Pertussis	7–10 days	21 days after onset of symptoms
2–3 weeks	Chickenpox	14–21 days	Until all lesions scab ^a
	Mumps	12–21 days	7 days after onset of sialadenitis
	Rubella	14–21 days	7 days after onset of rash
>3 weeks	Hepatitis A	2–6 weeks	Usually non-infective at diagnosis
	Hepatitis B	2–6 months	3 months after jaundice resolves ^a
	Hepatitis C	2–26 weeks	3 months after jaundice resolves ^a
	Human immunodeficiency virus (HIV)	Up to 5 y	Persists. ^a Average time from infection to acquired immunodeficiency syndrome (AIDS) is 10 y in the untreated
	Human papillomavirus (HPV)	30–180 days	While lesions present
	Infectious mononucleosis (Epstein–Barr virus)	30–50 days	Until fever resolved. ^a Once infected, patients intermittently excrete the virus asymptotically for the rest of their lives. Thus most people who develop infectious mononucleosis have not had contact with someone who has had a recent illness
	Syphilis	10–90 days	Until treated ^a
	Tuberculosis	14–70 days	Until treated ^a

^aCarrier states exist.

APPENDIX 21.3 SOME ANTIBACTERIALS

Antibacterial	Group	Examples
Aminoglycosides	–	Amikacin Gentamicin Neomycin Streptomycin Tobramycin
Beta-lactams	Penicillin	Benzyl penicillin Phenoxymethyl penicillin
		Flucloxacillin Temocillin
	Broad-spectrum penicillins	Amoxicillin Ampicillin Co-amoxiclav Co-fluampicil
		Piperacillin Ticarcillin
		Pivmecillinam
	Mecillinams	
	Cephalosporins	First-generation (cephalosporin)
		Second-generation (cefuroxime, cefamandole)
		Third-generation (cefotaxime, ceftazidime, ceftriaxone)
	Carbapenems	Imipenem–cilastatin Doripenem Ertapenem Meropenem
		Aztreonam
	Monobactams	
Glycopeptides	–	Teicoplanin Vancomycin
Lincosamides	–	Clindamycin

(Continued)

Antibacterial	Group	Examples
Macrolides	–	Azithromycin Clarithromycin Erythromycin Spiramycin Telithromycin
Nitroimidazoles	–	Metronidazole
Oxazolidinones	–	Linezolid
Quinolones (fluoroquinolones; 4-quinolones)	–	Ciprofloxacin Norfloxacin Ofloxacin
Sulphonamides and trimethoprim	–	Co-trimoxazole
Tetracyclines	–	Doxycycline Minocycline Tetracycline Tigecycline is related

APPENDIX 21.4 SUMMARY OF THE MAIN ANTIBACTERIAL AGENTS USED IN DENTISTRY

Antibacterial	Comments	Cautions and contraindications
<u>Penicillins</u>		
Amoxicillin	Given by mouth (absorption better than ampicillin) Broad-spectrum (effective against many Gram-negative bacilli) <i>Staphylococcus aureus</i> often resistant Not resistant to penicillinase	Contraindicated in penicillin allergy Rashes, particularly in infectious mononucleosis, lymphoid leukaemia, or during allopurinol treatment May cause diarrhoea
Ampicillin	Less well absorbed than amoxicillin, otherwise similar (many analogues, such as bacampicillin and pivampicillin – but few advantages) Available with cloxacillin (Ampiclox) or flucloxacillin (co-fluampicil)	Contraindicated in penicillin allergy. Causes transient rashes if given to patients with glandular fever, leukaemia or cytomegalovirus infection
Benzyl penicillin	Given i.m. or i.v. Most effective penicillin when organism is sensitive Not resistant to penicillinase	Contraindicated in penicillin allergy Large doses may cause K ⁺ to fall, Na ⁺ to rise
Co-amoxiclav	Mixture of amoxicillin and potassium clavulanate Inhibits some penicillinases (beta-lactamases) and therefore active against most <i>Staph. aureus</i> ; also active against some Gram-negative bacilli	Contraindicated in penicillin allergy May cause cholestatic jaundice
Flucloxacillin	Given by mouth Effective against most penicillin-resistant staphylococci	Contraindicated in penicillin allergy Treatment in elderly, or for more than 2 weeks, may result in cholestatic jaundice
Phenoxyethyl penicillin (penicillin V)	Given by mouth Not resistant to penicillinase Used for prophylaxis of rheumatic fever, in sickle cell disease, and after splenectomy	Contraindicated in penicillin allergy
Procaine penicillin	Depot penicillin Not resistant to penicillinase	Contraindicated in penicillin allergy Rarely, psychotic reaction due to procaine
Temocillin	Given by i.m. or i.v. injection Active against penicillinase-producing Gram-negative bacteria	Contraindicated in penicillin allergy
Triplopen	Depot penicillin (benzyl penicillin 300 mg, procaine penicillin 250 mg, and benethamine penicillin 475 mg) Not resistant to penicillinase	Contraindicated in penicillin allergy
<u>Tetracyclines</u>		
Tetracyclines	Very broad antibacterial spectrum. Little to choose between the many preparations, but doxycycline and minocycline (see later) are safer for patients with renal failure Given by mouth	Absorption impaired by iron, antacids, milk, etc. May predispose to candidosis

(Continued)

Antibacterial	Comments	Cautions and contraindications
	Many bacteria now resistant but still useful for infections with <i>Chlamydia</i> , <i>Rickettsia</i> , <i>Brucella</i> , Lyme disease, acne, leptospirosis, <i>Haemophilus influenzae</i> , methicillin-resistant <i>Staph. aureus</i> (MRSA)	Contraindicated in pregnancy and children up to at least 7 y (tooth discolouration)
Doxycycline	Given by mouth in a single daily dose	Dose reduced in renal failure, liver disease and elderly Frequent mild gastrointestinal upsets May rarely cause intracranial hypertension Contraindicated in pregnancy and children up to at least 7 y (tooth discolouration) Safer than other tetracyclines in renal failure; may rarely cause intracranial hypertension Reduce dose in liver disease and elderly
Minocycline	Given by mouth Active against some meningococci Absorption not reduced by milk	Mild gastrointestinal effects Safer than tetracycline in renal disease May cause dizziness and vertigo Contraindicated in pregnancy and children up to at least 7 y (tooth discolouration) May also cause bone pigmentation
<u>Macrolides</u>		
Azithromycin	Slightly less active than erythromycin against Gram-positive bacteria Long half-life (single daily dose) Fewer gastrointestinal effects than erythromycin	Reduced dose indicated in liver disease and long QT syndrome With terfenadine and pimozone may cause arrhythmias
Erythromycin	Given by mouth but absorption erratic and unpredictable Similar antibacterial spectrum to penicillin Avoid erythromycin estolate, which may cause liver disturbance Useful in those hypersensitive to penicillin Effective against some staphylococci and most streptococci May cause nausea or hearing loss in large doses Rapid development of resistance	Interacts with theophylline and lithium Caution in pregnancy Reduced dose indicated in liver disease and long QT syndrome With terfenadine and pimozone may cause arrhythmias Interacts with theophylline and lithium Caution in pregnancy
Clarithromycin	Fewer gastrointestinal effects than with erythromycin	Reduced dose indicated in liver disease and long QT syndrome With terfenadine and pimozone may cause arrhythmias Interacts with theophylline and lithium Caution in pregnancy
<u>Others</u>		
Cephalosporins, cephamycins and other beta-lactams	Rarely needed in dentistry; expensive	May cross-react with penicillins, causing hypersensitivity reactions in those allergic to penicillins
Clindamycin	Given by mouth Very reliably absorbed	Caution in pregnancy Cross-resistance with erythromycin Mild diarrhoea common Repeated doses may cause pseudomembranous colitis (antibiotic-associated colitis), especially in the elderly and in combination with other drugs
Gentamicin	Reserved for serious infections	Caution in pregnancy Can cause vestibular and renal damage
Metronidazole	Given by mouth Effective only against anaerobes Available as i.v. preparation but expensive	Contraindicated in pregnancy and myasthenia gravis Use only for 7 days (or peripheral neuropathy may develop, particularly in patients with liver disease) Avoid alcohol (disulfiram-type reaction) May increase warfarin effect Avoid in pregnancy
Rifampicin	Reserved mainly for treatment of tuberculosis May be used in prophylaxis of meningitis after head injury since <i>Neisseria meningitidis</i> and <i>Staph. aureus</i> are frequently resistant to sulphonamides	May interfere with oral contraception Occasional rashes, jaundice or blood dyscrasias
Sulphonamides	Main indication is for prophylaxis of post-traumatic meningitis but meningococci are increasingly resistant	Safe and effective but resistance rapidly develops Body secretions turn red Contraindicated in pregnancy and in renal disease

(Continued)

Antibacterial	Comments	Cautions and contraindications
Teicoplanin	Adequate hydration essential to prevent (rare) crystalluria Other adverse reactions include rashes, erythema multiforme and blood dyscrasias Reserved mainly for endocarditis and serious <i>Staph. aureus</i> infections, including some MRSA Occasional rashes, nausea, fever, anaphylaxis May cause hearing loss or tinnitus	Reduce dose in renal failure and elderly
Vancomycin	Reserved for serious infections (including MRSA) Given by slow (100-min) i.v. infusion	Contraindicated in renal disease or deafness May cause nausea, rashes, 'red man syndrome', tinnitus, deafness when given intravenously
Quinolones	Extravenous extravasation causes necrosis and phlebitis Effective by mouth for pseudomembranous colitis Can induce fits Can cause tendon damage	Contraindicated in patients with tendonitis, the elderly or those on steroids; epilepsy; diabetes; pregnancy; myasthenia gravis

Warn patients taking an oral contraceptive to use additional precautions if on antimicrobials for more than a single dose.

APPENDIX 21.5 BACTERIAL INFECTIONS SEEN MAINLY IN PEOPLE FROM THE DEVELOPING WORLD

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Anthrax	<i>Bacillus anthracis</i> (Central Asia and worldwide)	Contact with contaminated products or soil infected by animals (mainly cattle, goats, sheep). Spores survive for decades	Untreated infections may spread to regional lymph nodes and bloodstream, and may be fatal	Avoidance of direct contact with soil and products of animal origin (e.g. souvenirs made from animal skins). Vaccine available for people at high risk	Isolation from blood, skin or respiratory secretions	Ciprofloxacin, doxycycline or erythromycin
<i>Bartonella</i>	<i>Bartonella (Rochalimaea) henselae</i> , Gram-negative bacilli that appear to be transmitted by ectoparasites (worldwide)	Contact with cats	Cat scratch disease lymphadenitis Most common in children, in the cervical region; the typical case presents with a tender papule about 3–10 days after contact with the animal, and this is followed by cervical lymphadenopathy after up to 6 weeks Systemic features vary from none to a mild 'flu-like illness and only very rarely are there more serious sequelae such as encephalitis <i>B. henselae</i> or sometimes <i>B. quintana</i> in immunodeficient patients may cause epithelioid (bacillary) angiomatosis; clinical resemblance of the lesions to Kaposi sarcoma, but they are benign	Avoidance of cats	Warthin–Starry silver stain may show causal organisms, or they may be identified by in vitro DNA amplification or serological testing	Treatment, if required, involves use of tetracyclines, doxycycline or chloramphenicol, or erythromycin or other macrolides

(Continued)

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Brucellosis	<i>B. bacilliformis</i> (in some valleys of Colombia, Ecuador and Peru)	Transmitted by sandflies	Carrion disease is either acute with severe infectious haemolytic anaemia (or Oroya fever), or appears as benign cutaneous tumours (verruca peruana). Healthy blood carriers of the bacterium exist	Avoidance of sandflies		
	<i>B. quintana</i> (worldwide)	Bacterial reservoir is in humans only Transmitted by body louse	Trench fever, first described during the First World War, is a non-fatal disease of recurrent attacks of fever and bone pains. Can also cause endocarditis, bacillary angiomatosis and chronic or recurrent bacteraemia	Avoidance of lice		
	<i>Brucella</i> species (worldwide, mainly in developing countries and around the Mediterranean)	Humans seem to be the reservoir of <i>B. quintana</i> From cattle (<i>B. abortus</i>), dogs (<i>B. canis</i>), pigs (<i>B. suis</i>), or sheep and goats (<i>B. melitensis</i>), by direct contact with animals, skin or unpasteurized milk or cheese	Continuous or intermittent fever and malaise <i>Acute form</i> , symptoms are non-specific and 'flu-like, particularly fever, sweats, malaise, anorexia, headache, myalgia and back pain <i>Undulant form</i> (<1 y from illness onset), symptoms include undulant fevers, arthritis and epididymo-orchitis in males. Neurological symptoms may develop rapidly in up to 5% <i>Chronic form</i> (>1 y from onset), symptoms may include chronic fatigue syndrome-like depressive episodes and arthritis Brucellosis may be associated with chronic or intermittent lymphadenopathy	Avoidance of unpasteurized milk and milk products, and direct contact with animals, particularly cattle, goats and sheep	Blood or bone marrow culture and serology are required for diagnosis	Doxycycline and rifampicin are used in combination for 6 weeks to prevent recurring infection
Cholera	<i>Vibrio cholerae</i> , serogroups O1 and O139 from contaminated water, occasionally from food (developing countries, particularly in Africa and Asia, and to a lesser extent in Central and South America; endemic in Bangladesh and common throughout the tropics, currently in South America, the Middle East, Africa and Asia)	Ingestion of food or water contaminated directly or indirectly by faeces or vomitus of infected persons	Acute enteric disease varying in severity	Oral cholera vaccines gave little protection and have been abandoned	Stool culture	Treatment is with electrolyte-containing solutions and, if necessary, ciprofloxacin

(Continued)

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Diphtheria	<i>Corynebacterium diphtheriae</i> (where immunization has been neglected, diphtheria continues to re-emerge, as in Eastern Europe, e.g. Ukraine 2008)		Can cause massive diarrhoea with depletion of water and electrolytes, and can be fatal	All care should be taken to avoid consumption of potentially contaminated food, drink and drinking water		
		Human-to-human transmission by droplet infection and fomites	<i>C. diphtheriae</i> multiplies mainly on the nasal, pharyngeal or laryngeal mucous membranes to cause inflammation, surface necrosis and exudate (pseudomembrane)	Diphtheria immunization carried out in early childhood	Swabs should be taken for bacterial culture and for Gram and Kenyon staining	Antibiotics (usually penicillin or erythromycin) immediately
		Patients infectious for up to 4 weeks but carriers may shed for longer	Mild sore throat but disproportionate cervical lymph node enlargement, which in severe cases produces a bull neck. Nasal, laryngeal or tracheal diphtheria are variants			Diphtheria antitoxin if the patient has not been actively immunized
		Three biotypes – <i>gravis</i> , <i>intermedius</i> and <i>mitis</i> , the most severe disease being caused by the <i>gravis</i> biotype, but any strain may produce neurotoxin	Exotoxin causes potentially fatal myocardial, adrenal and neurological damage			Household contacts may need immunization
<i>Haemophilus meningitis</i>	<i>Haemophilus influenzae</i> type b (Hib) (worldwide where vaccination against Hib is not practised)	Direct contact with infected person	Palatal paralysis is a possible manifestation Meningitis in infants and young children; may also cause epiglottitis, osteomyelitis, pneumonia, sepsis and septic arthritis	Vaccination against Hib	White cell count	
Leprosy	<i>Mycobacterium leprae</i> (India alone accounts for 78% of new cases detected worldwide; endemic in tropical and subtropical areas of Asia, Africa and Latin America; also seen occasionally around the Mediterranean and Black Sea and in southern Europe)	<i>M. leprae</i> transmitted by direct contact and via the respiratory tract	Outcome of infection highly dependent upon cell-mediated immune reactions; if these are intact, infection results in localized form (tuberculoid leprosy); if deficient, generalized (lepromatous) leprosy	Hygiene	Hib culture from blood Based on one or more of three cardinal signs: hypopigmented or reddish hypo- or anaesthetic skin lesion(s); peripheral nerve involvement; and a positive smear from an open lesion, or biopsy, for acid-fast bacilli	Multidrug therapy (MDT) with clofazimine, rifampicin and prothionamide over 2 or more years; second-line drugs include ofloxacin, minocycline and clarithromycin
			<i>Tuberculoid leprosy</i> : a benign form and causes thickening of cutaneous nerves, flat and hypopigmented or raised and erythematous skin lesions, and enlarged lymph nodes		The lepromin test is of dubious value	

(Continued)

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Leptospirosis	Spirochaetes of the genus <i>Leptospira</i> worldwide (most common in tropics)	Contact between the skin or mucosae and water, wet soil or vegetation contaminated by animal urine, notably rats and foxes	<i>Lepromatous leprosy</i> : affects nerves (with hypoaesthesia); skin with macules progressing to papules and nodules or infiltration; lymph nodes; and other tissues, including bones, eyes, testes, kidneys and bone marrow Sudden fever, headache, myalgia, chills, conjunctival suffusion and rash. May progress to meningitis, haemolytic anaemia, jaundice, haemorrhages and hepatorenal failure	Avoidance of contact with rodents and contaminated waters, including canals, ponds, rivers, streams and swamps	Serological diagnostic tests capable of identifying and allowing treatment of early-stage leprosy are appearing Enzyme-linked immunosorbent assay (ELISA) serology	Doxycycline, penicillin
Listeriosis	<i>Listeria monocytogenes</i> (worldwide)	<i>Listeria</i> multiplies readily in refrigerated foods that have been contaminated (e.g. unpasteurized milk, soft cheeses, vegetables and prepared meat products)	Newborn infants, pregnant women, older and immunocompromised individuals are particularly susceptible. In pregnancy, causes fever and abortion. Meningoencephalitis and/or septicaemia in adults and newborn infants. In others, disease may be limited to a mild acute febrile episode	Avoidance of unpasteurized milk and milk products	Culture blood, urine, cerebrospinal fluid or amniotic fluid	Ampicillin plus gentamicin
Lyme disease	<i>Borrelia burgdorferi</i> (first recognized in 1977 when arthritis was noted in children in and around Lyme, Connecticut, USA)	Bite of infected deer ticks, which have become infected by feeding on small rodents, such as white-footed mice	Some individuals have subclinical infection but presentation is most often with a 'bull's-eye' rash (erythema migrans) and non-specific features, e.g. fever, malaise, fatigue, headache, muscle aches (myalgia) and joint aches (arthralgia)	Avoidance of areas where there could be deer	Serological testing initially with a sensitive ELISA or indirect fluorescent antibody (IFA) test, followed by testing with the more specific Western immunoblot (WB), which is confirmatory	Doxycycline or amoxicillin for 3–4 weeks
	British Lyme disease differs from the USA version, in having fewer complications	Spirochaetes disseminate from the tick bite via lymphatics and blood to nervous or musculoskeletal systems, or heart	Rash usually appears 7–14 days after tick exposure Early neurological manifestations may include lymphocytic meningitis, cranial neuropathy (especially facial nerve palsy) and radiculoneuritis Musculoskeletal manifestations may include migratory joint and muscle pains Cardiac manifestations rare but may include myocarditis and transient atrioventricular blocks			Cefuroxime or erythromycin for persons allergic to penicillin
Meningococcal disease	<i>Neisseria meningitidis</i> (epidemics in Saudi Arabia during Haj)	Humans	Meningitis	Hygiene		

(Continued)

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Paratyphoid	<i>Salmonella paratyphi</i> , <i>S. cholerae-suis</i> or <i>S. enteritidis</i>	Poultry, eggs, dairy products, other foods	Similar to typhoid but usually less severe	Vaccination is indicated Hygiene	Culture stool	Supportive therapy
Pertussis	<i>Bartonella pertussis</i>	Nasopharyngeal secretions	Catarrh, recurrent cough	Hygiene	Culture nasopharyngeal swab	Erythromycin, azithromycin
Plague	<i>Yersinia pestis</i> (Asia, Africa, South America; epidemics)	<i>Xenopsylla cheopis</i> (oriental rat flea) is primary vector Other routes of spread include direct contact with infected tissues or fluids from handling sick or dead animals or by droplets from cats Direct person-to-person transmission only in pneumonic plague	<i>Bubonic plague</i> : lymphadenitis with swelling and suppuration – buboes. Untreated bubonic plague is often fatal <i>Septicaemic plague</i> : may develop from bubonic plague or occur in the absence of lymphadenitis. Dissemination of infection in bloodstream causes meningitis, endotoxic shock and disseminated intravascular coagulation <i>Pneumonic plague</i> : results from secondary infection of lungs following dissemination from other sites. Direct infection of others may result. Untreated septicaemic and pneumonic plague are invariably fatal	Avoidance of contact with rodents Antibiotics for prophylaxis with tetracyclines or sulphonamides	Immunostain smear from affected tissues serology	Aminoglycosides, e.g. streptomycin and gentamicin
Q fever	<i>Coxiella burnetii</i> (worldwide)	Excreta or milk of cattle, sheep and goats	Fever, headache, malaise, myalgia, sore throat, chills, sweats, cough, nausea, vomiting, diarrhoea, abdominal and chest pain	Avoidance of contact with excreta or unpasteurized milk	Serology	Tetracycline, doxycycline
Salmonellosis	<i>Salmonella</i> serotype <i>typhimurium</i> and <i>Salmonella</i> serotype <i>enteritidis</i> (outbreaks in developing world mainly, e.g. Kenya 2008, but also in developed world, e.g. USA 2008)	Ticks Contaminated foods are often of animal origin, such as beef, poultry, milk or eggs, but any food, including vegetables, may become contaminated	Diarrhoea, fever or abdominal cramps	Avoidance of contact with uncooked food and not eating raw or undercooked eggs, poultry or meat Thorough cooking kills <i>Salmonella</i> Reptiles (turtles, iguanas, lizards, snakes) may harbour <i>Salmonella</i> . Chicks and birds may carry <i>Salmonella</i> in their faeces Hands should be washed immediately after handling reptiles or birds	Laboratory tests that identify <i>Salmonella</i> in the stool of an infected person	Usually resolves in 5–7 days and often does not require treatment other than oral fluids Persons with severe diarrhoea may require rehydration with intravenous fluids Antibiotics, e.g. ampicillin, trimethoprim–sulfamethoxazole or ciprofloxacin, are not usually necessary

(Continued)

Disease	Microorganism or parasite (areas of greatest risk)	Infection via	Possible outcomes	Prevention	Diagnostic aids	Management
Sodoku	<i>Spirillum minus</i> (Asia mainly)	From rat bites or scratches	High fever, headache and regionally swollen lymph nodes	Avoidance of rats, mice or squirrels	Darkfield microscopy	Penicillin
Tularaemia	<i>Francisella tularensis</i> (USA and other countries)	From ticks, water contaminated by rats, undercooked meat from an infected animal such as rabbit, and also from contaminated soil	High fever, generalized aching and swollen lymph nodes	Avoidance of rats	Serology	Aminoglycosides (e.g. gentamicin and streptomycin), chloramphenicol, fluoroquinolones and tetracyclines
Typhoid fever	<i>Salmonella typhi</i> (worldwide, especially North and West Africa, South Asia and Peru)	Contaminated water or food	Fever, rash, splenomegaly and leukopenia, and intestinal bleeding or perforation	Vaccination	Culture blood, vomit and stool	Chloramphenicol effective but toxic. <i>S. typhi</i> may be resistant in India, Middle East and South-East Asia, where ciprofloxacin is indicated
		A strict human pathogen, typhoid is always acquired from a human. Contact tracing is important		Hygiene		
				Avoidance of contaminated water or food		
Typhus fever (epidemic louse-borne typhus)	<i>Rickettsia prowazekii</i> (colder, i.e. mountainous, regions of Central and East Africa, Central America, and Asia. In recent years, most outbreaks have taken place in Burundi, Ethiopia and Rwanda)	Human body louse, rat or cat flea	Sudden fever, headache, chills, prostration, coughing and muscular pains	Avoidance of infestation by body lice	Serology after the first week	Doxycycline, azithromycin, rifampicin
			After 5–6 days, a macular skin eruption (dark spots) on the upper trunk and then rest of the body, except face, palms or soles Case fatality rate up to 40%		Polymerase chain reaction (PCR)	
Yersiniosis	<i>Y. enterocolitica</i> (worldwide)	Eating contaminated food, especially raw or undercooked pork products	Features typically develop 4–7 days after exposure and may last 1–3 weeks or longer Fever, abdominal pain, bloody diarrhoea and sometimes cervical lymphadenopathy	Hygiene	Culture stool or body fluids	Uncomplicated cases usually resolve spontaneously In severe or complicated infections, use aminoglycosides, doxycycline, trimethoprim–sulfamethoxazole or fluoroquinolones

APPENDIX 21.6 UNCOMMON BACTERIAL INFECTIONS THAT MAY HAVE IMPLICATIONS IN DENTISTRY

Organism	Main features	Orofacial lesions	Treatments
<i>Bacillus anthracis</i>	Anthrax	Painful or ulcerated swellings, mainly on palate	Penicillin
<i>Brucella melitensis, suis</i> and <i>abortus</i>	Brucellosis	Rare infections or cranial nerve palsies	Tetracycline with streptomycin
<i>Clostridium botulinum</i>	Botulism	Xerostomia, parotitis Muscle weakness	Antitoxin
<i>Clostridium perfringens</i> (<i>C. welchii</i>), <i>C. sporogenes</i> , <i>C. oedematiens</i> and <i>C. septicum</i>	Gas gangrene	Gas gangrene	Antitoxin
<i>Escherichia coli</i>	Enteric infections, mainly Also urinary tract, wound and other infection	Found in some oral infections, especially in denture wearers and immunocompromised	Penicillin Surgery Ampicillin Cefalexin Cefalotin Co-trimoxazole Streptomycin
<i>Francisella tularensis</i>	Tularaemia	Pharyngitis Stomatitis (often ulcerative) Faucial membrane Cervical lymphadenopathy	
<i>Mycoplasma hominis</i> and <i>pneumoniae</i>	Pneumonia	Rare infections or cranial nerve palsies?	Tetracyclines
<i>Neisseria meningitidis</i>	Meningitis Septicaemia	Reiter syndrome Petechiae Occasionally, herpes labialis Facial palsy	Erythromycins Penicillin
<i>Nocardia asteroides, brasiliensis</i> and <i>caviae</i>	Nocardiosis	Ulceration	Co-trimoxazole
<i>Proteus vulgaris</i>	Urinary tract and wounds	Cheek or gingivae Occasional infections	Ciprofloxacin
<i>Pseudomonas aeruginosa</i>	Skin and lungs	Opportunistic infections	Sulfadiazine Aminoglycosides
<i>Pseudomonas mallei</i>	Glanders (acute pneumonia)	Ulceration from nasal glanders Ulcers	Penicillin Cephalosporins
<i>Pseudomonas pseudomallei</i>	Melioidosis (lung or other localized infections or septicaemia)	Oral abscesses, or other infections	Tetracyclines
<i>Rickettsia rickettsiae</i>	Rocky mountain spotted fever	Parotitis Faucial gangrene	Tetracyclines
<i>Rickettsia akari</i>	Rickettsial pox	Vesicles	Tetracyclines
<i>Salmonellae typhi, paratyphi, cholerae, suis</i> and <i>enteritidis</i>	Typhoid and paratyphoid fever	Occasional infections	Co-trimoxazole Ampicillin

APPENDIX 21.7 IMMUNIZATION SCHEDULES (UK)^a

When to immunize	Diseases protected against	Vaccine
2 months old	Diphtheria, tetanus, pertussis, polio and <i>Haemophilus influenzae</i> type b (Hib) Pneumococcal disease Rotavirus	DTaP/IPV/Hib (Pediaceal) PCV (Prevenar 13) Rotavirus (Rotarix)
3 months old	Diphtheria, tetanus, pertussis, polio and Hib Meningococcal group C disease (MenC) Rotavirus	DTaP/IPV/Hib (Pediaceal) MenC (Neisvac-C or Menjugate) Rotavirus (Rotarix)
4 months old	Diphtheria, tetanus, pertussis, polio and Hib Pneumococcal disease	DTaP/IPV/Hib (Pediaceal) PCV (Prevenar 13)
Between 12 and 13 months old – within a month of the first birthday	Hib/MenC	Hib/MenC (Menitorix)

(Continued)

When to immunize	Diseases protected against	Vaccine
2 and 3 years old	Pneumococcal disease Measles, mumps and rubella Influenza	PCV (Prevenar 13) MMR (Priorix or MMR VaxPRO) Flu nasal spray (Fluenz; annual) If Fluenz unsuitable, use inactivated flu vaccine
3 years 4 months old or soon after	Diphtheria, tetanus, pertussis and polio	dTaP/IPV (Repevax) or DTaP/IPV (Infanrix-IPV)
Girls aged 12–13 years	Measles, mumps and rubella Cervical cancer caused by human papillomavirus types 16 and 18 (and genital warts caused by types 6 and 11)	MMR (Priorix or MMR VaxPRO; check first dose has been given) HPV (Gardasil)
Around 14 years old	Tetanus, diphtheria and polio MenC	Td/IPV (Revaxis), and check MMR status MenC (Meningitec, Menjugate or NeisVac-C)
65 years old	Pneumococcal disease	PPV Pneumococcal polysaccharide vaccine (Pneumovax II)
65 years of age and older	Influenza	Flu injection (annual)
70 years old	Shingles	Shingles (Zostavax)
<i>Immunizations for those at risk</i>		
At birth, 1 month old, 2 months old and 12 months old	Hepatitis B	Hep B
At birth	Tuberculosis	BCG
6 months up to 2 years	Influenza	Inactivated flu vaccine (annual)
2 years up to under 65 years	Pneumococcal disease	PPV Pneumococcal polysaccharide vaccine (Pneumovax II)
Over 2 up to less than 18 years	Influenza	Flu nasal spray (Fluenz; annual) If Fluenz unsuitable, use inactivated flu vaccine
18 up to under 65 years	Influenza	Inactivated flu vaccine (annual)
From 28 weeks of pregnancy	Pertussis	dTaP/IPV (Repevax)

APPENDIX 21.8 COMMON VIRAL INFECTIONS THAT MAY HAVE IMPLICATIONS IN DENTISTRY^a

Virus	Infection mainly in	Orofacial consequences	Antivirals that may have a role
Cytomegalovirus	Immunocompromised persons	Ulcers	Ganciclovir Foscarnet Valganciclovir
Epstein–Barr virus	Any	Ulcers	–
	Immunocompromised persons	Ulcers Hairy leukoplakia Lymphomas	Ganciclovir Aciclovir
Hepatitis B	Any	–	Usually none. Interferon-alpha 2b, adefovir, entecavir, lamivudine, telbivudine or tenofovir
	Chronic infection or immunocompromised persons	–	Interferon-alpha 2b, adefovir, entecavir, lamivudine, telbivudine or tenofovir
Hepatitis C	Any	Lichenoid lesions/lichen planus	Usually none. Interferon-alpha 2b and ribivirin. A protease inhibitor (e.g. boceprevir or telaprevir) may also be given
	Chronic infection or immunocompromised persons	Sicca syndrome	
Herpes simplex	Primary infections	Gingivostomatitis	Aciclovir
	Secondary infections (labial or orogenital)	Blistering	Aciclovir Penciclovir
		Ulceration Erythema multiforme Bell palsy	Aciclovir
	Secondary infections (oral)		
HIV	Encephalitis	–	Aciclovir
	See Ch. 20		
Influenza	Older or immunocompromised persons	–	Amantadine Oseltamivir

(Continued)

Virus	Infection mainly in	Orofacial consequences	Antivirals that may have a role
Papillomaviruses	Any	Warty lesions Oropharyngeal carcinoma	Rimantadine Zanamivir Interferon-alpha 2b Imiquimod Ribavirin
Respiratory syncytial virus	Young or immunocompromised persons	–	Ribavirin
Severe acute respiratory syndrome corona virus	Older or immunocompromised persons	–	Ribavirin
Varicella zoster virus	Chickenpox; any patient	Ulcers	Aciclovir
	Zoster; any patient	Pain Ulcers	Famciclovir Valaciclovir
	Zoster in immunocompromised	Pain Ulcers	Aciclovir

^aSee Table 21.10.

APPENDIX 21.9 VIRAL INFECTIONS PREVALENT MAINLY IN THE DEVELOPING WORLD

Disease	Virus	Infection via	Consequences	Epicentres of greatest risk	Prevention
Arboviruses	Many different arboviruses	Transmitted to humans by arthropods, mostly mosquitoes, sandflies or ticks	Fever with rashes, arthralgias, lymphadenopathy, CNS involvement or haemorrhagic features	Worldwide, especially Latin America, the southern USA, South-East Asia and Africa	Avoid insect bites (wear protective clothing and use insect repellants) and use prophylactic measures such as vaccination
Chikungunya	Togavirus	Mosquito	Similar to dengue; fever and joint pain, muscle pain, headache, nausea, fatigue and rash	Around Indian Ocean	Avoid mosquito bites
Dengue	Dengue virus – a flavivirus	<i>Aedes aegypti</i> mosquito, which bites during the day. There is no direct person-to-person transmission. Monkeys act as a reservoir host in South-East Asia and West Africa	Dengue fever – an acute febrile illness, macular skin rash and muscle pains ('breakbone fever') Dengue haemorrhagic fever Dengue shock syndrome	Tropical and subtropical regions of Central and South America, South and South-East Asia, and Africa below 600 m	Avoid mosquito bites
Ebola fever	See Haemorrhagic fevers				
Encephalitis viruses	Togaviridae or flaviviruses	Mosquito bites	Aseptic meningitis or encephalitis. Infections range from mild 'flu-like illness to frank encephalitis, coma and death, leaving mild to severe neurological deficits in survivors	Worldwide <i>Tick-borne encephalitis</i> is seen in forested areas of Austria, northern Europe and Scandinavia <i>Japanese encephalitis</i> virus is a flavivirus <i>St Louis encephalitis</i> virus is a flavivirus seen in the southern USA and Caribbean	Avoid bites of mosquitoes. A vaccine against tick-borne encephalitis is available for those walking or camping in forests in areas at risk

(Continued)

Disease	Virus	Infection via	Consequences	Epicentres of greatest risk	Prevention
Haemorrhagic fevers: Crimean–Congo haemorrhagic fever (CCHF), dengue, Ebola and Marburg haemorrhagic fevers, Lassa fever, Rift Valley fever (RVF) and yellow fever	Most haemorrhagic fevers, including dengue and yellow fever, caused by flaviviruses	Most viruses transmitted by mosquitoes	Sudden onset of fever, malaise, headache and myalgia followed by pharyngitis, vomiting, diarrhoea, rash and haemorrhages, including from the mouth. Fatal in over 50%	Tropics and subtropical regions	Avoid mosquitoes, ticks and rodents
	Ebola and Marburg caused by filoviruses, CCHF by bunyavirus, Lassa fever by arenavirus, RVF by phlebovirus	Ebola or Marburg viruses acquired from bats or monkeys or direct contact with body fluids of infected patients		Ebola and Marburg haemorrhagic fevers in sub-Saharan Africa. Marburg virus has been of concern since first reports in 1967 in persons working with monkeys in Germany and Yugoslavia	Filoviruses have very high transmissibility, morbidity and mortality
		CCHF transmitted by a tick bite		Lassa fever, the most infamous arenavirus, is named after the Nigerian town where infection was first recorded in 1969. Cases since reported from Liberia, Sierra Leone and Uganda	
		Lassa fever virus carried by rodents and transmitted by excreta, either as aerosol or direct contact		CCHF in steppe regions of Central Asia and Central Europe (including Greece and Turkey in 2008), as well as in tropical and southern Africa	
		RVF acquired either by mosquito bite or by direct contact with blood or tissues of infected animals		RVF in Africa and Saudi Arabia	
Hantavirus diseases – haemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS)	Hantaviruses – family bunyaviruses. HPS caused by sin nombre virus (SNV)	Direct contact with the faeces, saliva or urine of infected rodents such as deer, mice or by inhalation of the virus	Vascular endothelium is damaged, leading to vascular permeability, hypotension, haemorrhages and shock	Other viral haemorrhagic fevers in Central and South America	Avoid exposure to rodents and their excreta
			Impaired renal function with oliguria characterizes HFRS; fatal in up to 15% Respiratory distress due to pulmonary oedema in HPS; fatal in up to 50%	Worldwide. New World hantaviruses with distinct rodent hosts. A pan-American zoonosis, with an expanding clinical spectrum. Seen also in Europe	
Hepatitis viruses	Ch. 9				
Human immunodeficiency virus (HIV)	Ch. 20				
Influenza	Ch. 15				

(Continued)

Disease	Virus	Infection via	Consequences	Epicentres of greatest risk	Prevention
Japanese encephalitis	Japanese encephalitis (JE) virus – a flavivirus	Various mosquitoes of the genus <i>Culex</i> . Infects pigs and wild birds as well as humans	Fever, headache or aseptic meningitis. Severe cases rapid onset with headache, high fever and meningeal signs. May be neurological sequelae. Approximately 50% of severe cases are fatal	Asia, especially monsoon areas of South-East Asia	Vaccination. Avoid mosquito bites
Lassa fever	See Haemorrhagic fevers				
Marburg virus	See Haemorrhagic fevers				
Nipah and Hendra viruses	Paramyxoviruses	Animals (Nipah from fruit bats and pigs; Hendra from horses)		Nipah- Malaysia, Bangladesh; Hendra- Australia	Avoid excreta
Poliomyelitis	Ch. 13				
Rabies	Rhabdovirus of genus Lyssavirus	Bite of an infected animal such as a dog, fox or bat	Acute encephalomyelitis, which is almost invariably fatal. Initial signs include sense of apprehension, headache, fever, malaise and sensory changes around bite site. Excitability, hallucinations and aerophobia are common, followed in some cases by fear of water (hydrophobia) due to spasms of swallowing muscles, progressing to delirium, convulsions and death	Worldwide, especially in developing countries	Avoid contact with both wild and domestic animals, including dogs and cats. Vaccination
Severe acute respiratory syndrome (SARS)	Ch. 15				
Tick-borne encephalitis (spring–summer encephalitis)	Tick-borne encephalitis (TBE) virus – a flavivirus	Bite of infected ticks	Influenza-like illness, with a second phase of fever in 10% of cases. Encephalitis develops during the second phase and may result in paralysis or death	Below 1000 m in Eastern Europe, particularly Austria, Baltic States, Czech Republic, Hungary and Russian Federation	Avoid bites by ticks by wearing long trousers and closed footwear when hiking or camping in endemic areas
West Nile fever	West Nile virus (WNV)	Bite of an infected mosquito, and can infect people, horses, many types of birds and some other animals The virus can be transmitted through contact with the blood or other tissues of infected animals	Rarely, severe or sometimes fatal encephalitis	Africa, USA, southern Europe	Avoid mosquito bites Avoid handling WNV-infected tissues or fluids from animals
Yellow fever	Yellow fever virus – an arbovirus of the Flavivirus genus	Bite of <i>Aedes aegypti</i> mosquitoes Yellow fever virus infects humans and monkeys	Acute illness characterized initially by fever, chills, headache, muscular pain, anorexia, nausea and/or vomiting, with bradycardia. About 15% progress to second phase, with fever resurgence, jaundice, abdominal pain, vomiting and haemorrhages. 50% die after 10–14 days	Tropical areas of Africa and Central and South America below 2500 m	Vaccination. Avoid mosquito bites during the day, as well as at night

^aSee also Appendix 21.8 for the more common viral infections.

APPENDIX 21.10 MAIN ANTIFUNGAL DRUGS

Group	Examples	Comments	Oral dose
Polyenes	Amphotericin ^a	Active topically. Negligible absorption from gastrointestinal tract. Given i.v. for deep mycoses	10–100 mg 6-hourly
	Nystatin ^a	Active topically. Negligible absorption from gastrointestinal tract. Pastilles taste better than lozenges	500 000 unit lozenge, 100 000 unit pastille or 100 000 unit per mL of suspension 6-hourly
Imidazoles	Ketoconazole	Absorbed from gastrointestinal tract. Useful in intractable candidosis. Contraindicated in pregnancy and liver disease. May cause nausea, rashes, pruritus and liver damage. Interacts with anticoagulants, terfenadine, cisapride and astemizole	200–400 mg once daily with meal, for 14 days
	Miconazole ^a	Active topically. Also has antibacterial activity. Absorption from gastrointestinal tract. Theoretically the best antifungal to treat angular stomatitis. Interacts with anticoagulants, terfenadine, cisapride and astemizole. Avoid in pregnancy and porphyria	250 mg tablet 6-hourly or 25 mg/mL gel used as 5 mL 6-hourly, for 14 days
Triazoles	Fluconazole	Absorbed from gastrointestinal tract. Useful in intractable candidosis. Contraindicated in pregnancy and lactation, and liver and renal disease. Interacts with anticoagulants, terfenadine, cisapride and astemizole	50–100 mg daily for 14 days
	Itraconazole	Absorbed from gastrointestinal tract. Useful in intractable candidosis. May cause nausea, neuropathy, diarrhea and rash. In high dose, or in older people or those with cardiac disease or on calcium channel blockers, it may cause cardiac failure. Contraindicated in heart disease, pregnancy, liver disease. Interacts with terfenadine, cisapride and astemizole	100 mg daily for 14 days
	Posaconazole	Caution with cardiac patients. Contraindicated in porphyria	400 mg b.d.
	Voriconazole	Caution with cardiac patients, and liver or renal disease. Contraindicated in porphyria and breast-feeding	200 mg b.d.

^aDissolve in mouth slowly.

APPENDIX 21.11 IMPORTANT SYSTEMIC (DEEP) MYCOSES

Disease	Organism	Source	Main endemic areas	Clinical forms	Prognosis
Aspergillosis	<i>Aspergillus fumigatus</i> , <i>A. flavus</i> , <i>A. niger</i> and other <i>Aspergillus</i> spp.	Ubiquitous	Worldwide	Allergic bronchopulmonary, pulmonary, disseminated, aspergilloma	Variable
Blastomycosis	<i>Blastomyces dermatitidis</i>	Soil	Mississippi and Ohio valleys in USA, Canada, North Africa and Venezuela	Cavitary, pulmonary, disseminated, others	Often good, except in disseminated form
Coccidioidomycosis	<i>Coccidioides immitis</i>	Soil	South-western USA, Mexico, Latin America	Acute pulmonary, disseminated, chronic pulmonary, meningitis	Often good, except in disseminated or meningeal form
Cryptococcosis	<i>Cryptococcus neoformans</i>	Soil, pigeon droppings	Worldwide	Pneumonia, meningitis, disseminated, cryptococcoma	Poor in disseminated form
Histoplasmosis	<i>Histoplasma capsulatum</i>	Soil, bird and bat droppings	Mississippi and Ohio valleys in USA, Latin America, Africa, India, Far East, Australia	Benign pulmonary, disseminated, chronic pulmonary, cutaneous	Often good, except in disseminated form
Mucormycosis	<i>Mucor</i> , <i>Rhizopus</i> and <i>Absidia</i>	Ubiquitous	Worldwide	Rhinocerebral, pulmonary, gastrointestinal	Variable
Paracoccidioidomycosis (South American blastomycosis)	<i>Paracoccidioides brasiliensis</i>	Soil	South America, especially Brazil	Pulmonary, disseminated	Good in young patients
Pneumocystosis	<i>Pneumocystis jiroveci</i> (<i>carinii</i>)	Ubiquitous	Worldwide	Pulmonary, disseminated	Variable
Sporotrichosis	<i>Sporothrix schenckii</i>	Associated with thorny plants, wood, sphagnum moss	Worldwide	Lymphocutaneous, localized cutaneous, pulmonary, disseminated	Good

APPENDIX 21.12 MAIN PARASITIC INFESTATIONS^a

Disease	Microorganism or parasite	Infection via	Consequence	Areas of greatest risk	Prevention	Treatment
Angiostrongyliasis	<i>Angiostrongylus cantonensis</i>	Rat lungworm	Eosinophilic meningitis	Asia, Africa, Caribbean, Hawaii and other Pacific islands	Avoid eating undercooked or raw snails and slugs. Fish do not spread this parasite	None
Filariasis	Nematodes (roundworms) of family Filarioidea	Lymphatic filariasis transmitted through bite of mosquitoes Onchocerciasis transmitted through bite of blackflies	Lymphatic filariasis and onchocerciasis (river blindness)	Lymphatic filariasis throughout sub-Saharan Africa and South-East Asia Onchocerciasis in western and Central Africa, Central and South America	Avoid bites of mosquitoes and/or blackflies	Diethylcarbamazine, ivermectin
Giardiasis	Protozoan parasite <i>Giardia lamblia</i>	Ingestion of <i>Giardia</i> cysts in water (unfiltered drinking and recreational waters) contaminated by faeces of humans or animals	Anorexia, chronic diarrhoea, abdominal cramps, bloating, frequent loose greasy stools, fatigue and weight loss	Worldwide	Avoid ingesting any potentially contaminated (i.e. unfiltered) drinking water or recreational water	Metronidazole
Leishmaniasis	See text					
Malaria	See text					
Schistosomiasis (bilharziasis)	Parasitic blood flukes (trematodes), of which the most important are <i>Schistosoma mansoni</i> , <i>S. japonicum</i> and <i>S. haematobium</i>	Infection occurs in fresh water containing larval forms (cercariae) of schistosomes, which develop in snails infected as a result of excretion of eggs in human urine or faeces. The free-swimming larvae enter the skin of individuals swimming or wading in water	<i>S. mansoni</i> and <i>S. japonicum</i> cause hepatic and intestinal signs <i>S. haematobium</i> causes urinary dysfunction	<i>S. mansoni</i> in sub-Saharan Africa, Arabian peninsula, Brazil, Surinam and Venezuela <i>S. japonicum</i> in China, Indonesia and Philippines (not Japan) <i>S. haematobium</i> in sub-Saharan Africa and eastern Mediterranean areas	Avoid swimming or wading in fresh water in endemic areas	Praziquantel
Strongyloidiasis	<i>Strongyloides stercoralis</i> , <i>Strongyloides fuelleborni</i>	Infection acquired by walking barefoot in contaminated soil. Larvae enter the body by burrowing into the skin	At entry site, larvae petechial haemorrhages and intense pruritus. Larvae migrate into pulmonary circulation via lymphatic system and venules, produce haemorrhages and alveolar inflammatory response with eosinophilic infiltration (pneumonitis). Larvae migrate up pulmonary tree, are swallowed and reach gastrointestinal system, where they embed and can produce inflammatory reaction and malabsorption syndrome	<i>Strongyloides</i> spp. distributed worldwide but endemic in tropical and subtropical regions. Most prevalent in South-East Asia, Sahara Desert, Colombia and tropical Brazil. Infection rates in these areas can be 60%	Avoid walking barefoot	Albendazole

(Continued)

Disease	Microorganism or parasite	Infection via	Consequence	Areas of greatest risk	Prevention	Treatment
		Humans are principal host. Dogs, cats and other mammals too			Persons in household contact not at risk for infection Proper disposal of human excreta reduces prevalence	Tiabendazole
Trypanosomiasis:	Protozoan parasites <i>Trypanosoma brucei</i> (<i>T. b.</i>) <i>gambiense</i> and <i>T. b. rhodesiense</i>	Bite of infected tsetse flies	<i>T. b. gambiense</i> causes chronic illness after prolonged incubation period of weeks or months	<i>T. b. gambiense</i> present in foci in tropical countries of western and central Africa	Avoid contact with tsetse flies – bites are difficult to avoid because tsetse flies bite during day, can penetrate clothing and are not deterred by insect repellents	Consult experts
African trypanosomiasis (sleeping sickness)			<i>T. b. rhodesiense</i> causes more acute illness, with onset a few days or weeks after infected bite; often, a striking inoculation chancre. Initial signs include headache, insomnia, enlarged lymph nodes, anaemia and rash. In late stages, there is loss of weight and involvement of CNS. Without treatment, invariably fatal	<i>T. b. rhodesiense</i> in East Africa, extending south as far as Botswana		
Trypanosomiasis: American trypanosomiasis (Chagas disease)	Protozoan parasite <i>Trypanosoma cruzi</i>	Blood-sucking triatomine bugs ('kissing bugs'). Also by transfusion if blood is from infected donor	Chronic illness, progressive myocardial damage leading to cardiac arrhythmias and dilatation, and mega-oesophagus and megacolon	Mexico, Central and South America (to central Argentina and Chile)	Avoid exposure to blood-sucking bugs. Use bednets in houses and camps	Consult experts

^aA more comprehensive list is available at: <http://www.cdc.gov/parasites/az/index.html> (accessed 30 September 2013).

KEY POINTS

- Lifestyle habits underlie several malignant diseases
- Tobacco is responsible for a very wide range of malignant diseases
- Alcohol is also responsible for some malignant disease
- Infections such as with viruses (herpesviruses and papillomaviruses) are responsible for some malignant disease.

GENERAL ASPECTS

Malignant neoplasms or ‘cancers’ develop because of deoxyribonucleic acid (DNA) mutations – some spontaneously (possibly due to oxygen radicals), others from chemical carcinogens (e.g. tobacco, alcohol or betel), ionizing and ultraviolet radiation, or oncogenic microorganisms (e.g. hepatitis, herpesviruses and human papillomaviruses (HPVs); Fig. 22.1). Important chemical carcinogens are aromatic amines (including arylamines and heterocyclic amines) found in tobacco smoke and cooked foods. The list of known carcinogens is long; the most important – relevant in tobacco and alcoholic beverages – are shown in Box 22.1.

Various liver enzymes termed xenobiotic-metabolizing enzymes (XMEs) are involved in the metabolism of carcinogens or pro-carcinogens (Table 22.1); several are polymorphic and they may be involved in carcinogen activation or degradation. Other enzymes can reverse or repair some of the damage from mutations (DNA repair enzymes) but, when mutations involve genes such as tumour suppressor genes, the cell may become autonomous, despite attempts at DNA and cell repair, and the cell then proliferates and invades – the hallmark of cancer. Eventually, the tumour spreads elsewhere (metastasizes) to lymph nodes and through the blood.

Carcinomas are malignant neoplasms that arise from epithelia; they are a leading cause of morbidity and mortality, mainly in persons who are middle-aged or older, and are most common in the lung, breast, colon, cervix, stomach, pancreas, ovary, prostate and skin. They metastasize mainly to the brain, liver and bones.

Oral cancer is discussed below. Lung tumours are discussed in Chapter 15, breast, ovary and prostate cancer in Chapter 25, gastrointestinal and pancreatic cancer in Chapter 7, haematological malignancies in Chapter 8, brain tumours in Chapter 13, liver cancer in Chapter 9 and skin cancer in Chapter 11.

CANCER PREVENTION

The prognosis of malignant disease is generally poor and unfortunately treatment can also have significant adverse effects, so prevention and early detection are important. The European Code against Cancer summarizes the preventive aspects (Box 22.2). The World Cancer Research Fund advocates measures in addition to not using tobacco and alcohol, and avoiding sun exposure, as in Table 22.2.

Fig. 22.1 Diagrammatic simplification of the process of carcinogenesis.

Box 22.1 Some known common carcinogens

- Acetaldehyde
- Alkyl halides
- Arylamines
- Nitrosamines
- Polycyclic aromatic hydrocarbon
- Urethane

Table 22.1 Main xenometabolizing enzymes

Enzyme	Abbreviation	Main activities of some genotypes
Alcohol dehydrogenases	ADH	Activate ethanol
Aldehyde dehydrogenases	ALDH	Inactivate ethanol
Cytochrome P450	CYP	Activate ethanol, benzpyrene and nitrosamines
Glutathione S-transferases	GST	Metabolize benzpyrene, alkyl halides, epoxides and lipid peroxides
N-acetyl transferases	NAT	Acetylate arylamines

AVOIDANCE OF TOBACCO

Tobacco is best avoided; up to 30% of cancers in developed countries are tobacco-related. Tobacco smoke is a mixture of at least 50 compounds, including polycyclic aromatic hydrocarbons (PAHs), nitrosamines, aldehydes and aromatic amines. Tobacco, acting either singly or jointly with the consumption of alcohol, is responsible for 87% of lung cancer, and between 43% and 60% of cancers in oesophagus, larynx and oral cavity. Tobacco consumption is also linked to cancers of the bladder and pancreas, a minority of cancers of the kidney, stomach, cervix and nose, and myeloid leukaemia. On smoking cessation, the risk of cancer rapidly declines; benefit is evident within 5 years and is progressively greater over time.

Box 22.2 European Code against Cancer^a

Many aspects of general health can be improved and many cancer deaths prevented if we adopt healthier lifestyles:

- 1. Do not smoke; if you smoke, stop doing so. If you fail to stop, do not smoke in the presence of non-smokers
- 2. Avoid obesity
- 3. Undertake some brisk physical activity every day
- 4. Eat a variety of vegetables and fruits every day; eat at least five portions daily. Limit your intake of foods containing fats from animal sources
- 5. If you drink alcohol, whether beer, wine or spirits, moderate your consumption to two drinks per day if you are a man, or one drink per day if you are a woman
- 6. Care must be taken to avoid excessive sun exposure. It is specifically important to protect children and adolescents. For individuals who have a tendency to burn in the sun, active protective measures must be taken throughout life
- 7. Comply strictly with regulations aimed at preventing occupational or environmental exposure to known cancer-causing substances. Follow the advice of National Radiation Protection Offices

There are public health programmes that could prevent cancers developing or increase the probability that a cancer may be cured:

- 8. Women from 25 years of age should participate in cervical screening. This should be within programmes with quality control procedures in compliance with *EU Guidelines for Quality Assurance in Cervical Screening*
- 9. Women from 50 years of age should participate in breast screening. This should be within programmes with quality control procedures in compliance with *EU Guidelines for Quality Assurance in Mammography Screening*
- 10. Men and women from 50 years of age should participate in colorectal screening. This should be within programmes with built-in quality control procedures
- 11. Participate in vaccination programmes against hepatitis B virus infection

^a Third version: Boyle et al., 2003.

Although the greatest cancer hazard is caused by cigarette smoking, cigars can cause similar hazards, and both cigar smoking and pipe smoking are implicated in cancers of the oral cavity, pharynx, larynx and oesophagus. Bidi, a type of cigarette made of tobacco rolled in a dried temburni leaf, is smoked in India and is associated with a high incidence of oral leukoplakia and oral cancer. Tobacco smoke released to the environment by smokers, commonly referred to as environmental tobacco smoke (ETS) and which is responsible for ‘passive smoking’, has several deleterious effects on people who inhale it. It causes a small rise in the risk of lung cancer, and also some increase in the risk of heart disease and respiratory disease. It is particularly harmful to small children.

Tobacco-chewing in peoples from parts of Asia, along with a variety of ingredients in a ‘betel quid’ (betel vine leaf, areca nut, catechu and slaked lime, together with tobacco) appears to predispose to oral squamous cell carcinoma (OSCC). Smokeless tobacco, for example snuff-dipping in women in the south-eastern USA who place snuff in the buccal sulcus, predisposes to gingival and alveolar carcinoma close to where the snuff is placed, but the risk is low.

AVOIDANCE OF ALCOHOL

Alcoholic beverages may contain carcinogens or pro-carcinogens, including ethanol, nitrosamines and urethane contaminants. The total amount of ethanol ingested appears to be the key factor. Alcoholic beverages increase the risk of squamous cell cancers of the oral cavity, pharynx, larynx and oesophagus. Alcohol-drinking raises the risk of neoplasms, even in the absence of smoking, but alcohol-drinking and tobacco-smoking

Table 22.2 Ten rules for reducing cancer risk

Rule	Rationale
1. Be as lean as possible without being underweight	Convincing evidence shows that weight gain and obesity increase the risk of cancers, including bowel and breast. Maintain healthy weight through a balanced diet and regular physical activity to keep your risk lower
2. Be physically active for at least 30 min every day	Strong evidence shows that physical activity protects against cancers, including bowel and breast. Being physically active is also key to maintaining a healthy weight
3. Avoid sugary drinks. Limit consumption of energy-dense foods (particularly processed foods high in added sugar, or low in fibre or high in fat)	Energy-dense foods are high in fats and sugars, and often low in nutrients; especially when consumed frequently or in large portions, they increase the risk of obesity, which increases the risk of cancer. Fast foods like burgers, chips, fried chicken and pizzas, and snack foods like chocolate, crisps and biscuits tend to be energy-dense. Some energy-dense foods, such as nuts, seeds and vegetable oils, are important sources of nutrients, and have not been linked with weight gain as part of a typical diet
4. Eat more of a variety of vegetables, fruits, wholegrains and pulses such as beans	Evidence shows that vegetables, fruits and other foods containing dietary fibre (such as wholegrains and pulses) may protect against a range of cancers, including mouth, stomach and bowel. They also help protect against weight gain and obesity. As well as eating five portions a day, try to include wholegrains (e.g. brown rice, wholemeal bread and pasta) and/or pulses with every meal. Sugary drinks, such as colas and fruit squashes, can also contribute to weight gain. Fruit juices, even without added sugar, are likely to have a similar effect. Try to eat less energy-dense foods, such as vegetables, fruits and wholegrains instead. Opt for water or unsweetened tea or coffee in place of sugary drinks
5. Limit consumption of red meats (such as beef, pork and lamb) and avoid processed meats	There is strong evidence that red and processed meats are causes of bowel cancer. Aim to limit intake of red meat to less than 500 g cooked weight (about 700–750 g raw weight) a week. Try to avoid processed meats (bacon, ham, salami, corned beef, sausages)
6. If consumed at all, limit alcoholic drinks to 2 a day for men and 1 a day for women	There is evidence that alcoholic drinks can increase the risk of a number of cancers, including breast and colon. Any alcohol consumption can increase cancer risk. There is some evidence to suggest that small amounts of alcohol can help protect against heart disease. If you choose to drink, do so in moderation
7. Limit consumption of salty foods and food processed with salt (sodium)	Evidence shows that salt and salt-preserved foods probably cause stomach cancer and hypertension. Processed foods, including bread and breakfast cereals, can contain large amounts of salt
8. Do not use supplements to protect against cancer	High-dose nutrient supplements can affect cancer risk, so it is best to opt for a balanced diet without supplements. However, supplements are advisable for some groups of people
9. It is best for mothers to breast-feed exclusively for up to 6 months and then add other liquids and foods	Strong evidence shows that breast-feeding protects mothers against breast cancer and babies from excess weight gain
10. After treatment, cancer survivors should follow the recommendations for cancer prevention	Maintaining a healthy weight through diet and physical activity may help to reduce the risk of cancer recurrence

together greatly increase the risk. A probable carcinogenic mechanism of alcohol is the facilitation of the effect of tobacco and possibly of other carcinogens to which the upper digestive and respiratory tracts are exposed, particularly those of dietary origin. However, a direct carcinogenic effect of acetaldehyde, the main metabolite of ethanol, and of other agents present in alcoholic beverages, is likely. A diet poor in fruits and vegetables, typical of heavy drinkers, may also play a role.

Alcohol-drinking is also strongly associated with the risk of primary liver cancer, particularly among smokers and among people chronically infected with hepatitis C virus. A higher risk of colorectal cancer seems to be linearly correlated with the amount of alcohol consumed and independent of the type of alcohol. A greater risk of breast cancer has been consistently reported. More cases of breast cancer than of any other cancer are attributable to alcohol-drinking among European women. It has been suggested that alcohol acts on hormonal factors involved in breast carcinogenesis.

Few studies have analysed the relation between stopping alcohol-drinking and the risk of cancers of the upper respiratory and digestive tracts, but there is clear evidence that the risk of oesophageal cancer falls by 60%, 10 years or more after drinking cessation.

OTHER FACTORS

Weight reduction

Obesity is associated with a greater risk of cancer of the colon, breast (post-menopausal), endometrium, kidney and oesophagus (adenocarcinoma). In Western Europe, it has been estimated that being overweight or obese accounts for approximately 11% of all colon and breast cancers, 39% of endometrial cancers, 27% of oesophageal adenocarcinomas and 25% of renal cell cancers. A body mass index of below 25 kg/m² should, if possible, be maintained.

Greater physical activity

There is consistent evidence that regular physical activity is associated with a 40% reduction in the risk of colorectal, breast and oesophageal cancer and may possibly also lower the risk of prostate cancer. The protective effect of physical activity improves with increasing levels of activity. One hour per day of moderate physical activity, such as walking, may also be needed to maintain a healthy body weight, particularly for people with sedentary lifestyles.

Greater intake of fruit and vegetables

A low-fat diet with at least 11 servings of fruits, vegetables, whole-grains and beans daily may reduce the chances of colon cancer by 75%, breast cancer by 50% and lung cancer by 30%. There may also be a protective effect on the risk of a wide variety of other cancers, in particular oral, oesophagus, stomach, rectum and pancreas.

'Five-a-day' (minimum 400 g/day, i.e. two pieces of fruit and 200 g of vegetables) is advocated to lead to a lower cancer risk. Vegetables and fruits contain many potentially anticarcinogenic agents. Antioxidant activity seems important in cancer protection but the exact molecule(s) in vegetables and fruits that confer(s) protection is/are unknown and the mechanism of action unclear.

Avoidance of sun exposure

Ninety per cent of skin cancers are seen in white-skinned peoples and are caused by the sun's ultraviolet rays (Ch. 11). Squamous cell carcinoma of the skin or lip shows the clearest relationship with sun

exposure and the risk is greatest in outdoor workers. The recipients of transplanted organs are particularly at risk as a result of the combined effects of the unchecked growth of human papillomavirus (HPV) due to immunosuppression, and exposure to the sun (Ch. 35).

Malignant melanoma is more common in people of high socioeconomic status who work inside but who have the opportunity to spend leisure time in the sun, and this includes dentists. The incidence of melanoma has doubled in Europe in 30 years, and this is attributed to longer intense sun exposure. The fair-skinned are more susceptible, particularly those with red hair, freckles and a tendency to burn in the sun. These characteristics are genetically determined at least partially by the *MC1R* gene, which codes for the melanocyte-stimulating hormone receptor. Variants in the *MC1R* gene control the ratio of black melanin (eumelanin) to red (phaeomelanin) in the skin. The strongest phenotypic risk factor for melanoma, however, is the presence of large numbers of moles or melanocytic naevi, which may be normal in appearance but are also usually accompanied by so-called atypical moles. The latter are larger than 5 mm in diameter with variable colour and an irregular shape. The phenotype, described as the atypical mole syndrome (AMS) phenotype, is present in around 2% of the Caucasian population and is associated with an approximately tenfold higher risk of melanoma. Advice on sun protection is of particular importance to this population.

The best protection from the summer sun is to stay out of it. If outdoors, keep out of the sun between 11.00 a.m. and 3.00 p.m., wear close-weave heavy cotton and use sunscreens with high sun protection factor (SPF). Do not rely upon sunscreens for protection.

Avoidance of occupational exposures

The cancers that have most frequently been associated with occupational exposures are those of the lung, urinary bladder, mesothelioma, larynx, liver, nose and nasal cavity, and skin, as well as leukaemia (non-melanoma). The more common occupational exposures are solar radiation, passive smoking, crystalline silica, diesel exhaust, radon, wood dust, benzene, asbestos, formaldehyde, PAHs, chromium, cadmium and nickel compounds. There is no reliable evidence of a risk from power plants, power lines or mobile telephones.

Many chemicals are known or suspected carcinogens. Many are still widely used: for example, 1,3-butadiene and formaldehyde. Prevention of workplace exposures can be effective; the incidence of occupational bladder cancer fell after the ban on the use of beta-naphthylamine in the rubber and chemical industries.

Avoidance of environmental exposures

The term 'environmental exposures' usually refers to exposures of the general population that cannot be directly controlled by the individual; these include air pollution, drinking water contaminants, passive smoking, radon gas in buildings, exposure to solar radiation, food contaminants such as pesticide residues, dioxins or environmental oestrogens, chemicals from industrial emissions, ionizing radiation, waste from nuclear processes, and others. These exposures have been associated with cancers of the lung, urinary bladder, leukaemia and skin. The impact of several exposures that are widespread, such as disinfection by-products in drinking water, is still inconclusive. Agents in the general environment to which many are exposed for long periods (such as passive smoking or air pollution) may increase the relative risk for certain cancers only modestly, but may be responsible for a significant number of cases overall.

Table 22.3 Cancer screening^a

Cancer site	Methods
Breast	Self-examination/mammography/ <i>BRCA1</i> and <i>BRCA2</i> mutation in Jewish women
Cervix	Cervical cytology/human papillomavirus testing
Colon/rectum	Faecal occult blood/flexible sigmoidoscopy
Lung	Spiral computed tomography (CT) or chest radiography
Neuroblastoma	Urinary homovanillic acid (HVA) and vanillylmandelic acid (VMA)
Oral	Examination of the mouth
Ovary	Cancer antigen 125 (CA125) and/or ultrasonography
Prostate	Prostate-specific antigen (PSA)
Skin (melanoma)	Examination for moles
Stomach	<i>Helicobacter pylori</i> testing; breath test/endoscopy
Testis	Self-examination

^aFrom Boyle, et al. 2003.**Box 22.3** Common cancer types

- Bladder cancer
- Breast cancer
- Colon and rectal cancer
- Endometrial (cervical) cancer
- Kidney (renal cell) cancer
- Leukaemia
- Lung cancer
- Melanoma
- Non-Hodgkin lymphoma
- Oral cancer
- Pancreatic cancer
- Prostate cancer
- Skin cancer (non-melanoma)
- Thyroid cancer

Box 22.4 Features that may suggest cancer

- Abdominal pain
- Abnormal vaginal bleeding
- Anorexia
- Blood in faeces
- Blood in sputum
- Blood in urine
- Change in bowel habits
- Change in size or colour of a skin lump
- Change in urination
- Chronic backache
- Chronic headaches
- Dysphagia
- Fever
- Finger clubbing
- Hoarseness
- Lump in breast
- Lump in testicle
- Lymph node enlargement
- Night sweats
- Persistent cough
- Unexplained anaemia
- Weight loss

stage. Because of this, ‘tumour markers’ are used mainly in patients who have already been diagnosed with cancer in order to monitor treatment response or detect recurrences. The most widely accepted tumour marker assessment is the prostate-specific antigen (PSA) blood test, which is used (along with the digital rectal examination) to screen for prostate cancer; it also suffers from the drawbacks outlined in Chapter 25. Others tumour markers are shown in [Table 22.4](#).

Surgery, radiotherapy and chemotherapy are the main treatments for cancer.

Avoidance of hormones that may play a role

Hormone replacement therapy (HRT) for menopausal symptoms appears to raise the risk of breast cancer.

CANCER SCREENING

[Table 22.3](#) shows cancer screening methods.

CLINICAL FEATURES

There is a range of different cancers ([Box 22.3](#)), each with specific manifestations (see relevant chapters). Features that may raise suspicion of cancer are shown in [Box 22.4](#).

MANAGEMENT

Clinical examination, supplemented with imaging and biopsy, is invariably indicated to diagnose malignant disease. There is also considerable interest in tumour markers in blood or other body fluids, or in tissues; unfortunately, none of these tumour markers, including carcinoembryonic antigen (CEA), meets the goal of *reliably* finding cancer at an early

ORAL CANCER**GENERAL ASPECTS**

Oral cancer is usually squamous cell carcinoma (OSCC) and is the predominant cancer in the head and neck. It is mainly a disease of older males. High rates of OSCC are seen particularly in India, Sri Lanka, Brazil, Hungary and France, and there is a wide geographical variation in incidence. Risk factors are shown in [Box 22.5](#). The results of many studies of lifestyle risk factors have been summarized by the International Agency for Research on Cancer (IARC) and show the importance of specific factors (i.e. tobacco, betel and alcohol use).

Tobacco contains a number of addictive components, especially nicotine, and releases many carcinogens (see above). Tobacco use in all forms appears to carry a risk of OSCC. Oral cancer risks show a clear decline after stopping tobacco use. Snuff – finely powdered plant material, principally tobacco, used orally or nasally – is a risk factor for OSCC.

Betel quid (BQ) is probably used by 20% of the world’s population and may lead to:

- cancer: oral, oesophageal, pancreatic, hepatocellular
- other conditions:
 - oral submucous fibrosis
 - hypertension

Table 22.4 Tumour markers

Marker	Abbreviation	Comments
Alpha-fetoprotein	AFP	Useful to follow treatment response and follow-up in liver cancer (hepatocellular carcinoma) and testicular cancers (embryonal cell and endodermal sinus types). Raised AFP levels also seen in rare ovarian and testicular cancers (yolk sac tumour or mixed germ-cell cancer)
Beta ₂ -microglobulin	B2M	Raised in multiple myeloma, chronic lymphocytic leukaemia (CLL) and some lymphomas
Bladder tumour antigen	BTA	Found in urine in bladder cancer
Calcitonin	–	Raised blood levels in cancer of parafollicular C cells (medullary thyroid carcinoma; MTC)
Cancer antigens	CA15-3	Breast cancer
	CA19-9	Developed to detect colorectal cancer, but more sensitive for pancreatic cancer
	CA27.29	Breast cancer
	CA72-4	Ovarian and pancreatic cancer and digestive tract cancers, especially stomach
Carcinoembryonic antigen	CA125	Ovarian cancer
	CEA	Used to monitor treatment and recurrence of colorectal carcinoma and breast, lung, pancreatic and gastric malignancies
Chromogranin A	CgA	Neuroendocrine tumours (carcinoid tumours, neuroblastoma and small-cell lung cancer)
Immunoglobulins	Igs	Bone marrow cancers (e.g. multiple myeloma and Waldenström macroglobulinaemia)
Neuron-specific enolase	NSE	Neuroendocrine tumours (small-cell lung cancer, neuroblastoma and carcinoid tumours)
Soluble 100% in ammonium sulphate	S-100	Found in most melanoma cells
Tissue polypeptide antigen	TPA	Follow-up of patients treated for cancers in lung or bladder
Thyroglobulin	–	Thyroid diseases, including some cancers

metabolic syndrome
adverse birth outcomes
liver cirrhosis
chronic kidney disease
contact dermatitis
periodontitis
urinary calculi.

Increased consumption of alcohol-containing beverages is associated with a risk of OSCC. The risk decreases after stopping alcohol use but the effects appear to persist for several years. The type of alcoholic beverage appears to influence the risk – hard liquors conferring higher risks. There have been reports of oral cancer in marijuana smokers and in users of alcohol-containing mouthwashes but any relationships have yet to be confirmed by full epidemiological studies.

Charcoal-grilled red meat and fried foods have been implicated as risk factors, but an increased consumption of fruits and vegetables is associated with lower risk of OSCC. Higher risks of oral cancer have also been found in a number of occupations (Table 22.5).

Box 22.5 Risk factors for oral cancer

- Age (advancing)
- Diet low in fruit and vegetables
- Gender: male
- Graft-versus-host disease
- Immunosuppression
- Infections with human papillomavirus, *Candida* or syphilis
- Ionizing radiation
- Lifestyle habits:
 - Alcohol
 - Betel (areca)
 - Tobacco
- Low socioeconomic status
- Sun exposure

Table 22.5 Occupations associated with risk of oral cancer

Occupations	Main countries
Exposure to wood-stove fumes	Brazil
Building industry	Italy
Electricity production	
Machinery operations	
Plumbing	
Textile industry	
Carpet installation	USA
Exposure to fossil fuels	
Furniture industry	
Machining	
Metalworking	
Painting	
Petroleum industry	
Woodworking	
Blacksmithing	Uruguay
Butchering	
Driving	
Electricity working	
Masonry	
Railway working	
Metalworking	Brazil
Exposure to horses on farms, employment on construction work, pesticide use, grain production	Norway
Exposure to benzene	UK

Microorganisms implicated in the aetiology of OSCC include syphilis, *Candida albicans* and viruses such as herpesviruses and HPV. Syphilis is discussed in Chapter 32. Candidal leukoplakias are potentially malignant and autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), an autosomal recessive disease associated with a limited T-lymphocyte defect, seems to favour the growth of *C. albicans* and predisposes to OSCC. Viral infections, particularly with oncogenic HPV subtypes and possibly Epstein–Barr virus (EBV), can have a tumorigenic effect. Oropharyngeal cancer is significantly associated with oral HPV and also with a high lifetime number of vaginal-sex partners and oral-sex partners; HPV-16 DNA is detected in most.

Lip cancer is seen mainly in males with chronic sun exposure and in smokers. Antihypertensive agents increase the risk. Ionizing radiation exposure is a possible risk factor for second primary cancers.

Persons with poor oral hygiene appear to have an increased risk of OSCC, independent of any effect of tobacco, alcohol, or other well-proven risk factors; not all workers agree, however, so further studies are required. Polymicrobial supragingival plaque is a possible independent factor, as it possesses a relevant mutagenic interaction with saliva, and individual oral health is a cofactor in the development of OSCC. Viridans group streptococci of the normal oral flora can produce acetaldehyde *in vitro* during ethanol incubation via alcohol dehydrogenase. In particular, the clinical strain of *Streptococcus salivarius*, both clinical and culture collection strains of *Streptococcus intermedius* and the culture collection strain of *Streptococcus mitis* produced high amounts of acetaldehyde.

SYSTEMIC HEALTH AND ORAL SQUAMOUS CELL CARCINOMA

There is a highly significant increase in the incidence of OSCC in dyskeratosis congenita and systemic sclerosis, and an increase of potentially malignant lesions and OSCC in transplant recipients and in people with cancers elsewhere in the upper aerodigestive tract. There is a putative association of diabetes mellitus with oral cancer.

POTENTIALLY MALIGNANT DISORDERS

Some potentially malignant (pre-cancerous) oral clinical lesions that can progress to OSCC include the following, in particular:

- erythroplasia (erythroplakia) – the most likely lesion to progress to severe dysplasia or carcinoma
- leukoplakia, particularly where admixed with red lesions, as in speckled leukoplakia, and proliferative verrucous leukoplakia, sublingual leukoplakia, candidal leukoplakia and syphilitic leukoplakia (exceptionally rare now)
- lichen planus
- oral submucous fibrosis.

Apart from these lesions, most other potentially malignant lesions or conditions have only a very low incidence of dysplasia or malignant change (Table 22.6).

CLINICAL FEATURES

Common sites for OSCC are the lips, the lateral border of the tongue, and the floor of the mouth. There may be widespread dysplastic mucosa ('field change') or even a *second primary neoplasm* anywhere in the oral cavity, oropharynx or upper aerodigestive tract.

Cancer must be suspected, especially when there is a single oral lesion persisting for more than 3 weeks, and particularly when having the features shown in Box 22.6. Many OSCCs can be detected visually but early OSCC can be asymptomatic, may appear innocuous and can be overlooked, especially if the examination is not thorough. The whole oral mucosa should be examined, often along with the rest of the upper aerodigestive tract – and the cervical lymph nodes must always be carefully examined by palpation (Fig. 22.2). Various stains or lights purported to help diagnosis tend to lack sensitivity or specificity. Biopsy is invariably indicated.

CLASSIFICATION/GRADING

Oral cancer is a term that usually includes cancer of the lip, tongue, salivary glands and other sites in the mouth (gum, floor of the mouth and other unspecified parts of the mouth). Pharyngeal cancer is

Table 22.6 Potentially malignant oral disorders

Malignant potential	Lesion	Known aetiological factors
Very high ($\geq 85\%$) High in some instances ($\geq 30\%$)	Erythroplasia	Tobacco/alcohol
	Actinic cheilitis	Sunlight
	Chronic candidosis (candidal leukoplakia)	<i>Candida albicans</i>
	Dyskeratosis congenita	Genetic
	Leukoplakia (non-homogeneous)	Tobacco/alcohol
	Proliferative verrucous leukoplakia	Tobacco/alcohol/human papillomavirus (HPV)
	Sublingual keratosis	Tobacco/alcohol
	Submucous fibrosis	Areca nut
	Syphilitic leukoplakia	Syphilis
	Atypia in immunocompromised patients	?HPV
Low ($< 5\%$)	Leukoplakia (homogeneous)	Friction/tobacco/alcohol
	Discoid lupus erythematosus	Autoimmune
	Lichen planus	Idiopathic
	Paterson–Brown–Kelly syndrome (Plummer–Vinson syndrome)	Iron deficiency

Box 22.6 Warning features of oral cancer

- Red lesion (erythroplasia)
- Mixed red/white lesion, irregular white lesion
- Lump
- Ulcer with fissuring or raised exophytic margins
- Pain or numbness
- Abnormal blood vessels supplying a lump
- Loose tooth
- Extraction socket not healing
- Induration beneath a lesion (i.e. a firm infiltration beneath the mucosa)
- Fixation of lesion to deeper tissues or to overlying skin or mucosa
- Lymph node enlargement
- Dysphagia
- Weight loss

Fig. 22.2 Cervical lymph node enlargement in oral carcinoma.

Table 22.7 TNM classification of malignant neoplasms^a

Stage	Criteria
Primary tumour size (T)	
Tx	No available information
T0	No evidence of primary tumour
Tis	Only carcinoma <i>in situ</i>
T1, T2, T3, T4 ^b	Increasing size of tumour
Regional lymph node involvement (N)	
Nx	Nodes could not or were not assessed
N0	No clinically positive nodes
N1	Single ipsilateral node <3cm in diameter
N2a	Single ipsilateral node 3–6cm
N2b	Multiple ipsilateral nodes <6cm
N2c	Bilateral or contralateral nodes <6cm
N3	Any node >6cm
Involvement by distant metastases (M)	
Mx	Distant metastasis was not assessed
M0	No evidence of distant metastasis
M1	Distant metastasis is present

^aSeveral other classifications are available, e.g. STNM (S = site).

^bT1 = maximum diameter 2cm; T2 = maximum diameter 4cm; T3 = maximum diameter >4cm; T4, massive tumour >4cm in diameter, with involvement of adjacent anatomical structures.

Table 22.8 Prognosis for intraoral carcinoma

Stage	TNM	Approximate 5-year survival (%)
I	T1 N0 M0	85
II	T2 N0 M0	65
III	T3 N0 M0, or T1, T2 or T3 N1 M0	40
IV	Any T4, N2, N3 or M1	10

a term that includes cancers of the nasopharynx, oropharynx and hypopharynx.

Staging of OSCC should be made according to the TNM classification of the International Union against Cancer (UICC) – tumour size (T), nodal metastases (N) and distant metastases (M; Table 22.7) – since this classification relates well to overall survival rate (i.e. the earlier the tumour is detected, the better the prognosis and the less complicated the treatment).

It is generally accepted that prognosis is best in early carcinomas, especially those that are well differentiated and not metastasized (Table 22.8).

GENERAL MANAGEMENT

Any lesion of a potentially malignant or dubious nature persisting for more than 3 weeks should be biopsied and second primary tumours should be excluded by chest radiography and endoscopy. Tumours are staged using the TNM system (tumour, nodes, metastases).

OSCCs are routinely discovered late and have one of the lowest 5-year survival rates of any major cancer site, at approximately 50%; this has not changed in the past 30 years. Localized cancers have the

Fig. 22.3 Deformity after tumour resection.

highest 5-year relative survival rates (80%), those with regional disease intermediate (40%) and cancers with distant metastasis the lowest (20%). OSCC is also particularly dangerous because it may be associated with second primary tumours.

Patients with oral cancer are best managed by a team of specialists that includes dental and maxillofacial surgeons, as well as oncologists, nurses, speech therapists and hygienists.

Cancer treatment can be with surgery, radiotherapy, chemotherapy (cytotoxic drugs singly or in combination), targeted therapy stem-cell transplantation, immunotherapy (monoclonal antibodies and, on the horizon, vaccines) and now gene therapy.

The choice of surgery in the treatment of oral cancer depends on tumour location, size, proximity to bone, and depth of infiltration. In most cases in which bone is involved, a segmental resection of the tumour is necessary with microvascular reconstruction using free flaps to restore mastication and facial contour, and allow for the placement of osseo-integrated implants for orofacial and dental rehabilitation. Transoral robotic surgery and transoral laser microsurgery and minimally invasive surgery with curative intent have increased. Surgery can lead to complications, which are discussed in standard textbooks of surgery – not least some defects of aesthetics and function (Fig. 22.3).

Radiotherapy and chemotherapy are used mainly to damage or destroy proliferating malignant cells (particularly in malignant disease affecting blood cells and lymphomas [Ch. 8]), but also for some more solid tumours such as OSCC. They can affect many tissues and can have severe adverse effects on health, health care and quality of life. These treatments can also damage the developing fetus.

Radiotherapy and cytotoxic chemotherapy can also have profound adverse effects on oral health and quality of life, and can give rise to the major complaints of the patient undergoing cancer treatment – especially when the radiotherapy field affects the head and neck, and involves the oral cavity and salivary glands. Chemoradiation therapy (CRT) is commonly used for locally advanced head and neck cancers or as adjuvant therapy. Altered fractionation plus concurrent CRT improves tumour control and reduces late toxicity but is associated with more severe acute oral toxicities, especially mucositis. Intensity-modulated radiotherapy (IMRT) offers advantages; arc therapy reduces IMRT delivery time from 20 minutes to less than 5 minutes, while optimizing dose homogeneity and sparing normal tissue, including parotid gland sparing. Opinion varies as to the relative value of radiotherapy or surgery.

The role of targeted agents, such as cetuximab, as part of a combined modality treatment approach for locally advanced cancer has yet to be clearly defined.

Treatment of patients with oral and oropharyngeal tongue cancers has not shown a significant improvement in 5-year disease-specific

survival over decades. Poorer survival is significantly associated with ages of more than 45 years, oropharyngeal tongue cancers and advanced-stage disease. A multimodal approach of surgery for the primary tumour and the neck, followed by postoperative radio(chemo) therapy, seems superior to non-surgical treatment protocols, since it results in better disease-free and overall survival.

Many early carcinomas can be treated by either surgery or radiotherapy, but in the later stages surgery is the first option. Cancer of the floor of the mouth presents considerable problems in surgery and may necessitate partial mandibulectomy. Lingual and labial cancers are often managed with radiotherapy, which may also provide the best palliation in patients with advanced disease. Cytotoxic chemotherapy has not offered any better prognosis and, indeed, may cause greater morbidity and mortality, but newer drugs may help, as discussed below.

SURGERY

Surgery is the oldest form of treatment for oral cancer (see <http://www.oralcancerfoundation.org/facts/surgery.htm>; accessed 30 September 2013) and is often performed to achieve more than one of the following goals:

- *Curative surgery* – the removal of a tumour when it appears to be confined to one area. It may be used along with radiation therapy or chemotherapy, which can be given before or after the operation. In some cases, radiation therapy is actually used during an operation (intraoperative radiation therapy).
- *Debulking (or cytoreductive) surgery* – sometimes done when removing a tumour entirely would cause too much damage to an organ or surrounding areas. In these cases, radiation therapy or chemotherapy is also typically used.
- *Palliative surgery* – used to treat complications of advanced disease. It is not intended to cure the cancer.
- *Supportive surgery* – used to help with other types of treatment. For example, a vascular access device, such as a catheter port, can be placed into a vein to facilitate chemotherapy.
- *Restorative (or reconstructive) surgery* – used to restore aesthetics and function.

Transoral laser microsurgery is a new trend for complete resection of tumours with preservation of function. Advanced reconstructive techniques that allow free transfer of soft tissue and bone from all over the body improve the functional and aesthetic outcomes following major ablative surgery. With successful surgical reconstruction, dental and prosthetic rehabilitation choices are enhanced. Neck dissection has also greatly advanced – from radical to function-preserving surgery, with sensory and spinal accessory nerve-preserving neck surgery resulting in a lower incidence and severity of neck and shoulder pain and loss of function compared to patients who have the nerve removed, and less depression and better quality-of-life scores with lower pain intensity.

Wound infection is a common complication after OSCC surgery and may lead to significant functional morbidity, poor cosmetic results and prolonged hospitalization. The most important factors contributing to operative wound infections are male sex, tumour stage, reconstruction, tracheostomy, nasogastric tube or gastrostomy feeding, and the extent of surgery.

RADIOTHERAPY

Radiation therapy is commonly used to treat OSCC (see <http://www.oralcancerfoundation.org/facts/radiation.htm>; accessed 30 September 2013). Prior to therapy, a planning session is required, including a computed

tomography (CT) scan and measurements of the area to be treated, as well as skin markings to help with positioning during treatments. A porous mask is used in radiation treatment, to immobilize the patient's head so that radiation will only be delivered to the designated areas. The radiation therapy is given in small amounts (fractions) on a daily basis, usually 5 days in a row with a 2-day break each week. Normally, each daily treatment lasts about 10–15 minutes, with the majority of this time spent making sure that the radiation-blocking devices, which limit the radiation to the appropriate area, are properly in place, and the patient and machine are properly positioned. The daily dose must be great enough to destroy the cancer cells while sparing the normal tissues from excessive levels of radiation. Typically, 2 Gy is delivered five times a week to a total dose of 64–70 Gy.

Internal radiotherapy

Internal radiotherapy involves placing radioactive implants directly into a tumour or body cavity, resulting in less radiation exposure to other parts of the body. Brachytherapy, interstitial irradiation and intracavitary irradiation are types of internal radiotherapy.

External beam radiotherapy

This involves the use of machines to focus radiation on a cancer site. With modern radiation equipment, there is minimal scatter of X-ray energy outside the treatment beam.

X-rays were the first form of photon radiation to be used to treat cancer. Depending on the amount of energy they possess, the X-rays can be employed to destroy cancer cells on the surface of an area, or to penetrate to tissues deeper in the body. The higher the energy of the X-ray beam, the deeper the X-rays penetrate into the target tissue.

Linear accelerators produce X-rays of increasingly greater energy. Gamma rays are another available form of photon radiation and are produced spontaneously as certain elements (such as radium, uranium and cobalt 60) release radiation when they decompose or decay.

Intraoperative irradiation

In intraoperative irradiation, a large dose of external radiation is directed at the tumour and surrounding tissue during surgery.

Intensity-modulated radiotherapy

Intensity-modulated radiotherapy (IMRT) uses a different software programme to administer the radiation from multiple angles in smaller doses, with a new shuttering device to limit the size of the radiation beams, thus sparing the salivary glands.

Particle beam radiation therapy

This involves the use of fast-moving subatomic particles to treat localized cancers. A sophisticated machine is needed to produce and accelerate the particles required for this procedure. Some particles (neutrons, pions and heavy ions) deposit more energy along the path they take through tissue than do X-rays or gamma rays, thus causing more damage to the cells they hit. This type of radiation is often referred to as high linear energy transfer (high LET) radiation.

The consensus is that patients with OSCC with involved margins or extracapsular spread (ECS) should have adjuvant radiotherapy. IMRT, three-dimensional (3-D) conformal radiotherapy, and conventional radiotherapy provide similar disease control but IMRT produces less hyposalivation.

Chemoradiotherapy

Chemotherapeutic agents are increasingly used to enhance the effects of radiotherapy (chemoradiation) (see below).

DENTAL ASPECTS

Careful treatment planning, close monitoring and strict application of preventive measures can reduce the incidence of complications. Improved techniques, such as the application of lower radiation doses or IMRT, use of shielding, reduction in toxic drugs and improved oral hygiene, can also reduce complications. Pain control is of paramount importance; patients may need potent analgesics, such as opioids, sedatives or antidepressants, particularly if they have terminal cancer. Completion of dental treatment before cancer care benefits the patient greatly.

Patients with advanced disease have a high prevalence of oral treatment complications, particularly hyposalivation, which is seen in nearly three-quarters; often soreness, taste disturbances and difficulties with wearing dentures are also present. Candidosis is common.

The most obvious oral importance of tumours in other parts of the body is as a source of metastases that can form in the jaws or occasionally in soft tissues. Histological examination of all such swellings in a person with malignant disease elsewhere is therefore essential. Other oral manifestations of internal malignancy are summarized in Appendix 22.1.

RADIOTHERAPY INVOLVING THE ORAL CAVITY OR SALIVARY GLANDS

External beam radiotherapy is mostly used to treat oral cancer (Table 22.9). In the treatment of head and neck cancers, radiotherapy, despite being targeted at the cancer, inevitably damages surrounding normal tissues, causing mucositis, and often salivary damage and hyposalivation (Table 22.10). Hair loss and skin erythema are common in the path of the radiation beam (Fig. 22.4). Carotid stenosis may arise.

Careful treatment planning with precise dosimetry and careful shielding of the healthy tissues, as well as close monitoring of the oral cavity with application of preventive measures, can significantly reduce many complications.

Mucositis

Mucositis is virtually inevitable but can be mitigated by modifying the radiation schedule; protecting the mucosa with midline mucosa-sparing blocks; or, theoretically, by using amifostine, which, with its active metabolite, is a free-radical scavenger and is cytoprotective. However, amifostine is rarely used in clinical practice because of fears that the free-radical scavenging action may also reduce the effectiveness of radiotherapy on the cancer cells. Amifostine may cause severe nausea and vomiting, although it also reduces the risk of infection associated with neutropenia. Interventions apart from oral care protocols, that may help ameliorate symptoms in mucositis may include cryotherapy, laser therapy, recombinant human keratinocyte growth factor-1 (palifermin), benzydamine hydrochloride, systemic zinc supplements, and patient controlled analgesia with morphine/transdermal fentanyl/2% morphine mouthwash/0.5% doxepin mouthwash to treat pain.

Hyposalivation

Radiotherapy to tumours of the mouth, nasopharynx and oropharynx is especially liable to damage the salivary glands, depress salivary secretion and result in saliva of a higher viscosity but lower pH. The severity

Table 22.9 Types of external beam radiotherapy used to treat head and neck cancer

Type	Source	Used for
Electron beam	Electrical	Superficial lesions
Low-voltage	X-ray	Superficial lesions
Orthovoltage	X-ray	Skin lesions
Supervoltage	Cobalt-60	Deeper lesions
Megavoltage	Linear accelerator	Larger lesions

Table 22.10 Oral complications of radiotherapy involving the mouth and salivary glands

Week 1	Week 2+	Week 3+	Later
Nausea Vomiting	Mucositis Taste changes	Dry mouth	Infections Caries Pulp pain and necrosis Tooth hypersensitivity Trismus Osteoradionecrosis Craniofacial defects

Fig. 22.4 Radiation erythema and hair loss.

experienced depends on a number of factors but especially the volume of salivary tissue irradiated (Table 22.11) and the dose. Salivary secretion diminishes within a week of radiotherapy in virtually all patients and the saliva becomes thick and tenacious. Some salivary function may return after many months. Doses greater than 30 Gy generally lead to a persistently, if not permanently, dry mouth.

Both acute and long-term hyposalivation can be reduced by using IMRT; sparing at least one parotid gland during irradiation of patients with head and neck cancer; stimulating salivation pre-radiotherapy with pilocarpine; or by giving amifostine. Occasionally, submandibular gland transfer is used.

Table 22.11 *Fall in salivary flow with different radiotherapy fields*

Regimen	Approximate % fall in salivation
Mantle	30
Unilateral	50
Bilateral	75
Head and neck cancer	95
Nasopharynx	100

Infections

Hyposalivation predisposes the patient to infections (caries, oral candidosis and acute ascending sialadenitis).

Loss of taste (hypogeusia)

Loss of taste follows radiation damage to the taste buds. Taste may start to recover within 2–4 months and is typically restored by 6 months, but if more than 6000 cGy have been given, loss of taste may be permanent.

Radiation caries

Caries and dental hypersensitivity may follow radiotherapy. Patients frequently take a softer, more cariogenic diet because of mouth dryness and soreness, and loss of taste. Salivary protection is diminished. There is a change to a more cariogenic oral flora and the hypersensitive teeth make oral hygiene difficult. These factors combine to cause rampant dental caries, including in areas such as incisal edges and cervical margins, which are normally free from caries. Caries begins at any time between 2 and 10 months after radiotherapy, and may eventually result in the crown breaking off from the root. A complete dentition may be destroyed within a year of irradiation.

Caries may be minimized by controlling sugar intake, protecting salivary function as above, and using fluorides, sialogogues and mouth-wetting agents.

Trismus

Trismus may result from replacement fibrosis of the masticatory muscles following progressive endarteritis of affected tissues, with reduction in their blood supply. Fibrosis becomes apparent 3–6 months after radiotherapy and can cause permanent limitation of opening. Fibrosis must be differentiated from recurrence of the tumour and from osteoradionecrosis.

Osteoradionecrosis

Radiation therapy induces endarteritis obliterans, which leads to progressive fibrosis and capillary loss, leaving bone susceptible to avascular necrosis. The latter predisposes to the late and more severe complication of osteoradionecrosis (ORN), which may occur months to years later. ORN is a potentially serious complication of radiotherapy involving the jaws and often results from dental extractions carried out after radiotherapy. Oral sepsis, particularly from periodontal disease, may contribute.

The mandible, a compact bone with high density and poor vascularity, is more prone than the maxilla to ORN, and risk is greatest when radiation dose exceeds 60 Gy, when the floor of mouth is irradiated, from 10 days before to several years after radiotherapy (especially at

3–12 months after radiotherapy), and in patients who are malnourished or immuno-incompetent. ORN may follow months or years after radiotherapy but about 30% of cases develop within 6 months and are heralded by pain and swelling. Presentation is with exposed bone in an irradiated mouth, with or without external sinuses, pain and pathological fracture. In severe cases, the whole of the body of the mandible may be destroyed, and the bone may become exposed internally and externally. The area involved is often small (less than 2 cm in diameter) and, with antibiotics, the signs and symptoms of inflammation may clear within a few weeks.

ORN may be prevented by avoiding operations such as dental extractions after the jaws have been irradiated – which is best achieved by removing unsalvageable teeth at least 2 weeks before starting radiotherapy.

New developments in radiotherapy, such as 3-D conformal radiotherapy and IMRT, have allowed radiation oncologists to escalate the dose of radiation delivered to tumours while minimizing the dose delivered to surrounding normal tissue/bone, contributing to a remarkable decline in the prevalence of ORN to less than 4%.

Local measures used to treat ORN include meticulous oral hygiene, chlorhexidine mouthwashes after meals, wound irrigation, removal of loose sequestrate and antibiotic therapy (tetracycline, clindamycin, metronidazole). It is possible that ultrasound and hyperbaric oxygen (HBO) may help. The ‘Marx protocol’ consists of 20 HBO sessions prior to surgery and 10 sessions afterwards. However, a high-quality trial has demonstrated that HBO alone is not effective in treating ORN of the mandible compared to placebo. There is a lack of evidence regarding the effect of HBO on dental implants/ORN risk. Complete resolution of ORN can, however, take 2 or more years, despite intensive treatment.

Craniofacial defects

Craniofacial defects, tooth hypoplasia and retarded eruption can follow irradiation of developing teeth and growth centres in children. Children treated for neuroblastoma, therefore, are at particularly high risk.

Dental management of patients receiving radiotherapy to the head and neck

Before radiotherapy

Meticulous oral hygiene should be implemented, preventive dental care instituted and restorative procedures carried out. Unsalvageable teeth in the radiation path should be extracted at least 2 weeks before starting radiotherapy and no bone should be left exposed in the mouth.

During radiotherapy

During radiotherapy, mucosal and salivary gland protection with amifostine can minimize mucositis and hyposalivation. Smoking and alcohol should be discouraged.

Mucositis may be relieved by using warm normal saline mouthwashes and benzydamine (which has anti-tumour necrosis factor activity) oral rinses, or lidocaine 2% gel. A 0.2% chlorhexidine mouthwash improves oral hygiene. Antifungal drugs, such as nystatin suspension as a mouthwash used four times daily, may be required. Palifermin, transforming growth factor beta (TGFβ), interleukin-1 (IL-1) and IL-11 show promise.

A saliva substitute, such as carboxymethylcellulose, may provide some symptomatic relief, as may salivary stimulants.

Table 22.12 Chemotherapeutic drug groups

Drug group	Actions	Administration route	Examples
Alkylating agents	Directly attack DNA	Oral or intravenous	Cyclophosphamide and mechlorethamine, cisplatin, chlorambucil or melphalan
Nitrosoureas	Inhibit DNA repair	Oral or intravenous	Carmustine and lomustine
Antimetabolites	Interfere with DNA synthesis	Oral or intravenous	6-Mercaptopurine, 5-fluorouracil, methotrexate, fludarabine and cytarabine
Antitumour antibiotics	Prevent RNA synthesis and DNA replication	Intravenous	Doxorubicin and mitomycin-C, daunorubicin, idarubicin and mitoxantrone
Plant (vinca) alkaloids	Prevent cell division	Intravenous	Vincristine and vinblastine
Taxanes	Stop microtubules from breaking down and thus prevent cancer cells from growing and dividing	Intravenous	Paclitaxel and docetaxel
DNA-repair enzyme inhibitors	Attack DNA repair mechanisms	Oral or intravenous	Etoposide or topotecan
Steroid hormones	Modify growth of hormone-dependent cancers	Oral	Tamoxifen and flutamide

Trismus may be improved by jaw-opening exercises with tongue spatulas, wedges or TheraBite®, used three times a day.

After radiotherapy

Oral hygiene and preventive dental care should be continued; dryness of the mouth is managed as for Sjögren syndrome (Ch. 18).

Radiation caries and dental hypersensitivity can be controlled with a non-cariogenic diet, high-fluoride dentifrice and daily topical fluoride applications, such as fluoride mouthwash. The standard of care for natural teeth is by daily application of fluoride by means of custom-fabricated carriers. Amorphous calcium phosphate may be indicated.

If extractions become unavoidable, trauma should be kept to a minimum, raising the periosteum as little as possible, ensuring that sharp bone edges are removed, suturing carefully and giving prophylactic antibiotics in adequate doses from 48 hours preoperatively, continued for at least 4 weeks to prevent ORN. Clindamycin 600mg three times daily is an appropriate antibiotic since it penetrates bone well.

If dentures are required, they should be fitted at about 4–6 weeks after radiotherapy, when initial mucositis subsides and there is only early fibrosis.

CHEMOTHERAPY

Chemotherapy alone is rarely appropriate in OSCC but taxanes, cisplatin and 5-fluorouracil (TPF), or carboplatin, methotrexate and bleomycin may be used. Chemotherapy is used mainly for treating lymphoproliferative neoplasms. Mucositis may result.

Cytotoxic chemotherapy drugs act mainly by interacting with cancer cell DNA or RNA and affecting some phase of the cell's life cycle (<http://www.oralcancerfoundation.org/facts/chemotherapy.htm>; accessed 30 September 2013). The first phase of the cell cycle (G1) is when the cell prepares to replicate its chromosomes. The second stage (S) is when DNA synthesis occurs and the DNA is duplicated. The next phase (G2) is when the RNA and protein duplicate. The final (M) stage is the stage of actual cell division; the duplicated DNA and RNA split and move to separate ends of the cell, and the cell divides into two identical functional cells (mitosis). Chemotherapeutic drugs are divided into several broad categories, depending on their function (Tables 22.12 and 22.13).

Chemotherapy is given orally or, more usually, intravenously, then typically by catheter – a thin plastic tube – inserted into a central vein or artery and left in place throughout treatment; this eliminates the need for multiple needle insertions every time treatment is needed. Chemotherapy results in OSCC appear to be improving, and the technique of continuous intra-arterial infusion therapy may sometimes be

Table 22.13 Other drugs used in the treatment of malignant disease

Drug class	Examples
Aromatase inhibitors	Aminoglutethimide Anastrozole Formestane Letrozole
Hormones	For prostate carcinoma: Bicalutamide Cyproterone Flutamide Gonadotrophin-releasing hormone analogues (buserelin, goserelin, leuporelin, triptorelin) Oestrogen For breast carcinoma: Progestogens Tamoxifen Toremifene
Recombinant interleukin-2	Aldesleukin
Somatostatin analogues	Lanreotide Octreotide

as effective as surgery or radiation therapy, with an excellent cosmetic result, preservation of function and minimal side-effects.

Complications from cytotoxic chemotherapy

Most cytotoxic agents cause complications, particularly if treatment is prolonged or in high dosage (see Tables 22.12 and 22.13); they include alopecia, nausea and vomiting, anorexia, bone marrow suppression, hyperuricaemia, reproductive function damage, especially in males, and mucositis (Fig. 22.5) in particular. Some 90% of children and approximately 50% of adults develop oral lesions, more frequently so when chemoradiotherapy is given.

Mucositis

Chemotherapy-induced mucositis typically appears from 7 to 14 days after the initiation of drug therapy. At least 90% of patients treated with fluorouracil and cisplatin develop mucositis (Table 22.14). Etoposide, melphalan, doxorubicin, vinblastine, taxanes and methotrexate are also particularly stomatotoxic. By contrast, mucositis is uncommon with asparaginase and carmustine.

Table 22.14 Main chemotherapeutic agents responsible for oral mucositis

Alkylating agents	Anthracyclines	Antibiotics	Antimetabolites	Taxanes	Microtubule disassemblers
Busulfan	Daunorubicin	Actinomycin D	Cytosine arabinoside	Docetaxel	Etoposide
Cyclophosphamide	Doxorubicin	Amsacrine	5-Fluorouracil	Paclitaxel	Vinblastine
Mechlorethamine	Epirubicin	Bleomycin	Hydroxycarbamide		Vincristine
Melphalan		Dactinomycin	Methotrexate		Vinorelbine
Procarbazine		Daunorubicin	6-Mercaptopurine		
Thiotepa		Doxorubicin	Tioguanine		
		Mithromycin			
		Mitomycin			
		Mitoxantrone			

**Fig. 22.5** Adverse effects from chemotherapy.

If associated with neutropenia, mucositis predisposes to septicaemia. Potential pathogens include alpha-haemolytic streptococci, especially *Streptococcus oralis* and *Strep. mitis*, *C. albicans*, other *Candida* species, *Aspergillus* and *Mucor*. Mucositis may be a predictor of gastrointestinal toxicity and, after haemopoietic stem-cell transplantation (HSCT), may predict the onset of hepatic veno-occlusive disease.

General management

It is helpful to attempt to score the degree of mucositis for monitoring progress and therapy. Several systems have been devised but most lack standardization or validation, and none thus far has found universal acceptance; an example is shown in Table 22.15.

Despite the numerous approaches tried for the prevention and treatment of mucositis, virtually nothing works consistently or predictably. However, there is benefit from a soft diet (Table 22.16). Ice chips sucked for 30 minutes before 5-fluorouracil, methotrexate or melphalan

Table 22.15 Oral assessment guide

	1	2	3
Voice	Normal	Deeper or raspy	Difficulty talking
Swallow	Normal	Some pain	Inability to swallow
Lips	Smooth, pink and moist	Dry or cracked	Ulcerated or bleeding
Tongue	Pink and moist	Coated and shiny $\pm$ red	Blistered or cracked
Saliva	Watery	Thick	Absent
Mucous membranes	Pink and moist	Red and coated without ulcers	Ulcers
Gingivae	Pink and firm	Oedematous $\pm$ redness	Spontaneous or pressure-induced bleeding
Teeth/denture areas	Clean, no debris	Plaque and localized debris	Generalized plaque or debris

Table 22.16 Diet in oral mucositis

Diet that is typically acceptable	Foods to avoid	Lifestyle habits to avoid
Liquids	Rough food (chips, crisps, toast)	Smoking
Purées	Spices	Alcohol
Ice	Salt	
Custards	Acidic fruit (grapefruit, lemon, orange)	
Non-acidic fruits (banana, mango, melon, peach)		
Soft cheeses		
Eggs		

administration may be beneficial by reducing exposure of mucosae to the chemotherapy agent. Folinic acid (as calcium folinate), levofolinic acid or disodium folinate can reduce mucositis from methotrexate or fluorouracil. Palifermin, TGF β , IL-1 and IL-11 show promise.

Mucositis often necessitates the use of opioid analgesics for pain control; tube feeding; and prophylaxis for infectious complications. Interventions that may ameliorate symptoms include oral care protocols, oral cryotherapy, laser therapy, recombinant human keratinocyte growth factor-1 (palifermin), benzydamine hydrochloride, systemic zinc supplements, and patient controlled analgesia with morphine/transdermal fentanyl/2% morphine mouthwash/0.5% doxepin mouthwash to treat pain.

Infections

Cytotoxic agents predispose to infections with fungi, viruses, toxoplasma or bacteria. Oral candidosis is common, usually caused by *C. albicans*

or, less often, other *Candida* species. It is promoted especially by severe leukopenia and the use of antibiotics. Oral mucormycosis (phycomycosis) or aspergillosis is rare. Herpetic infections (herpes simplex or herpes zoster) are common and may cause chronic oral ulcers. Gram-negative oral infections may be caused by *Pseudomonas*, *Klebsiella*, *Escherichia*, *Enterobacter*, *Serratia* or *Proteus*, and dental infections may spread rapidly. Gram-positive bacterial infections (staphylococci) are less common as patients usually receive antibiotics prophylactically.

Bleeding

Drug-induced thrombocytopenia may cause gingival bleeding, mucosal petechiae or ecchymoses.

Hyposalivation

Cytotoxic agents (especially doxorubicin) can lead to hyposalivation, caries and other oral infections.

Craniofacial maldevelopment

Delayed and abnormal craniofacial, jaw and dentition development and abnormalities can follow prolonged chemotherapy.

Dental management of patients on cytotoxic chemotherapy

Before chemotherapy

A careful oral assessment should be carried out to enable extractions and any other surgery to be completed before cytotoxic treatment (Table 22.17). Oral hygiene should be improved as far as possible.

During chemotherapy

During chemotherapy, it may be possible to lessen the stomatitis by using ice-cold water or asking the patient to suck ice during infusion of the agent. Established mucositis or oral ulceration is managed by maintaining good oral hygiene with twice-daily 0.2% aqueous chlorhexidine mouth rinses; 2% lidocaine gel or benzydamine rinse or spray can lessen discomfort. Nystatin suspension as a mouthwash, 4–6 times daily, may be given prophylactically. Fluconazole may be more appropriate for patients with candidosis who develop fever. Dentures should be carefully cleaned and stored overnight in 1% hypochlorite to reduce candidal carriage. Prophylactic aciclovir has lowered the incidence of herpes simplex and zoster, and mortality from zoster. Oral herpetic infections should be treated with aciclovir suspension or

systemic aciclovir or valaciclovir (tablets or infusion). Zoster immune globulin may ameliorate varicella or zoster.

Although patients are frequently on several antibiotics already, Gram-negative infections may need treatment with gentamicin or carbenicillin, as the oral lesions can act as portals for systemic spread.

Possible drug interactions should be considered. Aspirin should not be given to patients on methotrexate, as it may enhance its toxicity. Some cytotoxic drugs enhance the effects of suxamethonium (Ch. 23); others cause more serious complications that can influence dental management (Appendices 22.2, 22.3, 22.4 and 22.5).

After chemotherapy

After chemotherapy, there should still be close attention to oral hygiene and preventive dentistry, as many patients continue to have anaemia and bleeding tendencies and to be susceptible to infection.

TARGETED THERAPY

Therapies that specifically target cell-signalling pathways that are dysregulated in tumours have focused mainly on epidermal growth factor receptor (EGFR or HER1) inhibitors, particularly cetuximab. These appear not to exacerbate the common effects associated with radiotherapy, such as mucositis, hyposalivation, dysphagia or pain. An acneiform rash is common, xerosis cutis and paronychia may be seen, and oral ulceration has been reported.

HAEMOPOIETIC STEM CELL TRANSPLANTATION (BONE MARROW TRANSPLANTATION)

See Chapter 35.

SALIVARY NEOPLASMS

See Chapter 14.

CHILDHOOD NEOPLASMS

These include the following:

- Leukaemias – common in childhood (Ch. 8).
- Solid tumours – rare but most are treated with surgery plus radiotherapy and/or chemotherapy, which can damage craniofacial and dental development. They include:
 - ◆ brain tumours, especially gliomas, which are the most frequent solid tumours in childhood, and are usually low-grade astrocytomas or medulloblastomas found in the posterior cranial fossa.
 - ◆ Wilms tumour, which arises from the kidney, is often associated with aniridia, and may metastasize to the lungs, liver or bone.
 - ◆ retinoblastomas, which have a strong hereditary basis, appear in pre-school children and cause blindness.
 - ◆ neuroblastomas, which arise from neural crest cells, especially abdominally, and metastasize to lymph nodes, lungs, bone and liver.

END-OF-LIFE CARE

The quality of life is as important as, or more important than, its duration. Good communication with patient, partners, family and friends

Table 22.17 Dental treatment for patients on cytotoxic chemotherapy

Blood cell type	Peripheral blood count	Precautions
Platelets	$>50 \times 10^9/L$	Routine management, though desmopressin or platelets needed to cover surgery
	$<50 \times 10^9/L$	Platelets needed for any invasive procedure ^a
Granulocytes	$>2 \times 10^9/L$	Routine management
	$<2 \times 10^9/L$	Prophylactic antimicrobials for surgery
Erythrocytes	$>5 \times 10^{12}/L$	Routine management
	$<5 \times 10^{12}/L$	Special care with general anaesthesia

^aAny procedure where bleeding is possible.

Table 22.18 Analgesics: routes of administration

	Buccal	Intravenous	Per rectum	Subcutaneous	Sublingual	Transdermal
Fentanyl	+					+
Hydromorphone		+	+	+		
Morphine		+	+	+	+	
Oxycodone			+			

is essential. Many different people are involved, so that (providing the patient consents) all should be aware of:

- the prognosis
- how much patients understand about their disease
- their psychological reactions to cancer
- the side-effects of treatment.

PSYCHOLOGICAL CARE

Hope is all-important and management must include particular attention to psychological problems. Patients may or may not know, or may not want to know, that they have malignant disease; even if they are aware of it, they may not appreciate, or be willing to accept, the prognosis.

PAIN CONTROL

Pain control is of paramount importance. Potent analgesics, such as opioids, sedatives or antidepressants, may be needed and are warranted in terminal cancer. The World Health Organization's three-step analgesic ladder (Ch. 3) is a guideline for cancer pain management, and is effective in relieving pain for approximately 90% of patients with cancer and over 75% of cancer patients who are terminally ill.

The five essential concepts in drug therapy for cancer pain are:

- by the mouth
- by the clock
- by the ladder
- for the individual
- with attention to detail.

Adjuvant drugs to enhance analgesic efficacy, treat concurrent symptoms that exacerbate pain, and provide independent analgesic activity for specific types of pain may be used at any step.

Step 1 in this approach is to give paracetamol (acetaminophen), aspirin or another non-steroidal anti-inflammatory drug (NSAID) orally for mild to moderate pain.

Step 2, when pain persists or worsens, is an opioid such as codeine or hydrocodone, which should be added (not substituted) to the NSAID. Opioids at this step are often administered in fixed-dose combinations with paracetamol or aspirin because this combination provides additive analgesia. Fixed-combination products may be limited by the content of paracetamol or NSAID, which may cause dose-related toxicity. When higher doses of opioid are necessary, the third step is taken.

Step 3, for pain that is still persistent, or moderate to severe, involves giving separate dosage forms of the opioid and non-opioid analgesic in order to avoid exceeding maximally recommended doses of paracetamol or NSAID.

Patients who have moderate to severe pain when first seen should be started at the second or third step of the ladder. Pain that is severe at the outset should be treated by giving more potent opioids or using higher dosages. Drugs such as codeine or hydrocodone are replaced by more potent opioids (usually morphine, hydromorphone, methadone, fentanyl or levorphanol). Fentanyl transdermal patches can be helpful (Table 22.18).

Medications for persistent cancer-related pain should be administered on an around-the-clock basis, with additional 'as-needed' doses, because regularly scheduled dosing maintains a constant level of drug in the body and helps to prevent a recurrence of pain. Patient-controlled analgesia (PCA), usually delivered via continuous systemic intravenous infusion, allows patients to control the amount of analgesia they receive. PCA can also be accomplished by mouth, subcutaneously or epidurally. Patient-administered boluses are required to treat breakthrough pain, and to provide a basis for more accurate and rapid upward titration of the continuous infusion rate. Intravenous or subcutaneous PCA allows patients to accommodate transient changes in analgesic requirements (such as during dressing changes or positioning) and to tailor analgesic doses according to their own requirements. Intravenous and subcutaneous PCA is contraindicated for sedated and confused patients. Morphine and diamorphine, often by intravenous infusion, are the drugs of choice for severe pain in hospitalized patients. Phenazocine may be valuable in patients intolerant of, or allergic to, morphine. Pethidine has too short an action and the metabolite norpethidine can accumulate in renal failure and then cause convulsions. Buprenorphine is a partial agonist and should be avoided. Dextromoramide is only very short-acting but can be useful to 'cover' painful procedures. NSAIDs may help ease bone pain, while dexamethasone is valuable for headaches associated with raised intracranial pressure. Carbamazepine or tricyclic antidepressants may relieve pain due to tumour infiltrating nerves. Transdermal fentanyl (skin patches) is increasingly used since it has an effect comparable with morphine and a duration of action of around 3 days. In the past, doctors have been anxious about giving sufficient opioids to terminally ill patients. However, if patients know that they can have opioids or other analgesics whenever they feel the need, the demand for these drugs falls.

QUALITY OF LIFE

Patients with any cancer may have severe psychological disturbances in view of the nature of the illness; these problems are compounded in oral cancer since there are additional disabilities, particularly interference with speech and swallowing, and disfigurement (e.g. 'Andy Gump' facies). Percutaneous endoscopic gastrostomy (PEG; Fig. 22.6) is a feasible and effective option when adequate oral nutrition is not possible. Patients are thus subject to considerable distress and up to a third have anxiety or depression, which occasionally leads to suicide. Counselling is especially important preoperatively but should be continued postoperatively, and include family members and partners.

Most general quality-of-life issues (emotional functioning, pain, insomnia, constipation) do not change after treatment or improve compared to baseline scores; most head- and neck-specific quality-of-life issues deteriorate after treatment but return to pre-treatment levels at 12 months, except for senses, opening mouth, sticky saliva and coughing, which remain deteriorated in the long term. Tumour site and stage, co-morbidity and extensive resections are significantly associated with adverse quality-of-life outcomes, as are marital status and age.

Fig. 22.6 Percutaneous endoscopic gastrostomy for feeding directly into the stomach.

PRESERVATION OF DIGNITY

Dignity is extremely important, and there are few other conditions that are as disfiguring as oral cancer. Feeding can be difficult, especially if there is dysphagia, when nasogastric (NG) intubation may be needed, but PEG is a better long-term solution, as it avoids the fear of choking and aspiration pneumonia. In some cases, hospice care is preferable.

The type of oral health care must be planned in relation to the interest that the patient has in their oral state. Just because patients are dying does not mean that they should be allowed to suffer from pain or that their appearance may be neglected. Indeed, the provision of oral hygiene, attention to halitosis and dental care (e.g. the construction of a new denture) may all help the patient's morale.

HEREDITARY CANCER SYNDROMES

These include:

- Cowden syndrome (gene; PTEN)
- Gardner syndrome or Familial Adenomatous Polyposis (FAP) (gene; APC)
- Gorlin syndrome (gene; PTCH1)
- Hereditary Breast And Ovarian Cancer (HBOC) (genes; BRCA1 and BRCA2)
- Li Fraumeni syndrome (gene; TP53)
- Lynch syndrome or Hereditary Nonpolyposis Colorectal Cancer (HNPCC) (genes; MLH1, MSH2, MSH6, PMS2, and EPCAM)
- Multiple Endocrine Neoplasia type 2 (MEN 2) (gene; RET)
- Peutz-Jegher syndrome (gene; STK11 or LKB1)

APPENDIX 22.1 ORAL MANIFESTATIONS OF INTERNAL CANCER

Metastases in jaws or (rarely) oral soft tissues, especially from cancer of:

- Breast
- Lung
- Prostate
- Thyroid
- Kidney
- Stomach
- Colon

Effects of tumour products

- Facial flushing (carcinoid syndrome)
- Pigmentations (ectopic adrenocorticotrophic hormone-secreting tumours)
- Amyloidosis (multiple myeloma)

- Oral erosions (glucagonoma)
- Swellings (acanthosis nigricans)

Changes caused by other functional disturbances

- Purpura, anaemia, infections (leukaemia)
- Infections (lymphoma)
- Bleeding (liver cancer)
- Anaemia (bleeding from gastrointestinal tumours)

Mucocutaneous diseases

- Dermatomyositis (carcinoma)
- Acanthosis nigricans (abdominal carcinoma)
- Erythema multiforme (lymphoma, leukaemia or carcinoma, especially after radiotherapy)
- Paraneoplastic pemphigus (lymphomas or Castleman disease)
- Pemphigoid
- Dermatitis herpetiformis

(Continued)

Inherited disorders with predisposition to internal malignancy and oral lesions

- Cowden syndrome
- Dyskeratosis congenita
- Gardner syndrome
- Gorlin–Goltz syndrome
- Maffucci syndrome
- Multiple endocrine neoplasia
- Neurofibromatosis (von Recklinghausen disease)
- Peutz–Jeghers syndrome
- Tuberous sclerosis
- Tylosis

APPENDIX 22.2 CHEMOTHERAPEUTIC AGENTS: MAIN USES AND TOXICITIES^a

Agent	Main uses	Main toxicities
<i>Alkylating agents^{b, c}</i>		
Busulfan	Chronic myeloid leukaemia (CML)	Myelosuppression Hyperpigmentation Pulmonary fibrosis
Carmustine	Multiple myeloma Lymphomas	Nephrotoxicity Pulmonary fibrosis
Chlorambucil	Chronic lymphocytic leukaemia (CLL) Lymphomas	Myelosuppression Erythema multiforme
Cyclophosphamide	Ovarian cancer	–
	CLL	Cystitis (avoid with mesna)
Estramustine	Lymphomas	Severe nausea and vomiting
	Prostatic carcinoma	Angina Gynaecomastia Liver dysfunction
Ifosfamide	CLL	Cystitis (avoid with mesna)
Lomustine	Lymphomas	–
	Hodgkin disease	Nausea and vomiting Delayed myelosuppression
Melphalan	Multiple myeloma	Delayed myelosuppression
Mustine	Hodgkin disease	Severe vomiting
Thiotepa	Malignant effusions	Enhances suxamethonium
Treoosulfan	Bladder carcinoma	–
	Ovarian carcinoma	Hyperpigmentation Pulmonary fibrosis Haemorrhagic cystitis
<i>Cytotoxic antibiotics^{b, d}</i>		
Aclarubicin	Acute myeloid leukaemia (AML)	Nausea and vomiting
Bleomycin	Squamous carcinomas	Pulmonary fibrosis
Dactinomycin	Paediatric tumours	Similar to doxorubicin but no cardiotoxicity
Daunorubicin	Kaposi sarcoma	Cardiotoxicity
Doxorubicin (Adriamycin)	Acute leukaemias	Mucositis
	Lymphomas	Nausea and vomiting
Epirubicin	Ovarian cancer	Supraventricular tachycardia Cardiomyopathy
	Breast carcinoma	Myelosuppression Cardiotoxicity

Agent	Main uses	Main toxicities
Idarubicin	Breast cancer Acute leukaemias	Cardiotoxicity –
Mitomycin	Upper gastrointestinal and breast carcinomas	Myelosuppression Nephrotoxicity Lung fibrosis
Mitoxantrone	Breast carcinoma Lymphomas	Myelosuppression Cardiotoxicity
Plicamycin (mithramycin)	Hypercalcaemia in malignancy	Thrombocytopenia
<i>Antimetabolites^b</i>		
Capecitabine	Colorectal cancer	Hand–foot syndrome (desquamation)
Cladribine	Hairy cell leukaemia	Myelosuppression
Cytarabine	Acute leukaemias	Myelosuppression
Fludarabine	CLL	Myelosuppression Immunosuppression CNS toxicity Pulmonary toxicity
Fluorouracil	Colon carcinoma	Mucositis
	Breast carcinoma	Myelosuppression Cerebellar syndrome
Gemcitabine	Non-small-cell lung carcinoma	Myelosuppression
Mercaptopurine	Acute leukaemias	Myelosuppression Hepatotoxicity
Methotrexate	Acute lymphocytic leukaemia (ALL) Rheumatoid arthritis Psoriasis	Mucositis Myelosuppression (ameliorate with leucovorin)
Raltitrexed	Colorectal cancer	Fever and cytokine release
Tegafur	Colorectal cancer	Nausea and vomiting
Tioguanine	Acute leukaemias	Myelosuppression
<i>Mitotic inhibitors^b</i>		
Etoposide	Small-cell carcinoma or lung lymphomas	Nausea and vomiting Myelosuppression
Vinblastine	Acute leukaemias Lymphomas	Myelosuppression Neurotoxicity
Vincristine	Acute leukaemias Lymphomas	Neurotoxicity Inappropriate antidiuretic hormone (ADH) secretion
Vindesine	Acute leukaemias Lymphomas	Neurotoxicity Myelosuppression
Vinorelbine	Breast cancer Lung cancer	Neurotoxicity Myelosuppression
<i>Other antineoplastic drugs^b</i>		
Aldesleukin (interleukin-2)	Renal cancer	Capillary leak Marrow, liver, CNS, thyroid and kidney toxicity
Alemtuzumab	CLL	Severe cytokine release syndrome (dyspnoea)
Amsacrine	AML	Mucositis Myelosuppression Arrhythmias
Bexarotene	T-cell lymphoma	Hyperlipidaemia Hypothyroidism
Carboplatin	Small oat cell carcinoma of lung	Myelosuppression Severe nausea and vomiting

(Continued)

Agent	Main uses	Main toxicities
Cisplatin	Ovarian carcinoma	Severe nausea and vomiting
	Testicular carcinoma	Ototoxicity
		Nephrotoxicity
Crisantaspase	ALL	Anaphylaxis
		Glucose intolerance
		CNS changes
		Liver dysfunction
Dacarbazine	Hodgkin lymphoma	Severe nausea and vomiting
		Myelosuppression
Docetaxel	Breast cancer	Fluid retention
Hydroxycarbamide (hydroxyurea)	CML	Nausea
		Rashes
		Myelosuppression
Irinotecan	Colorectal cancer	Acute cholinergic syndrome
Interferon-alpha	Kaposi sarcoma	'Flu-like symptoms
	Hairy cell leukaemia	Cardiotoxicity
	Non-Hodgkin lymphoma	Hepatotoxicity
		Depression
Oxaliplatin	Colorectal cancer	Neurotoxicity
		Myelosuppression
Paclitaxel	Ovarian cancer	Hypersensitivity
	Breast cancer metastases	Myelosuppression
		Arrhythmias
Pentostatin	Hairy cell leukaemia	Myelosuppression
		Immunosuppression
Porfimer	Lung cancer	Photosensitivity
Procarbazine	Hodgkin lymphoma	Myelosuppression
		Hypersensitivity
		Disulfiram reaction with alcohol
Razoxane	Leukaemia	Myelosuppression
Rituximab	Lymphoma	Cytokine release syndrome (dyspnoea)
Temozolomide	Glioma	Myelosuppression
Topotecan	Ovarian cancer	Diarrhoea
Trastuzumab	Breast cancer	Cardiotoxicity if used with anthracyclines
Tretinoin	Acute promyelocytic leukaemia	Dyspnoea
		Multiorgan failure

^aSee also Biologics, Chapter 19.

^bAll can produce mucositis, nausea, vomiting and alopecia.

^cAll can interfere with gametogenesis and predispose to acute leukaemias.

^dShould not be used with radiotherapy, as they enhance radiation toxicity.

APPENDIX 22.3 MAIN CHEMOTHERAPY COMPLICATIONS AND RESPONSIBLE AGENTS

Complication	Agent responsible
<u>Early</u>	
Alopecia	Alkylating agents Anthracyclines Cisplatin

Complication	Agent responsible
Diarrhoea	5-fluorouracil (5-FU) Irinotecan
Myelosuppression	Alkylating agents Anthracyclines Taxanes
Mucositis	Etoposide 5-FU Methotrexate
Nausea	All
Nephrotoxicity	Cisplatin
Neurotoxicity	Cisplatin Taxanes
Ototoxicity	Cisplatin
Dark urine	Anthracyclines
<u>Late</u>	
Cardiotoxicity	Anthracyclines
Infertility	Alkylating agents
Menopause	Alkylating agents
Myelodysplasia	Etoposide
Pulmonary fibrosis	Bleomycin Mitomycin

APPENDIX 22.4 MANAGEMENT OF EARLY ADVERSE EFFECTS FROM CHEMOTHERAPY

Adverse effect	Management
Anorexia	Megestrol acetate
Bladder damage (cystitis)	Mesna
Constipation	Docusate sodium, milk of magnesia
Diarrhoea	Loperamide, co-phenotrope (Lomotil)
Dry skin, hair loss	Emollients, vitamin E, zinc supplements
Extravasation injury to soft tissue	Dimethyl sulfoxide (DMSO) topically
Heart injury	Dexrazoxane
Kidney injury	Sodium thiosulfate injection
Nausea and/or vomiting	Ondansetron, granisetron, dolasetron, metoclopramide, dexamethasone
Nerve injury	Amifostine

APPENDIX 22.5 COLONY-STIMULATING FACTORS

Factor	Marrow cell stimulated
Erythropoietin alpha	Erythrocytes
Filgrastim	Granulocytes
Sargramostim	Granulocytes and macrophages
Oprelvekin	Platelets

KEY POINTS

- The metabolic syndrome is increasingly recognized and potentially fatal
- Inborn metabolic errors are rare but may be life-threatening

METABOLIC SYNDROME

Metabolic syndrome (metabolic syndrome X, insulin resistance syndrome, dysmetabolic syndrome, hypertriglyceridaemic waist, obesity syndrome, Reaven syndrome) is the name for a group of risk factors that increase the risk for ischaemic heart disease (IHD), diabetes and stroke (Fig. 23.1). The metabolic syndrome is diagnosed when at least three of the IHD risk factors listed in Table 23.1 are present. Whether the syndrome, which affects possibly 25% of the US population, is a specific syndrome, and nothing more than the sum of its parts, is controversial.

In general, a person with metabolic syndrome is twice as likely to develop IHD and five times as likely to develop diabetes as someone without it. The probability of developing metabolic syndrome is also closely linked to a lack of physical activity and the fact of being overweight/obese. Other causes include insulin resistance, ethnicity (often Asian), family history, older age and other factors (Box 23.1). Associated diseases and signs may be raised uric acid levels, hepatic steatosis, haemochromatosis and acanthosis nigricans. Metabolic syndrome may be associated with inflammatory periodontal disease.

Treatment of metabolic syndrome is to increase physical activity but to reduce weight, unhealthy diet, low-density lipoprotein cholesterol and high blood pressure; diabetes should also be controlled (Chs 5 and 6).

INBORN ERRORS OF METABOLISM

There are a vast number of rare metabolic disorders that result from inherited enzyme defects; some have a high prevalence in certain ethnic groups (Table 23.2). Most arise from recessive traits and thus manifest only when both parents are heterozygous carriers. They affect 1 in 4 of the offspring of heterozygous parents, often as a result of first-cousin marriage.

Some inborn errors of metabolism, especially suxamethonium sensitivity, malignant hyperpyrexia, hyperlipoproteinaemias and porphyria, can seriously complicate management if general anaesthesia (GA) is required (see Table 23.2 and Appendix 23.1). Many others are associated with learning impairment or neurological disease. Some others can also be relevant occasionally, such as haemochromatosis, homocystinuria and glycogen storage diseases. A few (e.g. hereditary pentosuria) are innocuous (see Appendix 23.1). Few inborn errors of metabolism will be encountered in primary care, but they are more common in paediatric or special care clinics.

DEFECTS IN CARBOHYDRATE METABOLISM

Gaucher disease

Gaucher disease is a rare lysosomal storage disease, common in Ashkenazi Jews; it is caused by glucocerebrosidase deficiency.

Fig. 23.1 Metabolic syndrome.

Table 23.1 The metabolic syndrome

Features	Detail ^a
Hypertension	Blood pressure $\geq 130/85$ mmHg
Hyperglycaemia	Fasting blood glucose ≥ 5.6 mmol/L
Dyslipidaemia	Triglycerides ≥ 150 mg/dL
	High-density lipoprotein (HDL) < 50 mg/dL for women and < 40 mg/dL for men
Abdominal obesity	Large waistline: ≥ 35 inches for women and ≥ 40 inches for men

^aFigures given by various expert bodies differ.

Box 23.1 Groups at risk for metabolic syndrome

- People with a sibling or parent with diabetes
- People with a personal history of diabetes
- Certain ethnic groups (e.g. South Asians)
- Women with a personal history of polycystic ovarian syndrome
- People with sleep apnoea
- People with a prothrombotic state (e.g. high blood fibrinogen or plasminogen activator inhibitor-1)
- People with a pro-inflammatory state (raised blood C-reactive protein)

Manifesting with hepatosplenomegaly, skeletal involvement (including honeycomb-like mandibular radiolucencies), anaemia and thrombocytopenia, it may present challenges with bleeding and – should the patient be splenectomized – a liability to infection.

Glycogen storage diseases

General aspects

Glycogen storage diseases (GSD) are rare disorders due to inherited defects in degradative enzymes that mobilize glycogen to glucose, so that it accumulates and hypoglycaemia results.

Table 23.2 *Inborn errors of metabolism*

Defect in	Diseases
Structural proteins	Clotting factor defects Connective tissue proteins Oxygen-carrying proteins – sickle-cell anaemia and thalassaemias
Carbohydrate metabolism	Fructose, galactose and glycerol disorders, glycogen storage diseases
Cholesterol and lipoprotein metabolism	Hyperlipoproteinaemias Hypolipoproteinaemias
Mucopolysaccharide and glycolipid	Mucolipidoses Mucopolysaccharidoses (MPS) Oligosaccharidoses Sphingolipidoses
Lysosomal storage	Lipid storage disorders (including Gaucher and Niemann–Pick diseases) Gangliosidosis (including Tay–Sachs disease) Leukodystrophies Mucopolysaccharidoses (including Hunter syndrome and Hurler disease) Glycoprotein storage disorders Mucolipidoses
Amino and organic acid metabolism	Amino-acid transport defects Specific amino acids Urea-cycle defects
Haem and bilirubin	Bilirubin metabolism disorders Porphyrias
Fatty acid metabolism	Disorders of beta-oxidation Disorders of carnitine-mediated transport and carnitine uptake
Metal metabolism and transport	Copper transport disorders (Wilson disease) Haemochromatosis
Peroxisomes	Disorders of peroxisome biogenesis Adrenoleukodystrophies
Nucleotide metabolism	Defects in purine nucleotide metabolism Lesch–Nyhan syndrome (hypoxanthine–guanine phosphoribosyltransferase [HGPRT] deficiency), severe combined immunodeficiency disease (SCID) – due to adenosine deaminase (ADA) deficiency; gout, renal lithiasis – due to adenine phosphoribosyltransferase (APRT) deficiency; xanthinuria – due to xanthine oxidase deficiency Defects in pyrimidine nucleotide metabolism Types I and II orotic aciduria, ornithine transcarbamylase deficiency
DNA or repair	Ataxia telangiectasia (AT) Bloom syndrome Cockayne syndrome Fanconi anaemia Xeroderma pigmentosum (XP)
Drug-metabolizing enzymes	Glucose-6-phosphate dehydrogenase (G6PD) deficiency Malignant hyperthermia Neuroleptic malignant syndrome (NMS) Suxamethonium sensitivity

Clinical features

Glycogen accumulates in liver and muscle, resulting in hepatomegaly, muscle pain, weakness, respiratory muscle weakness and cardiac failure. Hypoglycaemia is common, as are infections.

Dental aspects

Enlarged tongue, periodontal breakdown and masticatory muscle pain may be complaints. Patients with GSD type 1b have a bleeding tendency that can be corrected preoperatively by 24–48 hours of glucose infusion. Local anaesthesia (LA) appears to have no contraindications. Conscious sedation (CS) may be given if required. GA requires expert attention in hospital.

Defects in fructose metabolism

Hereditary fructose intolerance (aldolase B deficiency) and fructosuria – hepatic fructokinase deficiency – discourage the patient from ingesting sugar (sucrose) and are therefore associated with low dental caries rates.

DEFECTS IN CHOLESTEROL AND LIPOPROTEIN METABOLISM

Hyperlipoproteinaemia (hyperlipidaemia; hypercholesterolaemia)

General aspects

Cholesterol is found in some hormones, as well as in every cell, and thus is an essential element. However, high cholesterol (hypercholesterolaemia), which is directly related to hyperlipoproteinaemia (Table 23.3), predisposes to atherosclerosis (Ch. 5).

The lipoproteins consist of lipids (insoluble in plasma), phospholipids and apolipoproteins (apoproteins). Based on density and electrophoretic mobility, the lipoproteins are divided into four groups:

- *Chylomicrons* are large particles carrying mainly triglyceride to the liver, where lipoprotein lipase releases free fatty acids (Fig. 23.2).
- *Very low-density lipoproteins* (VLDLs) carry triglycerides and cholesterol from liver to the tissues, and are hydrolysed by lipoprotein lipase to free fatty acids and intermediate-density and low-density lipoproteins.
- *Low-density lipoproteins* (LDLs) are associated with a high risk of IHD; they contain a cholesterol core and are formed by hepatic lipase. LDLs bind to cell LDL receptors and are taken up by cells, especially when there is inhibition of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), which raises cellular cholesterol. The LDL lipoprotein-alpha inhibits fibrinolysis but promotes atherosclerosis.
- *High-density lipoproteins* (HDLs), formed in liver and gut, carry cholesterol from intracellular tissue pools back to the liver and are associated with a lowered risk of IHD. The main plasma lipids transported are triglycerides, cholesterol ester and phospholipids (lecithin, sphingomyelin, etc.). Non-esterified fatty acids and cholesterol are also present.

Hypercholesterolaemia can be due to abnormalities in lipoprotein levels related to diet, or secondary to obesity, diabetes, hypothyroidism, nephrotic syndrome, chronic renal failure, liver disease, alcoholism, smoking (lowers HDL) and use of oral contraceptives. In primary (familial) hyperlipidaemia (FH), genetic factors play a role, with defects, for example, in the LDL receptor (*LDLR*), apolipoprotein B-100 (*APOB*) and proprotein convertase subtilisin/kexin type 9 (*PCSK9*) genes.

Table 23.3 Primary hyperlipoproteinaemias

Type	Name	Pathogenesis	Alternative name and lipid changes	Features in addition to atherosclerosis
I	Hypertriglyceridaemia	Autosomal dominant (AD). May occur as a secondary defect in diabetes mellitus, pancreatitis and alcoholism	Hyperchylomicronaemia Lipoprotein lipase deficiency Abnormality in chylomicron removal	Xanthomas Acute pancreatitis, hepatosplenomegaly
Ib	Hyperlipoproteinaemia	Apolipoprotein c-II deficiency	Reduced low-density lipoprotein (LDL) and high-density lipoprotein (HDL); high triglycerides	No xanthomas Acute pancreatitis
Ic	Hyperlipoproteinaemia	Circulating inhibitor of lipoprotein lipase	Chylomicronaemia	Xanthomas Acute pancreatitis
II	Hyperbetalipoproteinaemia	AD. Also may be secondary to hypothyroidism, plasma cell myeloma, macroglobulinaemia and obstructive liver disease	Hypercholesterolaemia: increase in plasma beta-lipoproteins	Xanthomas and xanthelasmas (common) Premature coronary, cerebral and peripheral vascular disease
IIa	Hyperlipoproteinaemia	AD. Also may be secondary to hypothyroidism, plasma cell myeloma, macroglobulinaemia and obstructive liver disease	LDL receptor disorder; increase in plasma LDLs	Xanthomas, corneal arcus Premature coronary, cerebral, and peripheral vascular disease
III	Dysbetalipoproteinaemia	Autosomal recessive (AR). Rarely, secondary to severe diabetes and hypothyroidism	Broad-beta disease Apolipoprotein E deficiency	Peripheral vascular disease, hyperglycaemia, xanthomas (rare)
IV	Endogenous hyperlipoproteinaemia	AR. Rarely, secondary to diabetes mellitus, pancreatitis, alcoholism, hypothyroidism, glycogen storage disease, Gaucher disease, gout and hypercalcaemia	Carbohydrate-inducible hyperlipaemia	Mild glucose intolerance, hyperuricaemia, atherosclerosis and ischaemic heart disease, xanthomas (common)
V	Mixed hyperlipidaemia	AD	—	Acute pancreatitis Xanthomas, hyperuricaemia, abdominal pain, hepatosplenomegaly, paraesthesias and lipaemia retinalis

Fig. 23.2 Chylomicron structure.

Clinical features

Gout, arthralgias, arthritis and premature IHD may result. Yellowish cutaneous plaques called xanthomas, in soft tissue, tendons and subperiosteal and intraosseous locations (xanthelasmas on the eyelids; Fig. 23.3), are associated with accelerated IHD. Prominent xanthomas on elbows and knees, especially with yellow to orange discolouration of palmar creases, are unique to type II hyperlipoproteinaemia.

General management

Around 75% of FH is undiagnosed, so screening for *LDLR*, *APOB* and *PCSK9* genes may help. Dietary intervention and lipid-lowering drugs (particularly statins – HMG-CoA reductase inhibitors) are essential to treatment (Ch 5). Ezetimibe is an option for primary hypercholesterolaemia.

Fig. 23.3 Xanthelasma in familial hyperlipidaemia. Such lesions may suggest a high risk of ischaemic heart disease.

Dental aspects

LA is the safest method of pain control. CS can be given if required. GA may be a risk because of IHD.

Facial xanthomas may help recognition of these potentially dangerous diseases. Types IV and V hyperlipoproteinaemias may be complicated by sicca syndrome.

Hypolipoproteinaemias

Pulpal calcifications, unusual odontomes and orange deposits in the tonsils may be found in HDL deficiency (Tangier disease).

ERRORS IN AMINO ACID AND ORGANIC ACID METABOLISM

Homocysteine (Hcy), a sulphur amino acid, is an intermediate product in conversion of methionine to cysteine; it participates in the remethylation pathway, enabling maintenance of adequate cellular levels of methionine, or is catabolized by trans-sulphuration. Several hereditary defects in the enzymes involved and acquired deficiencies in the vitamin cofactors of these enzymes can cause hyperhomocysteinaemia.

Hyperhomocysteinaemia

An increased homocysteine level is associated with a higher risk of strokes. Carotid stenosis appears to have a graded response to increased levels of homocysteine; increased carotid plaque thickness has been associated with high homocysteine and low B₁₂ levels. Homocysteine may also be a risk factor for Alzheimer disease. Dietary folate and B₁₂ supplementation may normalize homocysteine levels and modify the risk of vascular disease.

Homocystinuria

Homocystinuria is a disorder of methionine metabolism, leading to an abnormal accumulation of homocysteine and its metabolites (homocystine, homocysteine–cysteine complex, and others) in blood and urine. Homocystinuria is an autosomal recessively inherited defect in the trans-sulphuration pathway (homocystinuria I) or methylation pathway (homocystinuria II and III).

Affected patients are tall with a Marfanoid appearance, joint hypermobility, ectopia lentis, and visual and mental deterioration. Blood vessel abnormalities, together with excessive platelet adhesiveness, predispose to thromboembolism, both spontaneously and postoperatively. Pyridoxine is the treatment. During and after surgery, aggressive hydration and prophylaxis for deep vein thrombosis (DVT) are recommended.

DEFECTS IN NON-AMINO-ACID NITROGEN METABOLISM

The porphyrias

General aspects

Porphyrias are rare inborn errors in enzymes involved in haem metabolism, which result in the accumulation of porphyrins, the intermediate

compounds in haem(oglobin) synthesis (Fig. 23.4). Classification is according to the principal site of enzyme defect: namely, liver (hepatic porphyrias) or erythrocytes (erythropoietic porphyrias; Table 23.4).

Most people with porphyrias enjoy entirely normal health. However, three porphyrias are significant clinically, since drugs precipitate acute illness. Patients may develop potentially fatal acute attacks of cardiovascular (hypertension and tachycardia) and gastrointestinal disturbances, accompanied by neuropsychiatric disturbance (porphyria in King George III of England probably explains his ‘madness’). These

Fig. 23.4 Haem synthesis. (Bold disorders are most significant). Adapted from James MF, Hift RJ. Porphyrias. *Br J Anaesth* 2000; 85:143

Table 23.4 Porphyrias			
Porphyrias	Type	Alternative name	Particular features
Acute	Acute intermittent porphyria ^a	Swedish porphyria	Acute, severe abdominal pain, cardiovascular disturbances, neuropsychiatric disturbance, autonomic dysfunction
	Hereditary coproporphyria ^a	Coproporphyria	Acute, severe abdominal pain, cardiovascular disturbances, neuropsychiatric disturbance, autonomic dysfunction
	Plumboporphyria	5-aminolaevulinic acid (ALA) dehydratase deficiency	Acute abdominal pain
	Variegate porphyria ^a	South African (Afrikaans) genetic porphyria	Acute, severe abdominal pain, cardiovascular disturbances, neuropsychiatric disturbance, autonomic dysfunction, rashes
Chronic	Congenital porphyria ^b	Erythropoietic porphyria	Red teeth, hypertrichosis, severe mutilating photosensitivity rashes and haemolytic anaemia
	Porphyria cutanea tarda	Cutaneous hepatic porphyria	Photosensitivity and iron overload. Drugs do not precipitate acute attacks but the condition is aggravated by alcohol, oestrogens, iron and polychlorinated aromatic compounds

^aClinically significant.
^bErythropoietic.

porphyrias are *variegate porphyria*, the commonest, found mainly in South Africans of Afrikaans descent; *acute intermittent porphyria*, seen less frequently but affecting all population groups; and *hereditary coproporphyria*, which is rare and may cause patients to appear normal, apart from severe photosensitivity rashes.

Most of the drugs that have been incriminated in attacks are enzyme inducers that also increase hepatic 5-aminolaevulinic acid (ALA) synthetase levels. Assessing drug safety in porphyria is an inexact science; for many drugs no such information is available, and for some others the data are of doubtful validity and often conflicting (Table 23.5). A wide array of other factors can cause exacerbations, including fasting, alcohol, infections and pregnancy.

Clinical features of attacks

Often a single dose of a drug of this type can precipitate an acute episode, but in some patients, repeated doses are necessary to provoke a reaction. Attacks are accompanied by cardiovascular disturbance (tachycardia and hypertension, sometimes followed by postural hypotension). Respiratory embarrassment or major convulsions and neuropsychiatric disturbance (typically a peripheral sensory and motor neuropathy, but sometimes agitation, mania, depression, hallucinations and schizophrenic-like behaviour) may occur. Autonomic dysfunction may cause profuse sweating, pallor and pyrexia. Severe hyponatraemia, due to inappropriate secretion of antidiuretic hormone, may cause convulsions or deteriorating consciousness.

General management

The essentials of treatment for attacks of porphyria are, if possible, to stop the administration of the triggering drug and to give an intravenous infusion of haem arginate, fluids, electrolytes and glucose. Alcohol is sometimes an important trigger and, in some, the disease may be controlled simply by its withdrawal. The diagnosis is confirmed by demonstrating ALA and porphobilinogen in urine, and attacks are accompanied by raised levels; the urine may turn red.

Dental aspects

Anaesthetics, analgesics, antimicrobials and anxiolytics (benzodiazepines) that are liable to precipitate attacks are absolutely contraindicated (see Table 23.5).

Congenital erythropoietic porphyria is characterized by red teeth (which fluoresce in ultraviolet light). Fewer than 100 cases have ever been reported, but it has been suggested that this disease might have been the source of the werewolf legend because of the red teeth (thought to be dripping with blood), the hairy facial features and avoidance of daylight.

DISORDERS OF METAL METABOLISM AND TRANSPORT

Haemochromatosis

Haemochromatosis is a disease that occurs as a result of significant iron overload.

General aspects

Iron overload causes high serum ferritin levels and deposition of iron as haemosiderin, and damages liver, abdominal lymph nodes,

Table 23.5 Drug use in porphyria^a

Drug group	Contraindicated	Safer
Local anaesthetics	Articaine	Bupivacaine
	Mepivacaine	Lidocaine (used with caution) Prilocaine (used with caution)
Conscious sedation agents	Diazepam	Flumazenil Midazolam
General anaesthetics	Barbiturates	Nitrous oxide

	Statins	

^aList is not exhaustive.

joints, skin, adrenals, pancreas, salivary glands, pituitary and heart (Fig. 23.5). Haemochromatosis can have genetic and non-genetic causes. Acquired haemochromatosis may appear after repeated transfusions, as may be needed in haemoglobinopathies.

Hereditary haemochromatosis, the genetic disease caused by the *HFE* gene on chromosome 6, is one of the most common genetic disorders in the West, and most often affects Caucasians of northern European descent. The condition affects more than 1 in 200 of the population and often remains undetected. The *HFE* gene codes for a transmembrane glycoprotein highly expressed in intestinal cells, and modulates iron uptake. *HFE* gene mutations can lead to increased dietary iron absorption and overloading. Once iron is absorbed, there is no physiological mechanism for excretion of the excess from the body other than blood loss (i.e. pregnancy, menstruation or other bleeding). After several decades of increased absorption, symptoms appear once 15–20 g of iron have accumulated in the body. Men tend to become symptomatic in middle age (40s) and women who stop menstruating develop symptoms about 15 years later.

Clinical features

The fibrotic reaction to haemosiderin deposits can produce pigmentation, adrenocortical insufficiency, cardiomyopathy, cirrhosis or diabetes (bronze diabetes). The most common complaint is joint pain but non-specific symptoms, such as weakness, fatigue, abdominal pain, and loss of libido due to hypopituitarism and hypogonadism, are common. About 30% of patients with cirrhosis develop hepatocellular carcinoma.

Fig. 23.5 Iron overload in haemochromatosis.

General management

A sensitive and relatively inexpensive method of screening involves the transferrin saturation test (serum iron divided by the total iron-binding capacity). High serum ferritin levels may also suggest the diagnosis. Treatment is iron removal by venesection and chelation using desferrioxamine. Liver transplantation is needed for end-stage haemochromatosis.

Dental aspects

A sicca syndrome from salivary haemosiderin deposition may be seen. LA is generally safe. CS can be given. Cirrhosis, adrenocortical insufficiency, diabetes or cardiomyopathy may complicate care.

Wilson disease

See Chapters 9 and 37.

DISEASES ASSOCIATED WITH DEFECTIVE DNA REPAIR

Several inborn errors predispose to malignancy because of impaired DNA repair mechanisms (Table 23.6; Chs 22 and 37). Xeroderma pigmentosum produces a liability to skin and lip cancers. Bloom syndrome, dyskeratosis congenita and Fanconi anaemia have a higher than normal risk of oral carcinomas.

Table 23.6 Diseases associated with defective DNA repair

Disorder	Main genetics	Features
Ataxia telangiectasia (AT)	Autosomal recessive (AR)	Cerebellar ataxia, telangiectases, immune defects, neoplasms
Bloom syndrome	AR	Proportionate pre- and postnatal growth deficiency; sun-sensitive, telangiectatic, and hypo- and hyperpigmented skin
Cockayne syndrome	AR	Dwarfism, precociously senility, pigmentary retinal degeneration, optic atrophy, deafness, marble epiphyses in digits, photosensitivity and learning disability. Disproportionately long limbs with large hands and feet and flexion contractures of joints. Knee contractures result in a 'horseriding' stance
Dyskeratosis congenital	AR or autosomal dominant (AD)	Abnormal skin pigmentation and nail growth, premature ageing and a highly increased risk of malignancy (skin, gut and oral). Bone marrow failure (aplastic anaemia) affects 80%
Fanconi anaemia	AR	All bone marrow elements depressed with cardiac, renal and limb malformations, dermal pigmentary changes and oral cancer
Xeroderma pigmentosum (XP)	AR	Sensitivity to sunlight carcinomas at an early age. Starts with freckle-like lesions in exposed areas, usually in early years

ENZYME DEFECTS AFFECTING DRUG METABOLISM

Drug responses vary greatly between individuals, owing to genetic as well as environmental effects on drug absorption, distribution, metabolism or excretion (pharmacokinetics), and on receptor or post-receptor sensitivity (pharmacodynamics). Genetic differences in drug metabolism can have profound effects on treatment in terms of genetically determined variation in the activity of enzymes involved in detoxification, or of other abnormal proteins that render an individual especially susceptible to some adverse reaction.

Pharmacogenetic variation is sometimes due to the actions of a single mutant gene (as in genetic polymorphism, or Mendelian disorders that exhibit discontinuous variation), or polygenic influences. For example, some Asians metabolize carbamazepine poorly and can thus suffer from overdose or other adverse events, so they should be screened for human leukocyte antigen (HLA). The HLA-B*1502 allele has been shown to be strongly correlated with carbamazepine-induced Stevens–Johnson syndrome and toxic epidermal necrolysis (SJS-TEN) in the Han Chinese and other Asian populations but not in European populations. The presence of the HLA-A*3101 allele was associated with carbamazepine-induced hypersensitivity reactions among subjects of northern European ancestry.

Drug-metabolizing enzymes include glucose-6-phosphate dehydrogenase, *N*-acetyltransferase, and the superfamily of cytochrome P450 (CYP) isoenzymes (CYP2D6, CYP2C9, CYP2C19 and CYP3A). Table 23.7 shows examples of major disorders that influence drug responses.

Glucose-6-phosphate dehydrogenase deficiency

Glucose-6-phosphate dehydrogenase (G6PD) is the enzyme responsible for maintaining the nicotinamide–adenine dinucleotide phosphate (NADPH) needed to keep glutathione in its reduced form to act as a scavenger for dangerous oxidative metabolites. Low G6PD activity is the most common enzyme deficiency, affecting 400 million people worldwide, and is seen mainly in people of Mediterranean, Middle Eastern, African or Asian descent. G6PD deficiency results in haemolysis and methaemoglobinaemia when red blood cells are exposed to oxidation during intercurrent infection, exposure to various drugs, broad beans (*Vicia fava*) or naphthalene; it occasionally occurs spontaneously.

General aspects

Haemolysis follows when oxidizing drugs are taken.

General management

The diagnosis is confirmed by G6PD enzyme assays. Haemolysis is self-limiting and splenectomy is rarely needed. If there is acute severe haemolysis, the drug may have to be withdrawn and blood transfusion may be needed. Hydrocortisone is given intravenously and the urine alkalinized to reduce acid haematin deposition in renal tubules.

Prevention is crucial. Drugs that can be dangerous in G6PD deficiency and should be avoided are shown in Table 23.8 and Appendix

Table 23.7 Variations in drug response due to genetic polymorphism

Pharmacogenetic variation	Inheritance	Frequency	Drugs involved
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	X-linked incomplete co-dominant	10 000 000 in the world	Many, including quinolines and most sulphonamides
Malignant hyperthermia	Autosomal dominant (AD)	1:20 000 of population	Anaesthetics, especially halothane and suxamethonium
Methaemoglobinaemia	Autosomal recessive (AR)	1:100 are heterozygotes	Same drugs as for G6PD deficiency
Neuroleptic malignant syndrome	AD	Seen in 0.02–3.23% of psychiatric patients receiving neuroleptics	Neuroleptics
Porphyria	AD	Acute intermittent type 15:1000 000 in Sweden; porphyria cutanea tarda 1:100 in Afrikaaners	Barbiturates, chloral, chloroquine, ethanol, sulphonamides, phenytoin and griseofulvin (many others)
Suxamethonium sensitivity	AR	Most common in Europeans and rare in Asians	Suxamethonium and mivacurium

Table 23.8 Drugs that may precipitate haemolysis in glucose-6-phosphate dehydrogenase deficiency

Analgesic/antipyretic	Antimalarial	Cardiovascular	Cytotoxic/antibacterial	Miscellaneous	Sulfonamides/sulfones
Aspirin	Chloroquine	Procainamide	Chloramphenicol	Alpha-methyldopa	Dapsone
Phenacetin	Hydroxychloroquine	Quinidine	Ciprofloxacin	Ascorbic acid	Most sulphonamides, including co-trimoxazole
Prilocaine	Mepacrine (quinacrine)		Furazolidone	Dimercaprol (BAL)	
	Pamaquine		Furmethonol	Hydralazine	
	Pentaquine		Moxifloxacin	Mestranol	
	Primaquine		Nalidixic acid	Methylene blue	
	Quinine		Neoarsphenamine	Naphthalene	
	Quinocide		Nitrofurantoin	Phenylhydrazine	
			Nitrofurazone	Pyridium	
			Norfloxacin	Toluidine blue	
			Ofloxacin	Trinitrotoluene	
			Para-aminosalicylic acid (PAS)	Urate oxidase	
				Vitamin K (water-soluble) and menadione	

Table 23.9 *Drugs contraindicated, and safer alternatives, in malignant hyperpyrexia in susceptible subjects*

Drug group	Contraindicated	Safer
General anaesthetics	Halothane	Local anaesthetics
	Ether	Thiopental
	Cyclopropane	Nitrous oxide
	Ketamine	
	Enflurane	
Conscious sedation agents	Benzodiazepines	Nitrous oxide
Muscle relaxants	Suxamethonium	Pancuronium
	Curare	
Antidepressants	Tricyclic antidepressants	
	Monoamine oxidase inhibitors (MAOIs)	Selective serotonin reuptake inhibitors (SSRIs)

23.2. Substances labelled 'low-risk' may often be given safely at normal therapeutic doses unless the patient is severely G6PD-deficient or has chronic non-spherocytic hemolytic anaemia, but there is no guarantee that they will not cause haemolysis. Avoid mothballs, artificial blue food colouring, legumes (broad beans, beans, peas, peanuts, soy, lentils, etc.), sulphites and tonic water. Read all labels on processed foods before feeding them to the patient. A diet rich in antioxidant foods is recommended to help minimize the effects of oxidative stress and the resultant hemolysis. Vitamins B₆, B₁₂, folic acid and *N*-acetyl cysteine (NAC) are also important.

Dental aspects

Aspirin up to at least 1 g a day is safe for most patients. Paracetamol (acetaminophen) also appears to be safe but doses should be limited. Codeine may also be used. LA with prilocaine may, in large doses, induce methaemoglobinaemia and should be avoided (see Table 23.8). CS is usually safely given as relative analgesia. GA is given in hospital. Metabolic acidosis causes haemolysis and must be avoided.

Malignant hyperthermia (malignant hyperpyrexia)

General aspects

Malignant hyperthermia (MH) is a rare, potentially fatal, inherited condition, related to the ryanodine receptor (*RYR1*) gene (the muscle sarcoplasmic reticulum calcium release channel) on chromosome 19. MH affects about 1 in 20 000, males predominantly. It is characterized by a rapid rise in temperature when the patient has a GA or other drugs that trigger an attack. The most common trigger is the combination of a halogenated volatile GA, such as halothane or enflurane, together with muscle relaxants such as suxamethonium and curare-like (non-depolarizing) agents (Table 23.9).

Clinical features

Suxamethonium, unlike pancuronium or vecuronium, causes jaw stiffness in many normal people, but poor muscular relaxation after induction of GA or complete failure of the jaw to relax after suxamethonium has been given can herald the onset of MH. However, it is controversial whether masseter spasm is a reliable early sign. The most reliable earliest signs of an MH reaction are rapid breathing and heart rate, and rising blood pressure. There is also a temperature rise, with arrhythmias. Hyperkalaemia, cardiac arrhythmias and disseminated

intravascular coagulation (DIC) may occur and the mortality rate of MH may approach 80% in the absence of treatment.

Two forms of MH are recognized: an autosomal dominant type, in which patients are clinically normal between attacks; and a recessive type, which affects young boys with various congenital abnormalities such as myotonia congenita, myotonic dystrophy, central core disease and Evan syndrome (proximal wasting, short stature, kyphoscoliosis).

General management

The family history is important, as emphasized by the fact that a patient reported to the writer had had 14 relatives die under GA. Raised serum creatine kinase and pyrophosphate levels indicate susceptibility, though nearly one-third of patients have normal levels of creatine kinase. Muscle biopsy shows excessive *in vitro* response of muscle to halothane, suxamethonium or caffeine, and raised myophosphorylase A levels.

Malignant hyperthermia is a medical emergency; management includes stopping the trigger, correcting respiratory acidosis and using dantrolene. All trigger agents (i.e. all anaesthetic vapours) must be withdrawn, dantrolene given and temperature, arterial blood gases, K⁺ and creatine phosphokinase (CPK) measured. Surface cooling, avoiding vasoconstriction, is needed. Serious arrhythmias are treated with beta-blockers, and hyperkalaemia and metabolic acidosis corrected. A clotting screen is done to detect DIC, a urine sample taken for myoglobin estimation and output measured for developing renal failure. Diuresis is promoted with fluids/mannitol. The patient should be referred to an MH unit.

Dental aspects

Infections should be treated quickly and effectively since they also may precipitate attacks of MH.

Dantrolene given preoperatively and postoperatively for about 3 days may prevent hyperthermia. Plain LA is safe (amides, including lidocaine and prilocaine, were once thought to be weak triggering agents but this has been dismissed). Adrenaline (epinephrine) may cause signs similar to an attack of MH, confusing the diagnosis, and may enhance calcium release inside muscle cells and aggravate an MH episode. Endogenous adrenaline release should be minimized (avoid stress, anxiety and pain) and effective LA must be used (which may mean choosing an adrenaline-containing LA). Benzodiazepines are contraindicated; CS can usually be safely carried out using relative analgesia. MH has been reported after administration of nitrous oxide but this is rare. Inquiry into the family history is essential before giving GA, as there are no absolutely reliable predictive tests. Unfortunately, absence of reaction to a previous GA does not exclude the possibility of a reaction on the next occasion.

In the event of hyperthermia, surgery must be stopped and the patient cooled. Oxygen, and a bicarbonate intravenous infusion to counteract the metabolic acidosis, should be given. Dantrolene sodium or procainamide is effective in controlling the reaction.

Methaemoglobinaemia

Methaemoglobin is a haemoglobin that is not functional in oxygen carriage. A small amount of methaemoglobin is always present in erythrocytes but is usually converted back to haemoglobin through successive electron transfers, by nicotinamide adenine dinucleotide (NADH)-dependent methaemoglobin reduction (in the diaphorase pathway). Cytochrome b5 reductase is important in this process because it

transfers electrons from NADH to methaemoglobin, and usually removes 95–99% of the methaemoglobin produced. Nicotinamide adenine dinucleotide phosphate (NADPH)-dependent methaemoglobin reduction, which utilizes glutathione production and G6PD to reduce methaemoglobin to haemoglobin, usually plays only a minor role – unless there are inherited cytochrome b5 reductase deficiencies.

There are two types of inherited methaemoglobinemia:

- Type 1 (erythrocyte reductase deficiency) – red blood cells are affected.
- Type 2 (generalized reductase deficiency) – there are defects in the haemoglobin molecule itself; this is called haemoglobin M disease.

Methylene blue and ascorbic acid are used to treat severe methaemoglobinemia. Alternative treatments include hyperbaric oxygen therapy and exchange transfusions.

Methaemoglobinemia may also be caused by exposure to certain drugs, chemicals or foods (acquired), including paracetamol (acetaminophen) and local anaesthetics – benzocaine, lidocaine and prilocaine (**Box 23.2**). Acquired methaemoglobinemia requires no treatment other than to avoid the agents implicated.

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome (NMS) is a rare, potentially fatal complication due to a dopamine receptor blockade from the use of neuroleptics (**Box 23.3**). Although potent neuroleptics (e.g. haloperidol, fluphenazine) are causally associated with NMS more frequently, all antipsychotics may precipitate it. NMS has also been associated with non-neuroleptics that block central dopamine pathways, such as amoxapine, lithium and metoclopramide.

NMS is characterized by fever, muscular rigidity, altered mental status and autonomic dysfunction. The relationship of NMS to malignant hyperthermia is unknown. Features may develop dramatically within hours of drug exposure, or insidiously over several days; they may persist for several days, or death can result from renal failure. There are disturbances in mental state, temperature regulation, and autonomic and extrapyramidal functions. Hyperthermia, muscle rigidity, fluctuating consciousness, obtundation, catatonia, pallor, sweating, tachycardia, labile blood pressure, incontinence, tremors, dysarthria, dysphagia and drooling result.

NMS is an emergency; withdrawal of the neuroleptic agent and assessment of the airway, breathing and circulation (ABC) are crucial, as are exclusion of other medical conditions and aggressive supportive care. Any patient with altered mental status should receive thiamine, dextrose (or rapid glucose determination) and naloxone.

Dental aspects

In NMS, LA can usually be safely given. CS dentistry can usually be safely given using relative analgesia. Phenothiazines should be avoided for patients who have stopped their levodopa before a GA. Levodopa can be given before GA, apart from the fact that it may cause vomiting.

Serotonin syndrome

Serotonin syndrome is a constellation of muscle rigidity, headache and rises in blood pressure and temperature, induced by drugs such as antidepressants or 5-HT₁ agonists (triptans) (**Box 23.4**).

Box 23.2 Agents that may precipitate methaemoglobinemia

Inorganic agents

- Nitrates – fertilizers, contaminated well water, preservatives, industrial products
- Chlorates
- Copper sulphate – fungicides

Organic nitrites/nitrates

- Amyl nitrite
- Isobutyl nitrite
- Sodium nitrite
- Nitric oxide
- Nitrogen dioxide
- Nitroglycerin
- Nitroprusside
- Trinitrotoluene (TNT), combustion products

Others

- Local anesthetics – benzocaine, lidocaine, prilocaine, phenazopyridine
- Antimalarials – primaquine, chloroquine
- Rasburicase
- Antineoplastic agents – cyclophosphamide, ifosfamide, flutamide
- Analgesics/antipyretics – paracetamol (acetaminophen), acetanilide, phenacetin, celecoxib
- Zopiclone
- Herbicides – paraquat (dipyridylum)
- Methylene blue
- Indigo carmine (indigotindisulfonate)
- Resorcinol
- Antibiotics – sulphonamides, nitrofurans, P-amino-salicylic acid, dapsone
- Industrial/household agents – aniline dyes, nitrobenzene, naphthalene (mothballs), aminophenol, nitroethane (nail polish remover)

Box 23.3 Precipitants of neuroleptic malignant syndrome

- Alcohol
- Amphetamines
- Antidepressants (tricyclic or monoamine oxidase inhibitors)
- Benzodiazepines
- Metoclopramide
- Neuroleptics (e.g. phenothiazines, haloperidol or flupentixol)
- Tetrabenazine
- Abrupt withdrawal of L-dopa

Box 23.4 Possible precipitants of serotonin syndrome

- 5-HT₁ agonists
- Antidepressants
- Buspirone
- Chlorphenamine
- Herbs (e.g. St John's wort)
- L-dopa
- Lithium
- Olanzapine
- Opioids
- Psychedelics
- Ritonavir
- Tramadol
- Valproate

Box 23.5 Conditions in which the action of suxamethonium may be prolonged

- Inherited suxamethonium sensitivity (scoline sensitivity)
- Myopathies:
 - Malignant hyperpyrexia
 - Dystrophia myotonica
 - Myotonia congenita
 - Myasthenia gravis
- Liver disease
- Renal disease
- Burns
- Drugs:
 - Aprotinin (trasyolol)
 - Cyclophosphamide
 - Cytotoxic drugs
 - Pancuronium
 - Phenothiazines
 - Procaine

Suxamethonium sensitivity (pseudocholinesterase deficiency; scoline apnoea)

Suxamethonium (scoline) is a depolarizing neuromuscular blocker widely used for muscle relaxation during GA induction. The usual response to a single intravenous dose of suxamethonium is muscular paralysis for about 6 minutes, after which it is rapidly destroyed by a plasma enzyme. About 1 in 2500 of the population has a defect in this enzyme (cholinesterase; butyrylcholinesterase; pseudocholinesterase) and are thus abnormally sensitive to the action of suxamethonium, so that muscle paralysis and apnoea persist. Suxamethonium sensitivity is an autosomal recessive trait due to mutant alleles of *CHE1* on chromosome 3; it is most common in Europeans and rare in Asians. Abnormal sensitivity to suxamethonium may also result from other diseases (Box 23.5) or may be a type of hypersensitivity reaction.

When given suxamethonium, patients with suxamethonium sensitivity remain unable to breathe and will die unless artificially ventilated until the drug action abates after 2 hours or more. Patients may also react similarly to other choline ester compounds, such as mivacurium, and can have severe reactions to cocaine.

LA action is occasionally prolonged. Nitrous oxide/oxygen sedation is preferable to GA.

ACQUIRED METABOLIC DISORDERS**AMYLOID DISEASE****General aspects**

Amyloidosis is not a disease in itself, rather a manifestation of several diseases. Amyloid consists of deposits in tissues of an eosinophilic hyaline protein with a characteristic fibrillar structure on electron microscopy. Up to 60 types of amyloid protein are known, categorized as primary (AL), secondary (AA) and hereditary (ATTR). In addition, there are other forms of amyloidosis, including beta₂-microglobulin amyloidosis and localized amyloidoses.

In *primary amyloidosis*, AL protein deposition is seen in conditions with immunoglobulin overproduction, as in benign monoclonal gammopathy, and has a prominent immunoglobulin light-chain component (Table 23.10). Primary amyloidosis can also occur with multiple

Table 23.10 Amyloid types

Amyloid type	Deposit	Comments
Idiopathic (primary) amyloidosis	AL	Derived from immunoglobulin light chains plus serum amyloid P
Myeloma-associated amyloidosis	AL	Derived from immunoglobulin light chains
Hereditary amyloidosis	AA	Derived from other proteins (lysozyme, fibrinogen, apolipoproteins)
Secondary amyloidosis	AA	The most common form of amyloid disease. Derived from serum amyloid A protein, an acute-phase protein released by the liver in chronic infections or inflammatory states such as rheumatoid arthritis and ulcerative colitis, via interleukin-1 from activated mononuclear phagocytes
Other forms of amyloidosis	Range of proteins	Mainly pre-albumin. A heterogeneous group, some related to senility, dialysis or drug abuse, and some localized to medullary carcinoma of thyroid or calcifying epithelial odontogenic tumour

myeloma but is not associated with any other diseases. It is treated with chemotherapy.

Secondary amyloidosis may occur secondary to conditions of chronic excessive stimulation of the reticuloendothelial system (see Table 23.10), such as infections (e.g. tuberculosis or osteomyelitis) or inflammatory diseases (e.g. rheumatoid arthritis, ankylosing spondylitis or autoinflammatory syndromes); the deposits are AA proteins related to acute phase proteins such as serum amyloid P (SAP; Fig. 23.6). Amyloid is then deposited mainly in the heart, skeletal muscle and gastrointestinal tract, and affects their functions. Other secondary amyloid is of uncertain origin but involves the spleen, liver, kidney and adrenals predominantly. Treatment is directed to the underlying illness.

Localized amyloid may be seen in a range of disorders (see Fig. 23.6) including Alzheimer disease. In various tissues, often with ageing, amyloid can be locally deposited to cause tissue injury.

Deposits of a protein transthyretin (TTR) are found in the rare autosomal dominant condition called *familial amyloidosis* (TTR amyloid or ATTR). Sephardic Jews and Turks inherit familial Mediterranean fever (FMF), which is associated with this amyloidosis and characterized by episodes of fever, joint and abdominal pains; these can be prevented by colchicine. Armenians and Ashkenazi Jews also have a higher incidence of FMF attacks but do not suffer amyloid.

Beta₂-microglobulin amyloidosis occurs when amyloid deposits develop in dialysis patients and are often found around joints.

Clinical features

Amyloid is a great mimic in medicine. The widespread lesions and the possible involvement of virtually any system make amyloid disease protean in its manifestations. There may also be a bleeding tendency related to a coagulation factor X defect.

General management

The diagnosis is established by biopsy of lesional tissue or by rectal, gingival or salivary biopsy examined with Congo Red and polarized light or thioflavin T.

An underlying cause must be sought and treated where possible. Combination therapy is used, with corticosteroids, melphalan and flouxymesterone.

Fig. 23.6 Types of amyloid. ApoA1 = apolipoprotein A1; CJD = Creutzfeld–Jakob disease.

Dental aspects

Dental management may be influenced by the underlying disorder, or by cardiac, renal, adrenal or corticosteroid complications, or a bleeding tendency.

LA can safely be given. CS can be given if required.

Macroglossia, gingival swellings, oral petechiae, bullae or, rarely, a sicca syndrome may result from amyloidosis, but virtually only in the primary type.

TRIMETHYLAMINURIA (TMA-URIA; FISH-ODOUR SYNDROME)

Trimethylaminuria is a rare autosomal recessive syndrome in which there is abnormal trimethylamine (TMA) excretion. TMA is found in some foods and is produced by gut bacteria from foods rich in TMA-oxide, choline, lecithin or carnitine. TMA is found in milk from wheat-fed cows, TMA precursors in choline (eggs, liver, kidney, peas, beans, peanuts, soya and brassicas [Brussels sprouts, broccoli, cabbage, cauliflower]), lecithin and lecithin-containing fish oil supplements. TMA *N*-oxide is found in seafood (fish, cephalopods and crustaceans).

TMA is normally oxidized by liver flavin mono-oxygenase 3 (*FMO3*) to odourless trimethylamine *N*-oxide (TMAO). Trimethylaminuria is an inherited *FMO3* gene mutation leading to impaired TMA oxidation. Unoxidized TMA then appears in and causes odour from urine, sweat, genital secretions, saliva and breath. Other causes of excess TMA include:

- deficient nicotine *N*-oxidation
- disorders of carnitine and choline intake
- haematological abnormalities
- Noonan syndrome
- Prader–Willi syndrome
- renal and hepatic disease
- Turner syndrome.

Similar symptoms may appear in some normal people under conditions such as fever, stress, exercise or menstruation. Trimethylaminuria is managed by diet (avoid eggs, fish, brassicas); antimicrobials (e.g. metronidazole); lactulose; activated charcoal and copper chlorophyllin; and riboflavin.

APPENDIX 23.1 INBORN ERRORS OF METABOLISM

Disease	Management problems
Abetalipoproteinaemia	Ataxia; haemorrhage
Acatalasaemia	Gingival ulceration
Acid lipase deficiency	Learning impairment; anaemia
Acrodermatitis enteropathica	Oral ulceration; neuropathies
Adenosine deaminase deficiency	Immunodeficiency
Alkaptonuria	Arthritis; aortic valve disease
Alpha1-antitrypsin deficiency	Hepatic disease; emphysema
Argininaemia	Spasticity; learning disability; epilepsy
Aspartylglucosaminuria	Learning impairment
Cerebrotendinous xanthomatosis	Dementia; ataxia; paresis; cataracts
Cholinesterase deficiency	Suxamethonium sensitivity
Chronic granulomatous disease	Lymph node abscesses (cervical, etc.); liability to severe bacterial infections
Combined hyperlipidaemia	Atherosclerosis
Congenital adrenal hyperplasia	Hypoadrenocorticism
Crigler–Najjar syndrome	Jaundice
Cystinosis	Renal disease
Cystinuria	Renal disease
Diphosphoglycerate mutase deficiency	Anaemia
Dubin–Johnson syndrome	Jaundice
Dysbetalipoproteinaemia	Atherosclerosis
Fabry disease	Neuropathy; thromboses; renal failure; pulmonary failure
Familial dysautonomia (Riley–Day syndrome)	Sensitivity to barbiturates; dysphagia; sialorrhoea; insensitivity to pain; learning impairment; epilepsy; labile blood pressure
Familial goitre	Hypothyroidism
Fanconi syndrome	Aminoaciduria; osteomalacia; oral cancer
Fucosidosis	Learning impairment
Galactosaemia	Learning impairment; hepatic disease; cataracts; hypoglycaemia
Gilbert disease	Jaundice
GM1 gangliosidosis	Learning impairment; epilepsy; blindness
GM2 gangliosidosis	Learning impairment; epilepsy; blindness
Tay–Sachs disease	Learning impairment; epilepsy; blindness
Sandhoff disease	Learning impairment; epilepsy; blindness
Gaucher disease	Learning impairment; spasticity; thrombocytopenia; leukopenia
Glucose-6-phosphate dehydrogenase deficiency	Haemolytic anaemia, care with drugs
Glutaric aciduria	Hypoglycaemia
Glycogen storage disease:	
Type I	Hypoglycaemia; caries; bleeding tendency
Type II	Cardiomyopathy; respiratory infection; neurological abnormalities
Type III	Hypoglycaemia
Type IV	Hepatic disease; cardiac failure
Type VI	Mild hypoglycaemia
Type Via	Mild hypoglycaemia
Type O	Mild hypoglycaemia

Disease	Management problems
Gout	Renal disease; hypertension; atherosclerosis
Haemochromatosis	Diabetes; hepatic disease; cardiomyopathy
Hereditary angioedema	Airways obstruction
Hereditary fructose intolerance	Hepatic disease; hypoglycaemia
Hereditary oroticaciduria	Severe anaemia; leukopenia
Hereditary spherocytosis	Haemolytic anaemia
Hexokinase deficiency	Anaemia
Histidinaemia	Hearing deficit; speech deficit; infections; learning disability
Homocystinuria	Learning impairment; epilepsy; blindness; hepatic disease; chest deformities; thrombotic disease
Hypercalcaemia	Renal disease; cardiac subaortic stenosis; learning disability (William syndrome)
Hypercholesterolaemia	Atherosclerosis
Hypercystinuria	Renal disease
Hyperornithinaemia	Learning impairment
Hyperoxaluria	Renal disease
Hypertriglyceridaemia	Atherosclerosis; pancreatitis
Hypophosphatasia	Skeletal abnormalities; dental hypoplasia
Krabbe disease	Learning impairment; blindness
Lecithin/cholesterol/ acetyltransferase deficiency	Haemolytic anaemia; atherosclerosis; renal disease
Lesch–Nyhan syndrome	Mutilation of tongue or lips; learning impairment; epilepsy; athetosis; renal failure
Lipoprotein lipase deficiency	Pancreatitis
Lysinuria	Epilepsy
Mannosidosis	Learning impairment
Metachromatic leukodystrophy	Learning impairment; blindness; psychoses
Methionine malabsorption	Epilepsy
Mucopolipidosis (I-cell disease)	Learning impairment; blindness; valvular heart disease
Mucopolysaccharidosis (MPS) I	Learning impairment; blindness; cardiac impairment; trismus
Hurler syndrome	
MPS II Hunter syndrome	As in MPS I
MPS III Sanfilippo syndrome	Learning impairment
MPS IV Morquio syndrome	Blindness; chest deformity; aortic valve disease; enamel hypoplasia
MPS V Ullrich–Scheie syndrome	Blindness; valvular heart disease
MPS VI Maroteaux–Lamy syndrome	Learning impairment; blindness
MPS VII	Learning impairment
Myeloperoxidase deficiency	Candidosis
Neuronal ceroid lipofuscinoses	Learning impairment; epilepsy; blindness
Niemann–Pick disease	Learning impairment; epilepsy; pancytopenia
Oxalosis	Renal disease; cardiac disease
Phenylketonuria	Learning impairment; epilepsy

(Continued)

Disease	Management problems
Porphyrias	Drug sensitivities; neuropathies; hypertension
Primary hypophosphataemia (vitamin D-resistant rickets)	Dwarfism; rickets; dental abscesses
Prolinaemia	Epilepsy; deafness
Purine nucleoside phosphorylase deficiency	Immunodeficiency
Pyruvate kinase deficiency	Anaemia
Refsum disease	Blindness; deafness
Renal glycosuria	Glycosuria (confusion with diabetes)
Rotor syndrome	Jaundice
Sandhoff disease	Learning impairment; epilepsy; blindness
Tay–Sachs disease	Learning impairment; epilepsy; blindness
Transcobalamin II deficiency	Macrocytic anaemia; pancytopenia
Triosephosphate isomerase deficiency	Anaemia
Tyrosinaemia	Hepatic disease
Tyrosinosis	Myasthenia; epilepsy
Wilson disease (hepatolenticular degeneration)	Hepatic disease; renal disease; spasticity; tremor; mental problems
Wolman disease	Learning impairment
Xeroderma pigmentosum	Skin cancers

APPENDIX 23.2 DRUGS CONTRAINDICATED IN GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENCY

Drug	Risk
Acetanilide	High
Acetylphenylhydrazine	High
Aminophenazone	Low
Antazoline	Low
Ascorbic acid	Low
Aspirin	High
Beta-naphthol	High
Chloramphenicol	High
Chloroquine	High
Ciprofloxacin	High
Colchicine	Low
Dapsone	High
Dimercaprol	High
Diphenhydramine	Low
Dopamine	Low
Doxorubicin	High
Ethanol	High
Furazolidone	High
Furosemide	High
Gadopentetate dimeglumine	High
Glibenclamide (glyburide)	High
Glucosulfone	High
Henna	High
Ibuprofen	Low
Isobutyl nitrite	High
Isoniazid	Low
Lamotrigine	High
Levofloxacin	High
Lisinopril	High
Mefloquine	High
Menadiol sodium sulfate (vitamin K ₄ sodium sulfate)	High
Menadione	High

Drug	Risk
Menadione sodium bisulfite (Vitamin K ₃ sodium bisulfite)	High
Menthol	High
Mesalazine	High
Metformin	High
Methylene blue	High
Mirtazapine	Low
Moxifloxacin	High
Nalidixic acid	High
Naphthalene	High
Nimesulide	High
Niridazole	High
Nitrofurantoin	High
Nitrofurazone	High
Norfloxacin	Low
Pamaquine	High
Para-aminobenzoic acid	Low
Paracetamol (acetaminophen)	Low
Pefloxacin	High
Pentaquine	High
Phenacetin	High
Phenazone (antipyrine)	Low
Phenazopyridine	High
Phenylbutazone	Low
Phenylhydrazine	High
Phenytoin	Low
Primaquine	High
Probenecid	High
Procainamide	Low
Proguanil	Low
Pyrimethamine	Low
Quinacrine	High
Quinidine	Low
Quinine	Low
Stibophen	High
Streptomycin	Low
Sulfacetamide	High
Sulfacytine	Low
Sulfadiazine	Low
Sulfadimidine	High
Sulfafurazole	High
Sulfaguanidine	Low
Sulfamerazine	Low
Sulfamethoxazole	High
Sulfamethoxypyridazine	Low
Sulfanilamide	High
Sulfapyridine	High
Sulfasalazine	High
Sulfathiazole	High
Sulfonylurea	Low
Sulfoxone	High
Tamsulosin	High
Tiaprofenic acid	Low
Toluidine blue	High
Trihexyphenidyl	Low
Trimethoprim	Low
Trinitrotoluene	High
Tripelennamine	Low
Vitamin K ₁	Low

KEY POINTS

- Trauma from interpersonal violence is an increasing global problem
- Trauma is potentially life-threatening, especially if involving the head, spine, airway or heart/major vessels
- Trauma can leave significant impairments

This chapter deals with: trauma to the head, maxillofacial area and spine; burns; gunshot and stab wounds; and human bites. Animal bites, sports injuries and child abuse are discussed elsewhere (Chs 25 and 33).

GENERAL ASPECTS

Injuries outrank cancer and heart disease as a leading cause of death in children, and in men up to the age of 35. It is males predominantly who are affected by trauma. Up to a third of these deaths are, theoretically, preventable. Violence (assaults or fights; Figs 24.1–24.3) and road traffic accidents are the major causes of trauma, with alcohol or other drugs being frequent cofactors. In the Western world, assaults are increasingly common but, in contrast, trauma from road traffic accidents (RTAs) has become less common since the institution of seatbelt-wearing. Nevertheless, 3500 people are killed and 40000 seriously injured each year from RTAs in Britain. Maxillofacial trauma is the single most common injury to occupants of vehicles involved in RTAs, even in seatbelted drivers. Airbags may be a supplemental restraint system but they themselves can cause injury – particularly in people of short stature, unrestrained or out of position within the vehicle. Industrial accidents, sport, falls, epilepsy and non-accidental injuries (child abuse) are other causes of trauma. Equine-related maxillofacial fractures mainly involve the young and predominantly females, and alcohol is rarely implicated.

The main causes of oral and craniofacial injuries are sports, violence, falls and RTAs. Cranial injuries are a leading cause of mortality and

oral–facial injuries can result in disfigurement and dysfunction, greatly diminish quality of life and cause social and economic burdens.

Sports

Craniofacial sports injuries arise mainly in contact sports, but also in activities such as cycling, skating and gymnastics, especially on trampolines (Ch. 33).

Fig. 24.2 Maxillofacial trauma.

Fig. 24.1 Subconjunctival haemorrhage.

Fig. 24.3 Maxillofacial trauma.

Violence

Domestic violence, including child abuse, spousal and elder abuse, and abuse of the disabled, is the single most common type of violence. Child abuse is of particular concern (Ch. 25) because more than 65% of cases involve head and oral–facial trauma, and in the young child, head injury is the most common cause of death. Dentists are required to report suspected cases. The incidence of specific injury patterns and outcomes of violence in adults are similar between the genders. Males, however, make up the majority of facial fracture cases (over 70%); the aetiology of their injuries includes altercations with strangers, often after consuming alcohol or using drugs, or violent gang activities. Males are more likely to be admitted with fracture but not soft-tissue injury only; more likely to be assaulted with a weapon; and more likely to be involved in an altercation, gang violence, arrest or robbery. Females are more prone to domestic violence and rape, and less likely to be involved in violent criminal activity or to have gang associations. One in six women in the USA has been a victim of sexual violence (a completed or attempted rape) at some time in her life.

Falls

Falls are a major cause of trauma to face, jaws and teeth in adults and children. Orofacial injuries are common from toddlers falling with a bottle, dummy or sippy cup in their mouth; bottles are most likely to be the source of injury, followed by dummies and sippy cups. Injuries consist mainly of mouth lacerations. Falls may indicate underlying pathology or simple locomotor inadequacy and are especially common after the age of 80 years. In old people, it is important to establish whether they are prone to falls, which may need further investigation. Important individual risk factors include:

- arthritis
- balance or gait deficits
- cognitive impairment
- epilepsy
- depression
- mobility limitation
- muscle weakness
- postural hypotension
- visual impairment.

Road traffic accidents

The effects of RTAs may range from minor and reversible effects to long-term medical, surgical and rehabilitative consequences. Post-traumatic headaches and chronic oral–facial pain is not uncommon. Whiplash-associated disorders (WADs) can lead to temporomandibular pain, predominantly in females. Neuromuscular and glandular damage may cause problems with chewing, swallowing and tearing – or result in facial tics or paralysis.

Craniofacial trauma

In conflicts, assaults and RTAs, injuries often involve multiple organs. Death may result immediately from trauma, especially if there is head injury and brain damage, airway obstruction or damage to the spine and other vital organs (e.g. heart or liver).

HEAD INJURIES

Head injuries are present in about 70% of patients admitted with multiple injuries, and about 3% of multiply injured patients have intracranial haemorrhage. Most head injuries are in previously fit young males because of their risk behaviour: RTAs and assaults are major causes (Fig. 24.4). Children and adolescents can sustain head injuries during sports or fights, and young children, particularly before they have perfected their walking skills, are also uniquely susceptible to head trauma because of higher cranial mass to body ratio.

Head injuries are a major cause of death – almost 50% of which happen before the patient reaches hospital – and most of the remaining deaths follow within the first few hours. Of those with brain injury, 12% die within 2 days. It is important to appreciate that the brain can be fatally damaged without fracture of the skull or even a blemish on the scalp.

IMMEDIATE CARE

Damage to the head, cervical spine, chest, liver or spleen can be immediately life-threatening. In particular, there can be hazards to the airway; damage to the cervical spine; severe haemorrhage; and damage to kidneys or bladder or to other bones. All patients with head injuries must be urgently assessed using the ABC system: *airway* and cervical spine, *breathing* and *bleeding*, and *chest* injuries (Table 24.1).

Fig. 24.4 Road traffic accident.

Table 24.1 Head injuries: initial and early management

Immediate care (ABC)	General assessment	Assessment of head injury	Assessment for other injuries
Airway and cervical spine	State of consciousness	Skull examination	Neck
Breathing and bleeding	Pulse	Examination for cerebrospinal fluid leak	Spine
Chest injuries	Blood pressure	Neurological assessment	Abdomen
	Respiratory rate	Skull radiography, including computed tomography	Perineum
	Pupil size and reaction	Blood analyses	Limbs

Airway establishment and maintenance has the highest priority. Respiratory obstruction is the most important preventable cause of early death and may be due to several causes, such as those shown in Box 24.1. Many patients have died from neglect of the airway before admission to hospital. Foreign bodies or the tongue can easily fall back to obstruct respiration, especially if there are bilateral fractures or comminution of the mandible, and the patient is unconscious. There is special danger to the airway if there has been trauma to and oedema of the tongue, fauces, pharynx or larynx, or uncontrollable nasoethmoidal haemorrhage.

Severely injured patients must have their airways (mouth and pharynx) cleared of debris and sucked out using direct vision and strong suction; they should be laid semi-prone on their side, face towards the ground, to allow any potential obstruction to fall forwards. Great care must be taken to avoid further neurological damage if a cervical spine injury is suspected. In the case of bilateral mandibular body fractures, a traction suture through the tongue will hold it forward; frequently, however, medial displacement of the posterior fragments prevents the anterior fragment from falling backwards unless the bone is comminuted. Posterior displacement of the maxilla in middle third injuries may cause the soft palate to occlude the airway. Obstruction can then be overcome by manual disimpaction of the maxilla. In the unconscious patient, a cuffed endotracheal tube may be needed to maintain the airway.

Should these non-invasive manœuvres fail to relieve obstruction immediately, a surgical airway, using endotracheal intubation or cricothyroidotomy, must be made. If there is supraglottic airway obstruction, a temporary airway can be established by laryngotomy using a wide-bore (2–3-mm) needle inserted through the cricothyroid membrane. In certain laryngotracheal crush injuries and other wounds that transect the trachea, it may be necessary to perform emergency tracheostomy (Fig. 24.5) or occasionally submental intubation. Indications for tracheostomy are summarized in Table 24.2.

Chest injuries, particularly those causing tension pneumothorax or flail chest, or those caused by inhalation of toxic or hot gases, further impair respiration (see Burns). Flail chest can be recognized by extreme difficulty in breathing, associated with paradoxical movements of the chest and cyanosis. Intermittent positive-pressure ventilation must be given via a cuffed endotracheal tube.

Box 24.1 Causes of respiratory obstruction

- Airway obstruction by loose objects, such as broken teeth, dentures or foreign bodies, or by accumulated blood and secretions
- Impaction of the middle third of the facial skeleton
- Injuries to the hyoid and its attached muscles
- Laryngeal spasm or oedema
- Prolapse of the tongue, especially after avulsion of the mandibular symphysis
- Swelling of the tongue and soft palate

Cervical spine stabilization is extremely important since injury is possible, especially in patients with injury above the clavicles or head injury resulting in an unconscious state, or any injury produced by high speed. Cervical spine injury is potentially fatal and may be symptomless whilst the patient is conscious due to protective muscle spasm that ‘stabilizes’ the spine; GA is very dangerous, as this protective muscle spasm is abolished on induction. Features can include neurological deficit and neck pain. Avoid any movement of the spinal column, and establish and maintain proper immobilization with the use of an appropriate neck splint until vertebral fractures or spinal cord injuries have been carefully ruled out with lateral cervical spine radiographs and computed tomography (CT).

Haemorrhage must be controlled. External bleeding is managed by direct pressure over any bleeding site until permanent control can be achieved by clamping and ligation. Shock due to bleeding that has led to hypovolaemia should be prevented or controlled and organ perfusion ensured by using intravenous fluid replacement (Ringer’s lactate, normal saline or blood transfusion). Vital signs should be monitored closely.

Severe haemorrhage or shock only rarely results from isolated head injuries or maxillofacial trauma, unless caused by gunshot wounds, so if such a patient is shocked, it is essential to exclude other injuries (damage to internal organs or fractures of the pelvis or limbs). Remember that bleeding may be concealed or occasionally aggravated by disseminated intravascular coagulation (Ch. 8). Severe haemorrhage can lead to cardiac or renal failure or cause fatal cerebral hypoxia. Haemorrhage into the pleural cavity from fractured ribs can embarrass respiration.

Latent haemorrhage may be recognized by rising pulse rate, falling blood pressure, increasing pallor, air hunger or restlessness. If haemorrhage is suspected, a surgical opinion should be sought, a blood sample should be taken for grouping and cross-matching, and the following quarter- or half-hourly observations should be recorded:

- Pulse rate
- Blood pressure

Fig. 24.5 Tracheostomy.

Table 24.2 Indications for tracheostomy		
What is obstructing the airway	Where positive pressure ventilation is needed	Where tracheobronchial suction is needed
Gross retroposition of the middle third of the face	Crushed or flail chest	Chronic obstructive pulmonary disease
Pharyngeal oedema	Prolonged mechanical ventilation	
Uncontrollable nasal haemorrhage		
Loss of tongue control		
Cancer surgery		

- Respiratory rate
- Urine output and fluid balance (usually hourly).

Blood transfusion may be indicated but is not needed to replace loss of less than 500mL in an adult, unless there was pre-existing severe anaemia or deterioration of the general condition warrants transfusion, since there are risks, such as from transfusion reactions, fluid overload and infection. Meanwhile, since time is needed to obtain correctly cross-matched blood, normal saline, plasma or a plasma expander, such as dextran 70 or 110, may be given initially. Dextran or other plasma expanders, together with tranexamic acid or desmopressin, may be the only possibility for Jehovah's Witnesses. Dextran can interfere with blood-grouping and cross-matching so that blood samples should be collected before a dextran infusion is started (Ch. 8).

Estimation of blood urea and electrolyte levels are needed in case there has been renal failure secondary to loss of blood, and as a baseline to monitor progress and the effects of intravenous fluid replacement. A full blood picture is also needed as a baseline for possible effects of transfusion and for any coincidental haematological disease. Early haemoglobin levels give no useful indication of the amount of blood lost, as haemodilution will not have had time to develop.

Blood and urine samples should be collected for analysis for alcohol, drugs and metabolic disorders, particularly diabetes. However, transient glycosuria unrelated to diabetes may follow the stress of head injuries.

The reader should consult the *Advanced Trauma Life Support Manual* and similar guides for full details on this important topic. A detailed assessment of maxillofacial injuries is only undertaken once the patient has been assessed and stabilized.

GENERAL ASSESSMENT

A good history must be obtained from the patient, if conscious, and witnesses. Reports of loss of consciousness, amnesia, nausea, vomiting or headache must be noted, as well as the medical history, especially use of drugs, including recreational agents or anticoagulants, or any history of epilepsy. A description of the mechanism of injury is useful, as it will give a clue as to what injuries to exclude. Family or friends may help with the patient's medical background.

CONSCIOUS STATE

Many patients are confused, concussed or comatose following head injury, though 30% of those with ultimately fatal head injuries may talk after injury and some are completely lucid for a time. However, the brain is invariably damaged in those who have lost consciousness for however brief a period, and sometimes in those who have not. Amnesia is common. Many are also suffering effects of alcohol or other drugs.

Maintenance of consciousness does not guarantee the absence of brain injury but the extent of retrograde amnesia is a rough measure of its severity.

Concussion, an immediate but transient loss of consciousness, is always associated with a short period of amnesia, and there is some brain damage even if after-effects are not detectable on neurological testing, cerebrospinal fluid (CSF) examination, CT or magnetic resonance imaging (MRI). Although the patient may lose consciousness only transiently, consciousness is almost invariably impaired after diffuse brain damage, and there is usually amnesia for the traumatic event, and afterwards (post-traumatic amnesia) for a period far exceeding that of coma. Consciousness may not be lost if brain damage is local, when, for example, the skull is penetrated by a sharp object.

Table 24.3 *Main cerebral causes of coma*

Brain lesions	Main causes
Cerebral cortex damage	Trauma, haemorrhage, hypoglycaemia, hypoxia, infection
Brainstem compression	Various
Brainstem localized pressure	Cerebellar haemorrhage, abscess, neoplasm
Brainstem reticular activating substance suppression	Drugs (alcohol and others)

Table 24.4 *Glasgow Coma or Responsiveness Scale (GCS)*

Eye opening	E	Motor response	M	Verbal response	V
Spontaneous	4	Obeys	6	Orientated	5
To speech	3	Localizes	5	Confused conversation	4
To pain	2	Withdraws	4	Inappropriate words	3
Nil	1	Abnormal flexion	3	Incomprehensible sounds	2
		Extends	2	Nil	1
		Nil	1		

Prolonged unconsciousness, when there are no complications such as brain haematomas and where there are no focal signs, is often caused by severe brain damage but sometimes by drugs (Table 24.3).

The most essential examination is immediately to assess, record and monitor the level of consciousness using the Glasgow Coma Scale (GCS), which scores points derived from three features: eye opening (E); motor response (M); and verbal response (V) (EMV score; Table 24.4). The degree of brain damage is initially assessed by the level of consciousness as measured by the GCS and, later, by the duration of coma and post-traumatic amnesia. It is important to consider causes of coma other than acute head injury (see Appendix 24.1). The EMV score or responsiveness sum can range from 3 to 15. A fully alert and otherwise well patient with a full and unchanging score of 15 and no neurological signs or symptoms and no skull fracture or intracranial haemorrhage on CT or MRI scan does not need hospital admission for observation, unless for other reasons. All patients who score below 15 points (see Table 24.4) should be admitted to hospital for observation – even if drugs or alcohol are the suspected causes. A score of 7 or less indicates coma in 100%; 9 or more indicates absence of coma. Patients with a GCS score of less than 8 require immediate neurosurgical attention (Table 24.5). About 85% of patients with a score of 3 or 4 succumb within 24 hours.

It is important also to recognize and to treat other factors that can contribute to morbidity and mortality, which can include airway obstruction, hypotension, meningitis, uncontrolled epilepsy, stress-induced gastric bleeding or diabetic ketoacidosis.

Patients who survive with head injuries fall into three main groups. Most are stable neurologically with gradual improvement in consciousness. Some progressively deteriorate in the level of consciousness with localizing signs, often because of intracranial bleeding with or without cerebral oedema, when the bleeding usually needs to be evacuated by craniotomy. Others have rising intracranial pressure (ICP), causing progressive deterioration in consciousness in the absence of localizing signs. ICP should be monitored. Cerebral oedema management remains controversial but general measures include optimal head

Table 24.5 Indications for neurosurgical attention after head injury

Immediate neurological attention indicated	Early neurological attention indicated	Admission to hospital for neurological observation
Glasgow Coma Scale score (GCS) < 8	GCS 8–14	GCS <15
Deteriorating consciousness	Convulsions	Minor skull fracture ^a
Neurological lateralization (pupillary inequality and hemiparesis)	Cerebrospinal rhinorrhoea or otorrhoea	Post-traumatic amnesia
Dilated fixed (unreactive to light) pupil	Orbital or retromastoid haematomas	Other serious injuries
Major skull fractures (depressed or compound)	Pneumoencephalocoele	Children
CT signs of compression or obliteration of mesencephalic cisterns, midline hemisphere shift, or one or more surgical masses	Worsening restlessness, headache and vomiting	Patients with psychiatric disease, drug abuse or learning impairment
Uncontrollable bleeding		Patients living alone or without a responsible adult companion
Rising blood pressure with bradycardia		

^aThere is some controversy among neurosurgeons about whether patients with skull fractures with no evidence of cerebrospinal fluid leak, cerebral haemorrhage or pneumoencephalocoele should receive observation or operative treatment.

and neck positioning 30° to the horizontal for facilitating intracranial venous outflow, avoidance of dehydration and systemic hypotension, and maintenance of normothermia, while specific therapeutic interventions are controlled hyperventilation, administration of corticosteroids and diuretics, osmotherapy, and pharmacological cerebral metabolic suppression. Ensuring adequate oxygenation, giving furosemide and restricting fluid are common strategies.

Patients must be carefully and regularly observed to detect the development of complications, especially intracranial haematomas, which need immediate neurosurgical attention. The level of consciousness should be charted, as assessed by the GCS and, later, by the duration of coma and of post-traumatic amnesia; this should take place at regular intervals – half-hourly or even more frequently – along with measurements of pulse, blood pressure, respiration, pupil reactivity and temperature.

Deterioration of consciousness is the most important sign, and is sometimes accompanied by worsening restlessness, headache and vomiting. Fixed dilatation of the pupil on the side of the fracture and decerebrate rigidity – late signs caused by raised ICP and brain shift – are soon followed by bilateral pupil dilatation, periodic respiration, respiratory arrest and death, unless there is immediate neurosurgical intervention. Focal signs, such as hemiparesis, dysphasia or focal epilepsy, are uncommon. In deep coma there are no verbal or motor responses, but in less severe cases the eyes may open transiently from time to time and there may be vague or weak responses to stimuli.

Up to 60% of all patients admitted in coma are alcoholics or other drug users who have often had a head injury. Toxic and metabolic disorders cause no focal or localizing neurological signs, although some drug misuse (opiates) can affect pupil reactivity. When there is disease of the central nervous system (CNS) itself, sensory or motor disturbances may indicate the lesion site. In some of these diseases, white cells, bacteria or blood may also appear in the CSF. Intoxications, whether the result of exogenous agents or disorders of metabolism and severe infections, all have essentially similar effects and will not be discussed further.

The level of consciousness is depressed further by sedatives and many analgesics, especially morphine and its analogues, which not only slow respiration but also disguise eye signs of rising intracranial pressure, by causing pupillary constriction. Pentazocine is also contraindicated. If analgesia is essential, codeine, diclofenac or buprenorphine can be used. Benzodiazepines should not be given for controlling fits or to allow suturing, since they cause respiratory depression, which can be fatal unless ventilation is given. If there are repeated fits,

phenytoin by intravenous infusion is less likely to depress respiration. Alcohol must be prohibited.

Pupil size and reaction must be checked for localizing signs of neurological damage. A dilated fixed (unreactive to light) pupil often indicates rising ICP and is usually a serious sign. Severe facial oedema may make examination of the eyes difficult and the eyelids should then be prised open. A fixed dilated pupil may also be caused by local damage to the optic or oculomotor nerves, and must be differentiated by clinical examination, radiographs (usually CT) and MRI, and by the absence of signs associated with brain damage or of rising ICP. Limb reflexes should be tested.

Regular monitoring of blood pressure and pulse rate is essential. A low or falling blood pressure with rising pulse rate is indicative of haemorrhage or shock, which can lead to fatal cerebral anoxia or renal failure. A systolic blood pressure of lower than 60 mmHg brings with it a risk of brain damage. A high or rising blood pressure with bradycardia, by contrast, is indicative of raised ICP secondary to cerebral oedema or haemorrhage as a result of the injury. Respiratory rate, urine output and fluid balance must also be monitored.

ASSESSMENT OF HEAD INJURY

Skull examination

Scalp lacerations may be associated with a fracture; they can cause severe loss of blood and provide a pathway for infection into the cranial cavity. The presence of a skull fracture greatly increases the risk of brain damage and an intracranial haematoma; significant intracranial lesions are found in two-thirds. A depressed skull fracture may be palpable, although it is often concealed by overlying oedema of the soft tissues. About 80% of skull fractures are linear, and many are associated with subepidural or epidural haematomas. Basal skull fractures are usually uncomplicated; they may not be visible on routine radiography but may be revealed by bleeding, which may show as haemotympanum (blood behind the ear drum), as ecchymosis over the mastoid process (Battle's sign), as periorbital ecchymosis (raccoon sign), or by CSF rhinorrhoea or otorrhoea. Alternatively, they may be suggested by cranial nerve lesions involving the olfactory nerve (cribriform plate fracture), optic nerve (sphenoid), facial nerve (petrous) or abducens and facial nerve (sella fracture).

Skull fractures can also cause cranial nerve damage and provide an entry to the CSF for infection or air (pneumocephalus).

Examination for cerebrospinal fluid leak

Particular care must be taken to examine for CSF leaks – rhinorrhoea or otorrhoea – and signs of orbital or retromastoid haematomas (which may indicate fractures with dural tears). In these instances, meningitis is a risk and an early neurosurgical opinion should therefore be obtained. In the early stages, leakage of CSF may be obscured by haemorrhage, but any clear watery discharge from the nose is suspect and should be tested for sugar and protein. CSF, unlike a serous nasal discharge, contains sugar but little protein. However, lacrimal fluid also contains small amounts of glucose, and CSF must therefore be positively identified by protein electrophoresis and accurate measurement of the glucose.

CSF rhinorrhoea is found in about 2% of all head injuries, and in 25% of fractures of the middle third of face and nasoethmoidal complex. CSF leaks usually persist for about a week and the risk of meningitis is greatest within the first fortnight. Post-traumatic CSF leaks will usually resolve without surgical intervention. Successful management in refractory cases often involves a combination of observation, CSF diversion and/or extracranial and intracranial procedures. Occasionally, the fistula may be occluded by herniated brain but the dural tear fails to heal. If there is a dural tear, meningitis may follow after some months or years and therefore dural repair is desirable.

In all patients with ocular or orbital injuries, the orbit should be examined radiologically, usually by CT for fracture; if the latter is suspected, the patient should undergo exploration and receive prophylaxis, as recommended for penetrating intracranial wounds.

Prophylactic antimicrobials are needed if there is a meningitis risk and should therefore be given to all patients with a penetrating brain injury (PBI), where the risk of intracranial infection is high because of contaminating foreign objects, skin, hair and bone fragments driven into the brain. Antimicrobials are also indicated in compound depressed skull fractures, CSF leaks or fractures of the middle third. The infecting agents in meningitis in one study were Gram-positive cocci (*Staphylococcus haemolyticus*, *Staphylococcus warneri*, *Staphylococcus cohnii*, *Staphylococcus epidermidis* and *Streptococcus pneumoniae*) or Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae* or *Acinetobacter anitratus*). Gram-positive strains were sensitive to vancomycin. All Gram-negative strains appeared resistant to ampicillin and third-generation cephalosporins, but sensitive to imipenem and to ciprofloxacin. Many bacteria causing post-traumatic meningitis are now resistant to sulphonamides. Recommended antimicrobials that readily reach the CSF and are well absorbed when given orally include co-amoxiclav, or cefuroxime with metronidazole, or azithromycin, or vancomycin and ceftazidime. Effective alternatives are rifampicin or minocycline.

Intracranial bleeding

Intracranial haematomas may be *intracerebral* (subarachnoid) haematomas – usually not amenable to surgical intervention; or *epidural* or *extradural* (between dura mater and skull) – usually due to tearing of the middle meningeal artery after a fracture of the temporal bone and evolving rapidly; these are neurosurgical emergencies requiring burr holes through the skull to drain the clot and ligate the bleeding vessel. The haematoma forms a tumour-like mass, which compresses part of the brain and raises ICP as it expands. Clinically, the typical story is of a heavy blow followed by loss of consciousness. There is usually then a period of apparent recovery (lucid interval), followed by signs of rising ICP. If the clot is not removed, death from respiratory

arrest follows. A radiograph showing a fracture line crossing the line of the middle meningeal artery strongly suggests extradural haemorrhage and CT scanning will confirm the diagnosis.

Subdural haematomas – between the dura and leptomeninges – are venous and associated with underlying brain contusion. *Acute subdural* haematoma is often caused by a tear in the arachnoid and may be associated with laceration or contusion of the brain. Clinically, there is a latent interval after the injury, followed by progressive deterioration of consciousness and development of symptoms somewhat similar to those of an extradural haematoma. Once coma has developed, up to 50% die. Early operation to evacuate the clot through burr holes improves survival. *Chronic subdural* haematoma can be caused by a very mild injury but, nevertheless, the veins between the pia and the dura mater get torn and blood leakage into the subdural space is very slow. There is a fibroblastic response and eventually the haematoma becomes enclosed in scar tissue or, occasionally, resorbed. Clinically, the head injury, especially in an elderly person, may be so slight as to have been forgotten but, after several weeks, or even months, symptoms such as headache, dizziness, slowness of thinking, or confusion and disturbance of consciousness develop. There may be localizing signs, such as hemiparesis or aphasia; the patient may have ptosis and be unable to look upwards (pressure on the third nerve).

Neurological assessment

After head injury, approximately 50% of patients have permanent after-effects, such as paralyses, loss of speech, impaired vision, epilepsy, disturbances of personality or severe mental defects, disabling them for life. Delayed effects may result from ischaemia, hypoxia, cerebral oedema, intracranial hypertension and/or abnormalities of cerebral blood flow. Cranial nerve injuries in patients with head injuries may indicate a basal skull fracture or other lesion; cranial nerves I, II, III, V, VII and VIII are most vulnerable (Table 24.6 and Ch. 13). Sense of smell is disturbed or lost (anosmia) in 5–10% of head injuries, since the olfactory nerves are damaged in frontal bone injuries and fractures involving the ethmoid cribriform plate. CSF rhinorrhoea is often associated. Traumatic anosmia improves in only about 10% and perversion of the sense of smell may develop during recovery, effects that are remarkably troublesome or even disabling, but untreatable. The goals of head injury treatment are therefore to detect any damage and prevent or reverse secondary insults to the damaged brain, such as from hypoxaemia, hypotension and intracranial bleeding or haematoma, and to allow recovery of as much damaged brain tissue as possible.

Skull imaging

Radiography should be carried out early before infection can reach the cranial cavity (typically anteroposterior, lateral and Towne's views). CT scans are essential to exclude skull fractures and brain lesions. MRI can provide better brain images but cannot always be used. Imaging may also reveal a depressed fracture involving the paranasal sinuses; this suggests a meningeal tear, which is occasionally confirmed by seeing intracranial air (aerocoele). A linear fracture indicates the possibility of intracranial haematoma but even normal radiographs do not exclude brain damage. About 50% of patients with intracranial injuries have no skull fracture, and approximately 90% of patients with fractures of the skull have no resulting intracranial injury. CT signs, such as compression or obliteration of mesencephalic cisterns, midline hemisphere shift, or one or more surgical masses, correlate with raised ICP and shortened survival.

Table 24.6 Cranial nerve lesions complicating head injuries

Nerve lesion	Usual site of injury	Comments
I (olfactory)	Ethmoidal complex (may be no fracture)	Anosmia (usually permanent); apparent loss of taste
II (optic)	Orbit ^a or sphenoid	Pupil dilated and unreactive to light, but consensual reflex retained ^b ; partial or complete blindness
III (oculomotor)	Orbit ^a	Affected eye looks down and out. Pupil dilated, unreactive to light. No consensual reflex. Loss of medial and vertical movement of eye. Divergent squint
IV (trochlear)	Orbit ^a	Diplopia only on looking down. Similar features result if superior oblique muscle is entrapped. Pupil reacts normally
V (trigeminal)	Middle fossa, orbit ^a , maxilla or mandible	Commonly extracranially. Anaesthesia or paraesthesia in sensory area
VI (abducens)	Orbit ^a or petrous temporal	Diplopia. Loss of lateral movement of eye. Convergent squint. Pupil reacts normally
VII (facial)	Direct trauma to nerve or basal skull fracture (see Facial paralysis)	Facial paralysis, which may be delayed for a few days
VIII (vestibulocochlear)	Petrous temporal	Deafness, vertigo and nystagmus alone or together. Deafness after head injury may also be caused by ruptured ear drum or blood in middle ear
IX–XII	Corticobulbar	Uncommon as a result of head injuries

^aMay be damage to orbital contents with or without fracture. These nerves are often injured together and urgent neurosurgery may be indicated, since nerve dysfunction, if caused by haemorrhage or oedema within the optic canal or other confined space, may be reversible. In the superior orbital fissure syndrome, there may be damage to the lacrimal, frontal, trochlear, abducens and oculomotor nerves with minimal damage to the globe.

^bConsensual reflex is constriction of the pupil as a normal response when a light is shone into the other eye.

Blood analyses

Sixty percent of coma patients are drug users or alcoholics who have often had a head injury.

ASSESSMENT FOR OTHER INJURIES

Multiply injured patients can be assessed using the revised trauma score (RTS), calculated mainly from the GCS, the blood pressure and the respiratory rate. Injuries can be categorized using the Abbreviated Injury Scale (AIS), which scores from minor (1) to fatal (6) injuries; the injury severity score (ISS) is calculated by the addition of the AIS for the three most severely injured areas of the body.

MEDICAL COMPLICATIONS OF HEAD INJURIES

Medical complications can arise, since the brain, via neurological and hormonal influences, can influence: the cardiovascular system (neurogenic hypertension, myocardial dysfunction, arrhythmias or deep vein thrombosis); the respiratory system (neurogenic pulmonary oedema – a form of acute respiratory distress syndrome [ARDS], infections, embolism); coagulopathy (disseminated intravascular coagulopathy); electrolyte imbalance (hyponatraemia, hypernatraemia or hypokalaemia); the endocrine system (inadequate or inappropriate secretion of antidiuretic hormone; Ch. 6); the gastrointestinal tract (stress gastritis and haemorrhage); fat embolism (mainly where there have been long bone fractures); or infections (of wounds, foreign bodies, CSF, intravenous lines, ICP monitoring devices, sinuses and lungs). Tetanus can be an issue (Ch. 21).

LATE SEQUELAE OF HEAD INJURY

Late sequelae may include: chronic extradural or subdural haematomas; epilepsy (Ch. 13); infection (see earlier); mental or physical disability; compensation neurosis (Ch. 10); or post-traumatic syndrome (which may result from mild brain damage or damage to the cochlear–vestibular apparatus). Complaints include temporary headache, irritability, inability to concentrate, short temper, loss of confidence, vertigo and hyperacusis. If symptoms persist, psychiatric advice should be sought.

MAXILLOFACIAL INJURIES

Most maxillofacial injuries are due to interpersonal violence and the majority are in previously fit young men; alcohol or another drug is frequently a factor. RTAs are also a major cause and produce fractures that often involve the midface, especially in patients who were not wearing seatbelts. Industrial accidents, sports and epilepsy are other causes. Other important sources of facial trauma include abuse (children and older individuals).

High-impact maxillofacial fractures often are associated with head and other bodily injuries that may be life-threatening. Patients are often multiply injured and may have hazards to the airway, head, cervical or thoracolumbar spine, eye, chest, liver, spleen, kidneys, long bones or bladder, and severe haemorrhage from massive midface injuries. Extensive soft-tissue injuries or avulsions and comminuted fractures are difficult to treat and may have poor outcomes. Low-impact maxillofacial fractures rarely result in mortality if proper treatment is administered.

Maxillofacial trauma demands special attention, since it may damage specialized functions, including breathing, sight, hearing, smelling, eating and speech – especially in middle third facial fractures (particularly Le Fort III fractures). The psychological impact of disfigurement can be devastating, and vital structures in the head and neck region are intimately associated.

The bones most commonly fractured are the nasal, zygoma, mandible and maxilla. Many fractures are reduced and fixed with miniplates (Champy plates are rarely used currently) and/or intermaxillary fixation. Closed reduction, open reduction and endoscopic techniques may be employed (see textbooks of maxillofacial surgery).

The management of patients with maxillofacial injuries is similar to that of head and other severe injuries (Box 24.2). Special problems also arise because of mechanical interference with breathing and swallowing. Shock is most unusual in uncomplicated maxillofacial injuries or head injuries, and its presence is often an indication of internal haemorrhage. The possibility of pre-existing disease must always be considered too, as must the possibility that foreign bodies may have been introduced. Management is divided into: emergency, immediate or initial care; early primary care; and reconstructive phases (definitive care and secondary care or revision).

Box 24.2 *Initial management of maxillofacial trauma*

- Maintain airway
- Control haemorrhage
- Reduce fractures
- Prevent infection
- Maintain fluid balance

Table 24.7 *Maxillofacial trauma: immediate and early assessment*

Step	Assess
Immediate care (ABC)	Airway and cervical spine Breathing and bleeding Chest injuries
General assessment	State of consciousness Pulse Blood pressure Respiratory rate Pupil size and reaction
Assessment of head injury	Skull examination Examination for cerebrospinal fluid leak Neurological assessment Skull radiography, including computed tomography Blood analyses
Assessment for other injuries	Chest Neck Spine Abdomen Perineum Limbs

EMERGENCY CARE

Life-threatening injuries must be addressed immediately – airway establishment and maintenance, and control of haemorrhage. A patent airway and an adequate fluid and nutritional intake can be difficult to achieve in maxillofacial injuries because of partial or complete obstruction of the respiratory or alimentary orifices. Altered level of consciousness is the most common cause of upper airway obstruction. Stabilize the cervical spine, which may be fractured, especially in any patient with injury above the clavicle, head injury resulting in unconsciousness, or any injury produced by high speed. Despite the extensive vascularity of the head and neck, massive blood loss due to maxillofacial injuries is uncommon. Penetrating injuries need to be explored. A nasogastric tube may be required for feeding in the immediate postoperative period if there are extensive intraoral wounds. Immediate and early assessment of maxillofacial trauma is summarized in [Table 24.7](#). Consult the *Advanced Trauma Life Support Manual* for full details.

EARLY CARE

The priorities of early management of a patient with maxillofacial and other injuries, especially if in coma, are as follows:

- Maintain a clear airway.
- Establish a neurological baseline.
- Establish baseline blood pressure, pulse and respiratory rates.
- Exclude other serious injuries to the head and neck, thorax and abdomen, other bones and eye, and CSF leak.

- Delay definitive treatment of maxillofacial fractures usually until the patient is out of danger, but stabilize grossly displaced or comminuted facial bone fragments early, as this may facilitate later management and lessen facial deformity. Reduce and immobilize fractures if they threaten the airway or there is severe haemorrhage. Avoid nasotracheal intubation in patients with upper face or upper midface fractures, as it can result in nasocranial intubation or severe nasal haemorrhage. Avoid clamping blind in order to prevent injuries to vital structures.
- Treat soft-tissue injuries early; large open wounds should be checked for foreign material (ultrasound is helpful), debrided and closed in a layered fashion promptly. Wounds that are to be used later for access to repair fractures, or those that are not a priority, may be closed in a temporary manner. In lacerations the skin is crushed and or torn, leading to an irregular skin edge injury, while in incised wounds the skin edges are less irregular; combinations of the two may coexist in the same injury. Nerve injuries in the maxillofacial region primarily affect the sensory (trigeminal) or motor (facial) nerves. In addition, the nerves of the orbit (ophthalmic, oculomotor, trochlear and abducent) may also be injured. Rarely, the other nerves of the head and neck may be injured. Facial fractures may compress or indirectly injure sensory nerves; typically, zygomatico-orbital injuries lead to infraorbital and/or zygomaticotemporal or zygomaticofacial nerve neuropraxias. Mandibular fractures often injure the inferior alveolar nerve along its course, manifesting as mental nerve altered sensation. Facial nerve injuries manifest as weakness or paralysis of the muscles of facial expression. For those injuries that result from transections of the nerve between the facial canal and a line drawn between the lateral canthus and angle of the mouth, early microneural repair is indicated. Salivary gland injuries can lead to fistulas or sialocoeles. Burns, chemical or thermal, also need attention. Appropriate protective dressings are applied and hydration is maintained.
- Prevent infection. Except for facial fractures affecting the ascending ramus, all fractures in which the periosteum is torn are compound and usually communicate with an internal mucous membrane wound and/or the external skin wound. Because of the contiguity of the naso-oral passages and the perforating nature of maxillofacial wounds, they are doubly exposed to contamination. Antibiotic therapy must be started early and maintained until fractures are immobilized ([Table 24.8](#)).
- Maintain oral hygiene, with particular attention to the teeth.

The reconstructive phase of care of maxillofacial injuries is discussed in maxillofacial surgery textbooks; a few comments only are included here. The maxillofacial region is divided into the upper face, where fractures involve the nasoethmoidal structures, frontal bone and sinus; the midface; and the lower face, where fractures are isolated to the mandible. Le Fort I fractures are in the lower midface. The upper midface is where Le Fort II and Le Fort III fractures occur and/or where fractures of the nasal bones, nasoethmoidal or zygomaticomaxillary complex, and the orbital floor occur.

A high-impact force is usually required to damage the supraorbital rim, mandible (symphysis and angle) and frontal bones. A low-impact force is all that is required to damage the zygoma and nasal bone.

Pan-facial injuries management is usually by internal rigid fixation using plates and screws.

Table 24.8 Antimicrobial prophylaxis in facial injuries

Injuries	Antimicrobial if indicated
Compound fractures	Penicillin or, in penicillin allergy, clindamycin
Contaminated skin lacerations	Cefazolin
Contaminated oral lacerations	Clindamycin
Fractures communicating with antrum	Amoxicillin
Fractures with dural tears or CSF leaks	Co-amoxiclav, or cefuroxime with metronidazole or vancomycin and ceftazidime

COMPLICATIONS OF MAXILLOFACIAL INJURIES

Infective problems

Actinomyces is discussed in Chapter 21.

Meningitis is an important complication of opening the cranial cavity (shown by leakage of CSF), as discussed above. It can also result from lacerations of the scalp when infection can reach the brain via the emissary veins.

Tetanus is discussed in Chapter 21.

Wound infection and osteomyelitis risks are greater when there is inadequate wound toilet, foreign bodies in the wound, teeth in the fracture line, gross delay in treatment or systemic disease with diminished resistance to infection, particularly alcoholism. Extreme care must be taken to identify foreign material within the tissues; some types of glass and plastic, and all wood, are radiolucent and may be missed unless the wound is systematically probed; they may also be identified on MRI. Gross debris, broken teeth, detached bone and foreign bodies should be removed. After preliminary wound toilet, lacerations can usually be sutured under LA. Larger lacerations can be covered with tulle gras and dry dressings for closure as soon as possible under GA. Teeth in the fracture line may need to be extracted unless required for stabilization of a bone fragment. Intramuscular benzyl penicillin or cefazolin is usually effective antimicrobial prophylaxis.

Ocular or orbital injuries

Zygomatic fractures or isolated orbital injuries may hazard vision. Diplopia (double vision) is common, often because of oedema and haemorrhage within the confined space of the orbit; circumorbital and subconjunctival ecchymoses are usually associated. Occasionally, periorbital emphysema is present. Diplopia sometimes arises from enophthalmos associated with orbital floor or wall fractures, from muscle or nerve injury, or from muscle entrapment. Untreated orbital blowout fractures also depress the level of the eye (this may be concealed initially, as intraorbital oedema maintains the level of the globe) and limit ocular movement, especially upwards.

The superior orbital fissure syndrome of ophthalmoplegia, ptosis, exophthalmos, a fixed dilated pupil or absence of consensual reflex, and some sensory loss over the distribution of the ophthalmic division of the trigeminal nerve, is caused by injury to cranial nerves III, IV, V and VI, where they pass through the orbital fissure. The syndrome may stem from disruption of the bony margins of the superior orbital fissure, haematoma or traumatic aneurysm at this site.

In all patients with ocular or orbital injuries, the orbit should be imaged by CT for fracture; if this is suspected, the individual should undergo exploration and receive prophylaxis, as recommended for penetrating intracranial wounds. If there are ocular injuries, an ophthalmological opinion should be sought, as the eye can be lost or vision impaired.

Fig. 24.6 Gunshot wound.

STAB AND OTHER PENETRATING WOUNDS

Stab wounds should always be treated with suspicion, as a small entrance wound can hide injuries to deeper structures or foreign bodies. Ultrasound can be helpful to detect the latter. Radiographs are indicated, especially where the wound is caused by glass, remembering that some glass is radiolucent. The wound may well need to be explored carefully before closure, especially if in the chest, neck, back or abdomen.

Computed tomographic angiography (CTA) has altered the management of patients with penetrating injuries in the neck, with fewer formal neck explorations and virtual elimination of negative exploratory surgery.

GUNSHOT AND EXPLOSIVE WOUNDS

Firearm wounds and deaths have increased dramatically in many countries recently. Gunshot wounds to the head, the most lethal of all firearm injuries, are the leading cause of head injury in many US cities and have a fatality rate of more than 90%, at least two-thirds of the victims dying before reaching a hospital. The management of wounds to the head and neck (Fig. 24.6) is discussed in surgical texts so salient points only are included here.

Bullets inflict tissue damage by laceration and crushing, shock waves and cavitation. Handguns usually inflict low-velocity bullet wounds that damage only the tissues they hit, mainly by laceration; the wounds are managed by conventional surgical methods. Traditionally, civilian injuries were inflicted with low-velocity weapons (90–210 m/s), while military wounds were typically caused by high-velocity weapons (610 m/s and up; Table 24.9). Owing to medium- to high-velocity weapons appearing on the streets, more civilians are suffering from military-type injuries. Such high-velocity missiles (from rifles or explosive blast fragments) can cause extensive tissue damage and contamination, and have a mortality rate 4–5 times higher – thus requiring specialized attention. The entrance wounds may be minute, but can hide extremely severe wounds caused by the cavitation effect of rapid compression and expansion with extensive necrotic tissue contaminated with clostridia spores, other bacteria, clothing and debris. The kinetic energy is directly proportional to the mass of the projectile and proportional to the square of the velocity at which the bullet is travelling. The most efficient missile enters tissues

Table 24.9 Gunshot wounds

Type of gun	Comment
Airgun	Can be left <i>in situ</i> if deep and not in orbit or causing damage
0.22 rifle	Can be left <i>in situ</i> if deep and not in orbit or causing damage
0.410 shotgun	May cause considerable damage at close range
Twelve-bore shotgun	Dangerous, even from a distance; widespread damage
High-velocity bullets	Cause more extensive damage than is initially evident
Explosive bullets	Cause more extensive damage than is initially evident

and imparts the majority of its kinetic energy to surrounding structures without exiting the victim.

All patients with gunshot wounds should be imaged to locate the missiles. To avoid gas gangrene, high-velocity wounds must be treated by excision of the damaged tissue and with antibiotics, followed 4–5 days later by delayed primary closure and, if necessary, skin grafts. Consider tetanus risk (Ch. 21).

HUMAN BITES

Human bites are more likely to cause infections than are animal bites (Ch. 33), since the oral flora contains many potentially pathogenic aerobic and anaerobic bacteria; among these are *Staphylococcus*, *Streptococcus*, *Clostridia* (and other anaerobes) and fusiform species, as well as viruses. Tetanus is rarely a concern unless the wound is contaminated by soil. Hepatitis B, hepatitis C and human immunodeficiency virus (HIV) are a concern, since they can be transmitted by bites both from biter to victim and the converse.

Staff working in areas posing a significant risk of biting should not be treated as performing exposure-prone procedures (EPPs). In October 2003, the UK Advisory Panel (UKAP) considered a review of the available literature on the risk of onward transmission from health-care professionals (HCPs) infected with blood-borne viruses to patients. The review showed that the published literature on this subject is very scarce. In follow-up studies of incidents involving infected HCPs working with patients known to be ‘regular and predictable’ biters, there were no documented cases of transmission from the health-care worker to the biter. However, where biters were infected, there were documented cases of seroconversion in their victims, and the risk of infection was increased in the presence of:

- blood in the oral cavity – risk proportionate to the volume of blood
- broken skin due to the bite
- bite associated with previous injury (i.e. non-intact skin)
- biter deficient in anti-HIV salivary elements (immunoglobulin A-deficient).

Based on the available information, it can only be tentatively concluded that, even though there is a theoretical risk of transmission of a blood-borne virus from an infected HCP to a biting patient, the risk remains negligible. The lack of information may suggest that this has not been perceived to be a problem to date, rather than that there is an absence of risk. UKAP has advised that, despite the theoretical risk, since there is no documented case of transmission from an infected HCP to a biting patient, individuals infected with blood-borne viruses should not be prevented from working in or training for specialties where there is a risk of being bitten.

Table 24.10 Effects of spinal cord damage

Early (spinal shock): losses of	Delayed (after 2–3 weeks):
Motor function: quadriplegia if damage in cervical cord, paraplegia if damage in thoracic cord	Motor function may improve if cord not completely transected
Sensation below lesion, leading to skin pressure ulcers	Sensation may improve if cord not completely transected
Reflexes below lesion, with muscle flaccidity	Reflexes: involuntary flexor then extensor spasms below level of lesion
Bladder and bowel sphincter control, leading to urinary or faecal retention	Bladder and bowel sphincter control impaired, causing irregular reflex micturition and defecation

It is important for biting incidents to be reported and for risk assessments to be conducted in accordance with National Health Service (or equivalent) procedures. Biting poses a much greater risk to HCPs than to patients. Therefore employers should take measures to prevent injury to staff, and HCPs bitten by patients should seek advice and treatment, in the same way as after a needlestick injury.

Patients with hand infections from bite wounds may require hospital admission, antibiotics (co-amoxiclav, most commonly), wound incision and drainage. Any human bite could stem from abuse and therefore should be assessed, preferably by a forensic dentist (<http://www.bafo.org.uk/>; accessed 30 September 2013). DNA should be retrieved where possible, and serial photographs and casts taken (Ch. 25).

SPINAL CORD INJURIES

Spinal cord injuries (SCIs) are a common result of road traffic or sports injuries. Cord injury is usually the result of vertical compression, sometimes with flexion or extension of the neck, or violent sudden extension of the neck (whiplash injury), as when a vehicle is hit from behind. The possibility of such damage should always be considered in patients involved in road traffic or contact sport accidents, since movement of the neck may then cause serious cord damage, spastic quadriplegia or death. The neck must therefore not be extended or rotated, and a support collar should be fitted prophylactically. Decompression by reduction of any vertebral dislocations should be carried out by the neurosurgeon within 2 hours of injury. Spinal cord damage can be most incapacitating (Table 24.10).

Most vertebral injuries affect the C1–2, C4–7 and T11–L2 vertebrae, the clinical sequelae being determined largely by the level of spinal cord damage, but the result can be fatal or appallingly severe disability (Table 24.11).

Traumatic atlanto-axial dislocation may be fatal. If not, there may only be weakness of the legs or even no immediate neurological sequelae. Transient blackouts, weakness of the limbs, sensory loss, facial paraesthesia, nystagmus, ataxia and dysarthria may be complaints. Atlanto-axial subluxation, or dislocation or fracture of the odontoid peg, may occur in other conditions, such as congenital anomalies of the odontoid process (as in Down syndrome), rheumatoid arthritis or ankylosing spondylitis.

The clinical effects of SCI develop in two main stages: spinal shock and reflex activity (see Table 24.10). If movement can be elicited or any sensation is retained during the first 2–3 days, the prognosis is more favourable. Paraplegia is common but high doses of methylprednisolone given within 8 hours of the injury may minimize cord damage. Any symptoms persisting after 6 months are likely to be permanent.

Most patients with thoracic cord injuries need wheelchairs. Mechanical bracing systems can restore upright mobility following SCI, and can improve bone density, urinary drainage, bowel function, spasticity, respiratory mechanics, contractures and psychological health,

Table 24.11 Effects of spinal cord injuries at different levels

Level of spinal cord damage	Features
C1–C5	Quadriplegia (tetraplegia) or death
C5–C6	Paraplegia. Hands paralysed. Arms paralysed, except for abduction and flexion
C6–C7	Paraplegia. Hands but not arms paralysed
T1	Paraplegia. Normal hand function. Patients can perform all functions of a non-injured person, with the exception of standing and walking
T2–T5	Paraplegia. Patients have partial trunk movement and may be able to stand, with long leg braces and a walker, and may be able to walk short distances with assistance
T6–T12	Paraplegia. Patients have partial abdominal muscle strength, and may be able to walk independently for short distances with long leg braces and a walker or crutches
T11–T12	Paraplegia. Sensory loss T12 and below
T12–L1	Legs paralysed below knees
L2	Patients have all movement in the trunk and hips
L3	Patients have knee extension
L4	Patients have ankle dorsiflexion
L5	Patients have extensor hallucis longus function. They are able to walk independently with ankle braces and canes, and may use wheelchairs for long distances
S1–S2	Patients have function of the gastrocnemius and soleus muscles and walk independently on all surfaces, usually without bracing

but are perceived by some to be less safe and more difficult to use than wheelchairs.

Most patients with injuries at or below the lumbar level are wheelchair-independent and may be able to walk independently, with long leg braces and crutches.

General management of paraplegics

Treatment in general is supportive and symptomatic, and mainly directed toward the prevention of complications such as muscle wasting or contractures, pressure sores (bed sores), postural hypotension, urinary infections, constipation or psychological problems.

Physiotherapy is essential to limit muscle-wasting and to maintain function in unparalysed or partly paralysed muscles. Joints must be passively moved on a regular basis, and the position of the patient carefully checked to prevent soft-tissue contractures and pressure sores.

Postural hypotension and autonomic dysreflexia can complicate high-level spinal cord lesions. Intense vasoconstriction below the level of the cord injury follows certain stimuli such as bladder contraction. The vasoconstriction is associated with rapid onset of hypertension, facial sweating and headache.

Urinary retention invariably complicates acute spinal cord lesions, and aseptic catheterization is needed. Infections must be treated promptly. Recurrent urinary infections were previously the main factor in renal disease and amyloidosis complicating paraplegia. Latex allergy commonly develops in such patients.

Dental aspects

Access to health care is a major problem since patients are at least chair-bound. Dental management may be uncomplicated, although postural hypotension in the early stages may necessitate treatment in the upright position and latex allergy should be considered (Ch. 17). Quadriplegics

Fig. 24.7 Prevention of occupational trauma.

are at risk from respiratory infections, so that GA should be avoided if possible. Other problems are dealt with in Chapter 13.

TRAUMA PREVENTION

Many of the problems caused by trauma could be avoided by abstention from drug and alcohol use and high-risk behaviour, the use of body protection, and application of health and safety laws and regulations in dangerous occupations, sports and other activities (Fig. 24.7).

BURNS

Burns can be caused by thermal injury, electricity, radiation or chemicals. Chemical burns are caused by exposure to corrosive substances, such as bleach, acids or alkalis, and pesticides.

First-aid care includes:

- airway maintenance
- oxygen administration if there has been exposure to hot air or smoke
- pain reduction by cooling the burn with cold water (not ice) and covering it with clingfilm or other non-adherent protective film. Give analgesics, such as oral paracetamol (acetaminophen), fentanyl (intranasal 1.5 mcg/kg) or morphine (5–15 oral mg for an adult or 0.1 mg/kg i.v.). Burns to the eyes require early copious irrigation with normal saline or water
- removal of any jewellery near the burn and clothing that has absorbed hot water. If clothing is stuck to the wound, do not pull it off; cut around it and remove the rest of the clothing
- ensuring that the electrical source is turned off if a casualty has been injured by a household electrical supply (240 volts). A non-conductive object should then be used to move the individual away from the electrical source. If a casualty has been injured by a high-voltage source (1000 volts or more), do not approach them but immediately call the emergency services.

Never:

- put yourself or others in danger
- over-cool an injury, as it can lower the body temperature of a casualty
- apply any oils or creams to burns
- break any blisters that have developed.

Assess the burn severity in terms of depth (Table 24.12). Anyone who has been injured with any of the following should receive immediate treatment in a burns or plastic surgery unit:

- Full-thickness burns
- Chemicals, electricity or explosives
- Large or deep burns – any burn bigger than the affected person’s hand – and full-thickness burns of all sizes
- Partial-thickness burns on the face, hands, arms, feet, legs or genitals – these are burns that cause blisters.
- Respiratory or ocular involvement – patients with a raised respiratory rate, abnormal breath sounds (rales) and bilateral diffuse interstitial and intra-alveolar oedema on radiography should be urgently admitted to an intensive care unit.

CLINICAL FEATURES AND MANAGEMENT

Burns are serious injuries, especially where there is airways or circulatory involvement or more than 10% of the body surface area is affected.

Table 24.12 Burn severity

Severity	Appearance	Pain	Common causes
Superficial	Dry, red, possibly small blisters, rapid capillary return	+	Sunburn
Partial-thickness, superficial	Moist, red, broken blisters, rapid capillary return	+	Scald
Partial-thickness, deep	Moist, white slough, red mottled, slow capillary return	–	Scald, transient flame contact
Full-thickness	Dry, charred, whitish. No capillary return	–	Flame, electrical or severe scald

Airway and breathing

- Immobilize the cervical spine if there is associated trauma.
- Assess for stridor, hoarseness, black sputum, respiratory distress, singed nasal hairs or facial swelling.
- Intubate immediately if there are oropharyngeal burns and significant neck burns, even if the airway is not yet compromised. If burns have been received in a closed or confined space, a change in voice, hoarseness, dysphonia, stridor and the coughing up of sooty sputum are all signs suggesting inhalation injury; endotracheal intubation or tracheostomy may be indicated. ARDS, sometimes a sequel to burns and other pulmonary injury, is characterized by diffuse alveolar damage, pulmonary oedema and hyaline membrane formation, and may culminate in respiratory failure; mortality is high.

Circulation

- Seek sources of overt or covert bleeding, as early hypovolaemia is rarely caused by the burn injury.
- For circumferential limb burns, check for circulatory obstruction and the need for an escharotomy; elevate the limb.
- For electrical burns, perform electrocardiography (ECG). High-voltage limb burns may require early fasciotomy.

Estimation of body surface area involved

- Calculate body surface area (BSA) involvement (Fig. 24.8).
- Remember that BSA involvement determines the need for fluid resuscitation and admission, as opposed to dressings and potential outpatient management (see below).

Fig. 24.8 Lund and Browder chart used to calculate involvement of body surface area (BSA) after burns.

Documentation

Document:

- time of burn
- extent of burn
- depth of burn
- first aid received
- tetanus status.

Full-thickness burns

Management of major burns (>10% BSA)

Airway and breathing

- If airway burn or lung injury is possible, intubate as soon as possible before airway swelling appears.

Fluids

- Insert an intravenous line through uninvolved skin. Give fluid replacement.
- If the burn covers more than 15% of the BSA or if there is significant perineal burn, insert a urinary catheter.
- If the burn consists of more than 15% deep partial-thickness or full-thickness burns, insert a nasogastric tube and start feeding within 6–18 hours.

Investigations

- Perform haemoglobin, electrolytes, blood glucose, blood group and hold.
- Measure carboxyhaemoglobin levels (if the fire was in a confined space).

Management of minor burns (isolated, <10% BSA)

- Give analgesia.
- Immobilize upper limb burns with a sling and splinting.
- Use closed dressings for partial-thickness burns.
- Remember that the depth of a partial-thickness burn may only be declared after 7–10 days.
- Note that blisters may have a protective function, and reduce pain if left intact for a few days. If they are small, not near a joint and not obstructing the dressing, they should be left intact. If overlying a joint, they should be deroofed, as they may limit function. Derroof if they are large (for assessment) or if blister fluid becomes opaque (suggests infection).

Superficial burns with erythema only

- Treated by exposure, if possible; alternatively, use a protective, low-adherent dressing (e.g. Mepitel™ + Melolin™) with crepe bandage.

Partial-thickness burns

- Cleanse the burn and surrounding area with saline. If the wound is dirty or treatment is delayed, use aqueous chlorhexidine 0.1% then saline.
- For small, superficial, partial-thickness burns, cover with a low-adherent dressing (e.g. Mepitel™ + Melolin™), then a crepe bandage or adhesive paper.
- For more extensive or deeper partial-thickness burns, apply a low-adherent silver dressing (e.g. Acticoat™ or Acticoat 7™).

Facial burns

- Remember that superficial burns only require Vaseline™ to be applied twice daily, whereas partial-thickness burns may need silver dressings. Good education regarding care of the burn is essential.

Care at home

- Clean the face gently with saline or water.
- Apply 1/2 cm thick Vaseline™ to the face by using a large cotton swab, gauze or clean hands.
- Clean and reapply the Vaseline™ twice a day. If it is rubbed off in between, apply more Vaseline.

VULNERABLE PEOPLE

In the UK, the Safeguarding Vulnerable Groups Act 2006 (SVGA; www.legislation.gov.uk/ukpga/2006/47/notes/contents, accessed 30 September 2013) has been amended by the Protection of Freedoms Act 2012 (PoFA). See also <http://www.justice.gov.uk/protecting-the-vulnerable/mental-capacity-act>; accessed 30 September 2013). These are the salient points:

- A judgment about vulnerability is based on the capacity for self-protection.
- Self-protection refers to being able to demonstrate behaviour that results in defending oneself against threats to one's safety results in successfully meeting one's own basic (safety) needs.
- Vulnerability means being defenceless against threats to one's safety.
- Children and older people may be especially vulnerable to threats to safety. Children from birth to 6 years old, especially infants, are always particularly vulnerable, as are people who are physically handicapped. Individuals who are cognitively limited are also vulnerable.
- A person's vulnerability helps inform what must be done to manage threats and assure protection.

The emotional, mental health or behavioural problems of vulnerable people may irritate and provoke others to act out toward them or to avoid them totally. Regardless of age, intellect and physical capacity, people who are highly dependent and susceptible to others, who are unable to defend themselves against aggression, who cannot or will not seek help and protection, or who are so passive or withdrawn that they are not able to make their basic needs known are vulnerable. Regardless of age, some people who are not visible and not noticed or observed, may have continuing or acute medical problems and needs that make them vulnerable. A 'vulnerable adult' is:

a person aged 18 years or over who is, or may be in need of, community care services by reason of mental or other disability, age or illness; and who is, or may be, unable to take care of him or herself, or unable to protect him or herself against significant harm or exploitation.

The term encompasses those with physical or mental impairments, including dementia and other degenerative illnesses.

Abuse (as defined by the UK Department of Health; [Tables 24.13 and 24.14](#)) may be:

- *physical*: hitting, slapping, pushing, kicking, burning or other show of force; misuse of medication; restraint; or inappropriate

Table 24.13 *Features of abuse in a dental practice/domiciliary setting^a*

General signs	Behaviour of patient	Behaviour of carer	Features of domestic environment
Appointments often missed	Appearing passive or afraid of carer	Attitudes of indifference or anger to vulnerable adult	Lack of amenities, e.g. TV, personal grooming items
Difficulties in arranging appointments/frequent cancellations	Remaining quiet while carer responds to questions	Ignoring of vulnerable adult	Dirty, smelly, unsanitary conditions
Poor compliance with treatment regimens	Withdrawal/detachment	Refusal to allow vulnerable adult to speak	Soiled bed
Injuries inconsistent with explanation given	Anxiety	Inappropriate displays of affection	Indications of unusual confinement, e.g. patient is closed off in a particular room, tied to furniture
Conflicting or vague explanations of injuries	Poor eye contact	Verbal intimidation, berating or use of humiliating language	Obvious absence of assistance or attendance
Delay in presentation for treatment of dental problems/injuries	Closed body position/holding head down	Blame of vulnerable adult (e.g. for bad behaviour, incontinence or forgetfulness)	Obvious absence of protection, e.g. to prevent patient with severe dementia falling out of bed
	Minimization of injuries	Threats of punishment or deprivation	

^aAfter Moore and Newton 2012.**Table 24.14** *Type of abuse presenting indicators in general dental practice/domiciliary setting^a*

Physical abuse	Neglect	Psychological abuse	Financial abuse	Sexual abuse
<u>General signs</u>				
Cuts, lacerations, puncture wounds, open wounds	Impaired skin integrity/ulcers, rashes, sores, lice, unkempt	Helplessness	The vulnerable adult suffers from substandard care in the home	A vulnerable adult telling you that they have been sexually assaulted or raped
Recognizable shape or pattern to bruises, such as slap mark, bite	Soiled clothing or bed	Hesitation to talk openly, fearfulness	Disappearance of a vulnerable adult's possessions in an institutional setting, despite adequate financial resources	Signs of psychological abuse (see left)
Bruises, welts, discoloration, black eyes, burns, bone mark, rope mark	Appearance, body odours	Withdrawal, passive affect	Vulnerable adult poorly dressed	
Fractures, concussion	Inappropriate clothing	Denial of a situation	Signatures on cheques, etc. that do not resemble the vulnerable adult's	
Signs of restraint (visible restraint or bruising, e.g. rope marks)	Malnourishment, emaciation or dehydration without an illness-related cause	Confusion or disorientation	The inclusion of additional names on an older person's bank account signature, or signed when the adult cannot write	
Untreated injuries in various stages of healing or not	Lack of appropriate physical aids, such as glasses, hearing aids, assistance with eating and drinking	Anger without apparent cause	Unpaid bills	
Broken glasses	Failure to provide a safe environment	Sudden change in behaviour	Confusion of a vulnerable adult regarding his/her financial situation	
A vulnerable adult disclosing an experience of being hit, slapped, kicked or mistreated	A vulnerable adult telling you he/she is left alone for long periods of time	Emotional upset or agitation	A vulnerable adult telling you that someone has taken their money	
Overdosing or underdosing of medication		Depression		
		Unusual behaviour (sucking, biting, rocking)		
		A vulnerable adult telling you they are being verbally or emotionally abused, isolated, or left alone for days on end		
<u>Orofacial signs</u>				
Lip trauma	Poor oral hygiene, halitosis		Lack of dental care	Oral signs of sexually transmitted diseases, e.g. syphilitic or herpetic ulceration
Fractured, subluxated or avulsed teeth	Rampant dental disease		Care-giver questions dentist on necessity of dental work for older person 'at his age'	
Fractures of the mandible, maxilla or zygomaticomaxillary complex	Absence of dentures			
Missing teeth	Glossitis, angular cheilitis			
Eye injuries, orbital fractures	other oral infections			
Bruising of the edentulous ridges or the facial tissues	Xerostomia			
Unexplained alopecia (from pulling hair)				
Evidence of prior trauma to dental or orofacial structures				

^aAfter Moore and Newton 2012.

sanctions. Victims may suffer physical injuries that are minor, like cuts, scratches, bruises and welts, or more serious, such as head injuries or broken bones. Physical injuries can also lead to premature death and aggravate existing health problems.

- *sexual*: including rape and sexual assault or sexual acts to which the vulnerable person has not consented, or could not consent or was pressured into consenting.
- *psychological*: including emotional abuse, threats of harm or abandonment, deprivation of contact, humiliation, blaming, controlling, intimidation, coercion, harassment, verbal abuse, isolation, or withdrawal from services or supportive networks. Such behaviours harm a person's self-worth or emotional well-being (e.g. verbal abuse, name-calling, scaring, embarrassing, refusing access to friends and family).
- *financial or material abuse*: theft, fraud, exploitation, pressure in connection with wills, property or inheritance or financial transactions, or the misuse or misappropriation of property, possessions, assets or benefits.
- *neglect and acts of omission*: ignoring medical or physical care needs, failure to provide access to appropriate health, social care or educational services, withholding of the necessities of life, such as medication, adequate nutrition and heating. Neglect is failure to meet a person's basic needs (e.g. food, housing, clothing and medical care). Abandonment is when a caregiver leaves a person alone, no longer providing care.
- *discriminatory*: including racist, sexist, that based on a person's disability, and other forms of harassment, slurs or similar treatment.

Risk factors in the vulnerable adult person may include:

- social isolation
- dependence on abuser for essential care
- physical and cognitive deterioration
- dementia
- challenging behaviour.

ELDER MALTREATMENT

Elder maltreatment includes violence inflicted upon those aged 60 and older. The violence usually occurs at the hands of a care-giver or a person the elder trusts, and victims are often fearful and anxious. Elder maltreatment can be prevented by:

- listening to elders and their care-givers
- reporting abuse or suspected abuse
- learning how to recognize and report elder abuse and how to differentiate it from the normal aging process.

REPORTING ABUSE

Local social services are the lead agencies to which disclosures of abuse should be made. Telephone referrals to social services should be followed up in writing within 48 hours. Difficulties or concerns should be discussed with a senior colleague and the defence organization. As with all patient information, it is essential that all records are kept entirely confidential.

CONSENT

The patient's consent must first be obtained before disclosing an incident or suspected incident of abuse to social services. The disclosure

must be carried out in an appropriate manner so that the patient is not put at increased risk of harm. Details of the discussions and agreement of the patient to disclosure of information to social services should be recorded in the dental records. Disclosure of information can be made without consent in a number of situations where:

- the adult is believed to be at risk of death or serious harm
- the adult is not competent to give consent
- information is required under a court order or another legal obligation.

It is the responsibility of the HCP to 'act at all times in the best interests of the patient based on a risk-benefit assessment, accept final responsibility for his or her actions, and be able to justify them if subsequently challenged'.

RECORDS

Accurate contemporaneous records should be kept of all allegations or suspicions of abuse. Precise factual information of the alleged abuse must be recorded. Details of any discussions and decisions taken and reason for those decisions should be clearly recorded. There should be comprehensive documentation of injuries, including details of site, size, colour, swelling and other distinguishing features. Body maps are recommended and, where appropriate, clinical photos should be taken – with informed consent. In cases where the patient is unable to give informed consent, the dental practitioner should take clinical photos if it is considered to be in the patient's best interest. All injuries should be treated, or a referral made for treatment.

APPENDIX 24.1 CAUSES OF COMA

- Acute disseminated encephalomyelitis
- Addison disease
- African sleeping sickness
- Alcohol poisoning
- Asphyxia
- Brain compression
- Brain infection
- Brain inflammation
- Chagas disease
- Concussion
- Creutzfeldt–Jakob disease
- Diabetic ketoacidosis
- Eclampsia
- Ehrlichiosis
- Encephalitis
- Head trauma
- Heatstroke
- Hepatitis
- High-altitude cerebral oedema
- HIV/AIDS
- Hyperparathyroidism
- Hypothermia
- Japanese encephalitis
- Kidney failure
- Lead poisoning
- Liver failure
- Melioidosis
- Meningitis
- Mountain sickness
- Poisoning
- Progressive multifocal leukoencephalopathy
- Pulmonary embolism
- Reye syndrome
- Rift Valley fever
- Rocky Mountain spotted fever
- Shock
- Streptococcal toxic shock syndrome
- Stroke
- Subarachnoid haemorrhage
- Toxoplasmosis
- Typhoid fever
- Viral haemorrhagic fevers
- Yellow fever

EITHER GENDER

CHILDREN

In the UK, people up to the age of 16 years are regarded as children. It may be necessary to take at least part of the history from a parent.

General aspects

At birth the neonate is classified as premature or preterm (less than 37 weeks' gestation), full-term (37–42 weeks' gestation) or post-dates (born after 42 weeks' gestation). Premature babies are at particular risk from a number of problems.

Premature babies

Up to 10% of all births are preterm, usually with a low birth weight (below 2500 g). Low birth weight may result from intrauterine growth retardation. Causes include multiple pregnancy, infection, maternal smoking, pre-eclampsia, severe anaemia, and heart and renal disease. These babies may go on to have lower IQs and smaller stature. In about 40% the cause is unknown but may be related to maternal issues: that is, elective delivery due to pregnancy complications such as pre-eclampsia (maternal hypertension, fluid retention and proteinuria) or placenta praevia (low-lying placenta). Maternal periodontal infection may possibly be a risk factor. Predictors are shown in [Table 25.1](#).

Preterm babies, depending on the degree of prematurity, may suffer apnoea or irregular breathing, a weak cry, inactivity, ineffective sucking and swallowing (with poor feeding), shiny wrinkled skin with fine body hair (lanugo), soft, flexible ear cartilage, enlarged clitoris (female) or a small scrotum (male). Preterm babies are less able to maintain body temperature and haemostasis, and are prone to several health consequences ([Table 25.2](#)). Up to a half suffer long-term sequelae, including low IQ, behavioural disorders, coordination problems, and respiratory and feeding problems.

Neonates

A neonate is a newborn infant up to 1 month old. Neonate behaviour is characterized by six states of consciousness: quiet sleep, active sleep, drowsy waking, quiet alertness, fussing and active crying. The amount a healthy infant cries in the first 3 months varies from 1 to 3 hours a day. Periodic breathing is normal. Temperature control, skin colour, stooling, yawning, gagging, hiccupping, vomiting and sleep are easily affected by stress and stimulation. Sleep/wake cycles occur in random intervals of 30–50 minutes and gradually increase as the child matures. By 4 months old, most infants will have one long period of uninterrupted sleep and breathing stabilizes. The neonate can see objects within a range of 8–12 inches, has excellent colour vision, can track moving objects up to 180° and sees faces. Infants prefer the frequencies of the human voice. Senses of hearing, touch, taste and smell are mature at birth. Vestibular senses are also mature and the infant responds to rocking and changes of position.

During the neonatal period, most congenital defects (e.g. congenital heart disease) are detected. Congenital infections (e.g. rubella, herpesviruses, toxoplasmosis) may manifest. Immunological immaturity

Table 25.1 Predictors of preterm birth

Primary predictors	Secondary predictors
African heritage	Anaemia
Chronic kidney disease	Bacterial vaginosis
Chronic respiratory disease	Chorioamnionitis
Cigarette smoking	Hydramnios
Depression	Inadequate prenatal care
Diabetes mellitus	<i>In vitro</i> fertilization (IVF)
Domestic violence	Low maternal weight gain
Family history	Multiple fetuses
Hypertension	Pre-eclampsia
Inflammatory gene polymorphism	Raised fibronectin, alpha-fetoprotein, alkaline phosphatase or granulocyte colony-stimulating factor
Low body mass index	Vaginal bleeding
Low socioeconomic status	
Previous pre-term birth or abortion	
Stress	
Substance abuse	
Young mother	

Table 25.2 Possible consequences of preterm birth

Early	Long-term
Bronchopulmonary dysplasia (BPD)	Attention deficit disorder
Hypocalcaemia	Cerebral palsy
Hypoglycaemia	Hearing impairment
Intraventricular brain haemorrhage or periventricular infarction	Learning impairment
Necrotizing enterocolitis	Retinopathy
Neonatal jaundice	
Patent ductus arteriosus	
Respiratory distress syndrome (RDS; hyaline membrane disease)	
Sepsis	

predisposes to candidosis. Infections may be transmitted by parents or carers, or from the environment; even tongue spatulas can be a source of infection.

This is a period of rapid growth and development. Facial, skull, jaw and tooth development can be impaired by radiotherapy, chemotherapy and some immunosuppressants during this time. Oropharyngeal or orogastric intubation may result in palatal grooving, acquired cleft palate and damage to the deciduous dentition. Appliances can be constructed to protect against this damage.

Infants

The first year of life is referred to as infancy. The healthy infant possesses a number of primitive reflexes ([Table 25.3](#)). Physical development begins at the head and then progresses to other parts (sucking precedes sitting, which precedes walking). Mental and neurological functions develop, with gross motor (e.g. head control, sitting,

Table 25.3 Normal infant reflexes

Reflexes	Composition
Babinski reflex	Toes fan when sole of foot is stroked
Moro reflex	On momentarily releasing head from a supported sitting position, arms abduct, hands open and then arms adduct
Palmar hand grasp	Closure over finger
Plantar grasp	Flexion of toe and forefoot
Rooting and sucking	Turns head in search for nipple when cheek is touched and begins to suck when nipple touches lips
Stepping and walking	Takes brisk steps when both feet placed on a surface, with body supported
Tonic neck response	Leg extends on side of head direction, flexion occurs in opposite arm and leg

Table 25.4 Developmental milestones in infancy

Months	Milestones
0–2	Infant can lift and turn its head when lying on its back Cannot support the head upright when held in a sitting position Has fistled hands and flexed arms
3–4	Can track objects and discriminate objects from backgrounds with minimal contrast Can sit, with support, and keep the head up. Can raise upper torso and head when prone Hand and feet actions start to come under willed control and reflexes have disappeared, or are in the process of so doing
5–6	Begins to grasp objects using ulnar–palmar grasp Rolls from supine to prone position and starts to sit alone, without support, for short periods
6–9	May pull self into standing position while holding on to furniture; can walk while holding the hand of an adult Able to sit steadily without support, for long periods Learns to sit down from standing position
9–12	Begins to balance while standing alone Takes steps and begins to walk alone Says ‘mum’ and ‘dad’

walking), fine motor (e.g. holding a spoon, pincer grasp), sensory, language and social development. There are several recognized ‘milestones’ in development, as shown in Table 25.4.

Children from 1 year (pre-school children)

Development proceeds with gross motor development recognized by milestones (Table 25.5), as the child becomes able to stand alone, stoop, pick something up and recover to standing (toddler). Young children strive constantly for independence, creating not only special safety concerns, but also discipline challenges.

Children aged 5–12 years (schoolchildren)

School-age children typically have fairly good gross motor skills, but there is wide variance in coordination, endurance, balance, physical tolerance and fine motor skills. They are usually able to use simple, complete, short sentences consistently. Receptive language skills necessary to understand long or complex instructions and the use of increasingly complex sentences develop. Delayed language development may indicate hearing or learning impairment. The attention span increases from about 15 minutes in 5-year-olds to about an hour by the

Table 25.5 Developmental milestones in early (pre-school) childhood

Months	Milestones
14–15	Child is walking well by 14 months and learns to walk backwards and up steps Begins to scribble and can place a block in a cup and begin to stack blocks Can use 2–3 words (other than mum or dad)
16–18	Able to kick a ball forward; at about 18–24 months is able to throw ball overhand Can combine two words
22–24	Can jump Can often state their name Able to point to named body parts and to name pictures of items and animals

age of 10. By about 10 years old, most children can follow five commands in a row. Reduced attention may herald attention deficiency.

Puberty

Puberty refers to the physical and psychological changes during maturation into an adult capable of reproduction. Manifest by the development of secondary sexual characteristics, it begins between 9 and 16 years of age, but children vary as to exactly when. On average, girls enter puberty 2 years earlier than boys.

The hypothalamus and pituitary gland hormones that control growth and maturation trigger rapid growth at puberty, with increases in height and weight, the appearance of secondary sexual characteristics and increased sexual interest (‘sex drive’). Oil glands become more active and acne may appear. Sweat glands become more active and produce more of an odour.

In girls, the ovaries begin to increase oestrogen production (along with other ‘female’ hormones). Girls experience rapid growth in height and increased hip width, breast enlargement, pubic, axillary and leg hair growth and vaginal secretions, followed by the onset of menstrual periods (menarche). The ovaries begin to release ova that, over 3 or 4 days, travel along Fallopian tubes to the uterus. Meanwhile, the endometrium (uterine lining) thickens by filling with blood and fluid. If the ovum is not fertilized, it dissolves and the endometrium sloughs, causing menstruation (menses). Menstrual cycles occur over about 1 month (28–32 days) and may be irregular initially. There may also be cyclical hormonal and physical changes, such as emotional or depressive reactions – the premenstrual syndrome (PMS) – and cramping menstrual pain. In girls, full physical maturation is usually complete by age 17, but educational and emotional maturity is ongoing.

In boys, the testicles increase testosterone production so that puberty usually occurs between 13 and 15 years of age. The pubescent boy experiences accelerated growth, especially in height, shoulder width and growth of penis and testicles, voice changes and growth of pubic, beard and axillary hair. Sperm is manufactured constantly in the testes (a process termed spermatogenesis) and is stored in the epididymis. This is released following masturbation or sexual intercourse, or during sleep – when it is known as a nocturnal emission or a ‘wet dream’.

Adolescence

Adolescence refers to the transition from child to adult, between 13 and 19 years of age. As well as sexual maturation, there are psychological changes resulting in emotional, behavioural and social changes. Specific health concerns for this age group are shown in Box 25.1.

Box 25.1 Adolescents: health concerns

- Accidental injuries (leading cause of death [70%] from motor vehicle accidents, drowning or poisoning [usually drug- or alcohol-related])
- Unlawful killing, often gang-related (second leading cause of death)
- Suicide (third leading cause of death)
- Substance abuse
- Stress, depression, eating disorders
- Sexually transmitted diseases
- Pregnancy
- Assaults (gang-related)

Table 25.6 Drugs that may be contraindicated in children

Drug contraindicated	Possibility of
Antidepressants	Suicide attempts
Aspirin (salicylates)	Reye syndrome
Codeine	Respiratory depression
Diazepam	Paradoxical reactions
Kaopectate	Reye syndrome
Promethazine	Drowsiness and respiratory depression
Propofol	Propofol syndrome
Tetracyclines	Tooth discolouration

General management

Children rely on parents for protection from harm and for discipline. Accidents are the major cause of morbidity and mortality; children are at increased risk because of a need for strenuous physical activity, a desire for peer approval and increased adventurous behaviour. Continued emphasis upon wearing seatbelts remains the single intervention most capable of preventing major injury or death due to a motor vehicle accident. Children should be taught to play sports in appropriate, safe and supervised areas, with proper equipment and rules, and with safety equipment (such as a bicycle helmet and other safety helmets; knee, elbow, wrist pads/braces, etc.; Chs 24 and 33). Safety instructions regarding contact sports, vehicle use, swimming and water sports, matches, fires, lighters and cooking are important to prevent accidents.

Dental aspects

Care of children is discussed fully in textbooks of paediatric dentistry. Important issues include consent; the treatment of trauma, caries and malocclusion; and issues related to anaesthesia and sedation.

Informed consent can be difficult to ensure in children too young to understand but conversely may be possible in some children under age 16 (Gillick competence). Children may present behavioural challenges in dental treatment; relative analgesia and local anaesthesia (LA) may be difficult or impossible to administer to some. Some drugs are contraindicated in childhood (Table 25.6). Children may also have some unusual reactions to drugs, such as diazepam and intravenous anaesthetics.

Drug doses should be checked in the paediatric *British National Formulary* or equivalent, and adjusted for weight as necessary. Drug doses must be lowered for children and sugar-free preparations used.

After the eruption of the teeth, drugs that cause hyposalivation and procedures such as radiotherapy involving the salivary glands predispose to caries, especially in children. Preventive dental care and dietary counselling are of crucial importance.

**Fig. 25.1** Child non-abuse injuries.

Lengthening survival rates of premature infants have revealed several long-term sequelae, including orofacial defects. Some 20–55% have enamel hypoplasia, compared with 2% of controls, caused by birth trauma, infections and metabolic or nutritional disorders. Calcium disturbances are also common. Laryngoscopy can damage the unerupted maxillary anterior teeth and intubation with an oropharyngeal tube can cause grooving of the anterior maxillary ridge. The latter has few serious consequences.

Disturbed orofacial development can result from a range of causes in childhood, including radiotherapy, chemotherapy, drugs, infections or toxins. Disturbed odontogenesis can have similar causes. Children may also be the subjects of abuse, resulting in orofacial and other injuries.

CHILD ABUSE (BATTERED CHILD SYNDROME; NON-ACCIDENTAL INJURY, NAI)

General aspects of abuse are also discussed in Chapter 24.

General aspects

Up to 50% of children sustain injuries to their mouth by the time they leave school – mostly from accidents. The head and face are also the areas most commonly affected in physical abuse, however; they are involved in 65% of cases (Figs 25.1 and 25.2).

Remember
Concerns are raised by:

- injuries to both sides of the body
- injuries to soft tissue
- injuries with particular patterns
- any injury that doesn't fit the explanation
- delays in presentation
- untreated injuries

Fig. 25.2 Child abuse injuries.

Child abuse is any act of omission or commission that endangers or impairs the physical or emotional health or development of a child. The threshold beyond which actions or omissions become abusive or neglectful is, to a certain extent, socially and culturally defined. A child is considered to be abused if he or she is treated in a way that is unacceptable in a given culture at a given time. For example, physical punishment of children has become progressively less acceptable in the UK.

Abuse and neglect are described in four categories, as defined in the UK Department of Health's document 'Working Together to Safeguard Children'; these are physical abuse, emotional abuse, sexual abuse and neglect. Some level of emotional abuse is involved in all types of ill-treatment of a child, though it may occur alone. Physical abuse may involve hitting, shaking, throwing, poisoning, burning or scalding, drowning, suffocating or otherwise causing physical harm to a child. Physical harm may also be caused when a parent or carer fabricates the symptoms of, or deliberately causes, illness in a child.

Abused children are usually below 1 year of age; most are less than 3. The injuries are usually inflicted by an adult, usually a parent, parent's partner or an older sibling, and affected families are predominantly of socioeconomic classes IV and V. Causal factors may be related either to the parent, to social factors or to the child – and often all three (Table 25.7). Young or single parents, parents with learning difficulties, those who themselves have experienced adverse childhoods and those with mental health problems (including drug or alcohol abuse) are all more at risk of abusing their children. The assaulter may be supported by an

Table 25.7 Non-accidental injury: associated factors

Parental	Social	Child
Marital disharmony	Poor housing	Abnormal pregnancy or delivery
Emotionally deprived, abused themselves	Poverty	Neonatal separation
Chronic physical illness	Social isolation	Being unwanted
Low intelligence		Hyperactivity, illness or aggression
Young age or single parents		Being a stepchild
Drug/alcohol dependence		Age below 1 year
Mental disorders		

Box 25.2 Findings suggestive of non-accidental injury

- Cowed child
- Long interval before attendance for treatment
- Evidence of previous injury (or a previous history of injury)
- Injuries often committed at night
- Multiple injuries incompatible with history at unusual sites

inactive partner. Families living in adverse social environments – for example, due to poverty, social isolation or poor housing – may also find it both materially and socially harder to care for their children.

Children with disabilities are much more at risk of experiencing abuse of all kinds.

Clinical features

Recognition of child abuse is important since there is a very high risk of further assaults on, or death of, the child and of siblings; some 35–60% of physically abused children suffer further injury, with a 5–10% mortality rate. The child who has been subjected to abuse is often cowed, and may also be malnourished and generally neglected; there may be evidence of previous trauma. Psychological trauma from abuse can result in sleep disturbances, eating disorders, developmental growth failure in young children, and nervous habits such as lip- and fingernail-biting and thumb-sucking. Effects may also include chronic underachievement at school and poor peer relationships. In abusive families, physical neglect is commonplace, with inadequate provision of basic needs, including medical and oral health care; there may well be delay in seeking care (Box 25.2). Some suffer significant neurological, intellectual or emotional damage.

The injuries in child abuse can be varied and are often multiple, including bite marks (Ch. 24), bruises, black eyes, torn frenulum, hair loss, laceration, wheals, ligature marks, marks from a gag, burns and scalds, often from cigarettes or demarcated from other objects. Lacerations of the upper labial mucosa and tearing of the lip from the gingiva are found in about 45% of victims but are not diagnostic of child abuse.

Teeth may be devitalized, broken or lost. Bone fractures are common – mainly affecting ribs or long bones – but the skull and jaws can also be fractured. Head injuries are the commonest cause of death in abused children.

General management

After genuine accidents, children are usually taken immediately for medical or dental attention but, when children are abused, there is

often considerable delay. Child abuse should also be suspected if any injuries are incompatible with the history and if any of the features in Box 25.2 are noted. Health-care professionals are obliged to know and follow the local child protection procedures (<http://www.cpd.t.org.uk/>; accessed 30 September 2013). Full records must be kept. The child must be examined fully and immediately to exclude serious injury, especially subdural haematomas or intraocular bleeding, and must therefore be admitted to hospital. A skeletal radiographic survey should be undertaken to reveal both new and old injuries (osteogenesis imperfecta may need to be excluded). All injuries, including those to facial and oral tissues, must be carefully recorded, preferably with photographs.

Patients should be kept in hospital until the diagnosis is confirmed, since there is a high risk of further injury, which may be fatal. A paediatrician should be consulted and the general medical practitioner, social services and a child protection agency must be involved early on, but strict confidentiality must be observed. Social services departments keep registers of non-accidental injuries, which help identify known offenders. The child may already be on the ‘at-risk’ register. Dentists should also inform their medical defence society, as there may later be legal involvement.

Dental aspects

Orofacial lesions are common. Abuse or neglect may present in a number of different ways, such as through a direct allegation (sometimes termed a ‘disclosure’) made by the child, a parent or some other person; signs and symptoms that are suggestive of physical abuse or neglect; or observations of child behaviour or parent–child interaction.

SEXUAL ABUSE

Sexual abuse can take many forms but, in addition to physical and psychological injury, the victim may also acquire one or more sexually transmitted infection, including human immunodeficiency virus (HIV).

EMOTIONAL ABUSE

Emotional abuse is more difficult to define and prove, but can manifest as development delay, failure to thrive, a watchful ‘radar’ gaze, behavioural problems and limited attention span.

SELF-INFLICTED (FACTITIOUS) ORAL LESIONS

See Chapter 10.

OLDER PEOPLE

General aspects

Older people now account for some 15% of the UK population and this is set to increase. A growing proportion of the population, especially in developed countries, is over the age of 65 (a chronological criterion of ‘elderly’), with a rise in the proportion of older females, a significant number of whom are single (Fig. 25.3).

Many older people enjoy *le troisième âge* but, over the years, they are increasingly likely to need health care (Table 25.8). Up to 75% have one or more chronic diseases (30% have more than three), 11% are housebound, 8% walk with difficulty and some 3% are bedridden. Mobility is one of

Fig. 25.3 The grey age (*le troisième âge*).

Table 25.8 Approximate number of years that older people are likely to be free from disability		
Age group	Men	Women
65–69	9	11
70–74	7	9
75–79	5	7
80–84	3	5
85+	1	3

Fig. 25.4 Walking aids.

the major issues, and walking aids such as sticks, crutches and frames are commonly needed (Figs 25.4 and 25.5). Problems may be compounded if older people are from non-dominant populations (Fig. 25.6; see also Ch. 30). In the case of many older individuals, history taking can take considerable time; partners or care-givers may be able to help.

Medical problems

Many older patients have difficulty in accessing health care and some are reluctant to seek attention, especially if they fear consequent hospitalization. There is a greater incidence and severity of many diseases, especially arthritis and cerebrovascular disease, and these may cause ataxia and falls (Table 25.9). Alcohol related problems, mechanical and motor problems are important causes leading to falls among the elderly. Fractures and bruising may result, and senile purpura is common in many older people (Fig. 25.7). Defects of hearing or sight increase the liability to accidents, feelings of isolation and reduction of independence. The eyes may also show an arcus senilis (Fig. 25.8). Common causes of ataxia, faints and falls are visual impairment, transient cerebral ischaemic attacks, parkinsonism, postural hypotension (often drug-related), cardiac arrhythmias or ischaemic heart disease. Cancers are more common at advanced ages.

Fig. 25.5 Walking aids: frame.

Atypical symptomatology is common; physical disease may present in a less florid and dramatic way in older people. Temperature regulation may be so disturbed that respiratory, urinary or even more serious infections often fail to cause fever. Older patients also readily become hypothermic, especially if thyroid function is poor. Many disorders in older patients also present with non-specific features, such as general malaise, social incompetence, a tendency to fall and mild amnesia. Dementia becomes increasingly common with age. If responses are slow, it may be caused by underlying physical disease, especially if the

Fig. 25.6 Old age and culture.

Table 25.9 Diseases especially affecting the older person ^a					
Blood and others	Cardiorespiratory	Genitourinary	Musculoskeletal	Neurological and psychiatric	Oral or predominantly oral
Accidents	Cardiac failure	Prostatic hypertrophy and cancer	Osteoarthritis	Acute confusional states	Atypical facial pain
Anaemia (especially pernicious anaemia)	Chronic bronchitis and emphysema	Renal failure Urinary retention or incontinence	Osteoporosis	Alzheimer disease	Candidosis (denture-induced stomatitis and angular stomatitis)
Cancer	Hypertension Ischaemic heart disease		Paget disease	Ataxia	Carcinoma
Chronic leukaemia	Pneumonia			Dependence on hypnotics	Herpes zoster and post-herpetic neuralgia
Myelodysplasia	Temporal arteritis			Insomnia	Lichen planus
Nutritional deficiencies				Loneliness and depression	Mucous membrane pemphigoid
					Pre-malignant lesions
				Multi-infarct (cerebrovascular) dementia	Sjögren syndrome
				Paranoia	Sore tongue
				Parkinson disease or parkinsonism	Trigeminal neuralgia
				Strokes	
				Visual impairment	

^aMultiple conditions are common.

symptoms are of acute onset. A confusional state may result acutely from disorders as widely different as minor cerebrovascular accidents, respiratory or urinary tract infections, or left ventricular failure. Confusional states may be more chronic when caused by poorly controlled diabetes mellitus, hypothyroidism, carcinomatosis, anaemia, uraemia or drug therapy.

Social disabilities are common as a result of such causes as loss of the spouse, isolation from family, poverty, and lack of mobility and independence. Old people may need to be thrifty and careful with food purchasing and the heating of their accommodation, contributing to overall self-neglect. Nutrition may also be defective due to apathy, mental disease or dental defects. Malnutrition may, in turn, lead to poor tissue healing and predispose to ill-health. Deterioration in the senses of smell and taste may also result in a poor or unhealthy diet. Psychological disorders, such as loneliness and depression, may follow. Depression may also be a feature in hypothyroidism or a side-effect of medications.

Older people are more likely to be given medication and complications account for about 10% of admissions to geriatric units. Polypharmacy, abnormal reactivity towards many drugs, poor compliance, inappropriate treatment and deteriorating renal and other metabolic pathways affecting drug metabolism can result in toxicity and serious interactions. Older people tend to be more liable to adverse drug reactions, and the reactions tend to be more serious and last longer than in younger people.

Drugs may also precipitate or aggravate physical disorders that are more frequent in the older person. For example, drugs with antimuscarinic activity, such as atropine or antidepressants, may precipitate glaucoma, or may cause dry mouth or, if there is prostatic enlargement,

urinary retention. Phenothiazines may precipitate or aggravate parkinsonism or hypotension, or may cause apathy, hypothermia, excessive sedation or confusion. Drowsiness, excessive sedation or confusional states may also be provoked by the benzodiazepines or tricyclic antidepressants, while depression and postural hypotension not uncommonly follow the use of hypotensive agents. Drugs should therefore be used cautiously (Table 25.10).

The capacity to carry out activities of ordinary life (dressing, eating, bathing, etc.) is assessed with specific tests: for example, the activities of daily living scale (ADLS) or Katz; based on this assessment, the older person is classified as functionally independent or dependent.

General management

Social support is crucial, preserving as much independence and dignity as possible.

Dental aspects

Many older people receive no dental attention whatsoever, despite much evidence of their need. It has been found in one study, for example, that 81% had oral lesions and 20% needed further investigation to exclude serious oral disease. Access to dental care can be a major difficulty for the person who is frail or has limited mobility. Handling of older patients may demand immense patience, but remember always to treat the older patient with sympathy and respect. It can take a long time for a patient in a wheelchair or using a Zimmer frame to get into the surgery and on to the dental chair. Domiciliary care may be more appropriate and avoids the physical and psychological problems of a hospital or clinic visit. Older people are often extremely anxious about treatment and should therefore be sympathetically reassured and, if necessary, sedated.

Mucosal lesions may be present in up to 40% of older people. Most of these are fibrous lumps or ulcers, but a minority are potentially or actually malignant lesions. Oral cancer is mainly a problem of older people and is a further reason for regular oral examination (Ch. 22). Atypical facial pain (often related to depressive illness), migraine, trigeminal neuralgia, zoster and oral dysaesthesias are more common as age advances.

Many older people with remaining teeth have periodontal disease. Dental caries are usually less acute but root caries are more common. Caries may become active if there is hyposalivation, especially if there is overindulgence in sweet foods. Hyposalivation is even more likely with medications such as neuroleptics or antidepressants (Ch. 10). Poor salivation may contribute to a high prevalence of root caries and oral candidiasis, which especially affect hospitalized patients.

Fig. 25.7 Senile purpura.

Fig. 25.8 Arcus senilis (corneal arcus).

Table 25.10 Drug use in the older person

	Problems	Possible solutions
Analgesics	Sensitivity to their effects	Restrict dose
Dosage regimens	Difficulties remembering regimens	Simplify regimens and write clear instructions; use dosette boxes
Drug dose	Overdose from sensitivity to agents	Restrict dose
Form of medicine	Difficulty swallowing tablets	Take with water or use liquid preparations
Non-prescribed drugs	Self-medication without medical advice	Restrict drug availability
Psychotropics	Sensitivity to their effects	Restrict dose

Very many older patients are edentulous and some problems of dental management are thereby greatly reduced. It seems, however, that the proportion of edentulous older patients is gradually falling and, as a consequence, more of them need restorative dentistry or surgery of various types. Many edentulous older people have little alveolar bone to support dentures, and have a dry mouth as well as frail, atrophic mucosa. Implants may be helpful. Inability to cope with dentures, or a sore mouth for any reason, or being unable to afford appropriate care readily demoralizes the older patient, and may tip the balance between health and disease.

Food can become tasteless and unappetizing as the result of declining taste and smell perception. Older patients should be encouraged to add seasonings to their food instead of relying on excessive consumption of salt and sugar to provide flavour.

The dentist therefore has an important role in supporting morale and contributing to adequate nutrition. Handling of older patients may demand increased time and patience.

Sound teeth should be conserved if they can serve, at least for a few years, as abutments or retainers for prostheses. It may also be unwise to alter the shape or occlusion of dentures radically when they have been worn for years. It is wise to label the dentures with the name of the patient, particularly for those living in sheltered or other residential accommodation, as dentures can easily be mislaid or mixed up between patients.

Attrition and brittleness of the teeth may complicate treatment, and it may be necessary to provide cuspal coverage in complex or large restorations. Endodontic therapy may be more difficult in view of secondary dentine deposition. Hypercementosis, brittle dentine, low bone elasticity and impaired tissue healing may also complicate surgical procedures.

The major goals of oral health care are preventive and conservative treatment for conditions such as hyposalivation, root caries, secondary caries, periodontal disease and gingival recession, and the elimination/avoidance of pain and oral infections.

Independent people with no serious medical problems may be treated in primary dental care. Dependent people may need domiciliary dental care with portable dental equipment. When significant medical problems are present, the older person may be best seen in a hospital environment, though this raises issues of adequate transportation and availability of escorts.

Prevention is of paramount importance in caring for older adults. Therefore, the most important considerations for dental professionals are how well the patient has compensated for his or her medical problem and the exact dental intervention needed. Non-invasive procedures in patients with minimal incapacity carry less risk than do surgical procedures. Older people tend to be more sensitive to drugs and to trauma. Dental treatment planning may be conditioned by factors such as oral health status, capacity to move, motor and mental skills to follow a preventive programme, survival prognosis and economic resources. The whole range of dental treatments may be considered. Dental implants are not at all contraindicated, and they may help to maintain the remaining alveolar bone.

Appointment times may be conditioned by systemic diseases. Sympathetic reassurance is indicated and, if necessary, sedation, with short-acting benzodiazepines. Treatment is often best carried out with the patient sitting upright, as few like reclining for treatment and some may become breathless and panic. Dentists should recognize that older people, especially women, also heal slowly and bruise readily if tissues are not handled carefully.

To control pain and anxiety, dentists should use LA whenever possible, since the risks of using general anaesthesia (GA) are greater than

Box 25.3 Elder abuse

- Most abuse is perpetrated against people who are over the age of 70
- Two-thirds of abuse is committed at home
- In nearly a half, two types of abuse occur simultaneously
- In one-third of cases, the abuse is perpetrated by more than one person
- Only rarely is the abuser the main family carer
- 46% of abusers are related to the person they are abusing; a quarter of those who are abusers are sons or daughters
- Staff in care homes or visiting carers may also abuse

in younger patients. LA used in recommended dosages has no effect on cardiac arrhythmias in the ambulatory older patient. Intravenous sedation in the dental chair is best avoided if there is any evidence of cerebrovascular disease, as a hypotensive episode may cause cerebral ischaemia. The risks of conscious sedation (CS) or GA are greater than in the young patient, not least because of associated medical problems. Relative analgesia is preferable to benzodiazepines for sedation, and benzodiazepines are preferable to opioids. GA may be necessary for patients unable to cooperate and those with dementia. After long operations, older patients are prone to pulmonary complications, such as atelectasis, deep vein thrombosis and pulmonary embolism; they may also become confused in an unfamiliar environment.

Polypharmacy should be avoided, not only because of the danger of drug interactions but also because of the practical difficulties that the patient may have in taking the correct doses at the correct times. Older people frequently have difficulties in understanding the medication and in remembering to keep to a regimen. Compliance may therefore be lacking. If there is hepatic or renal disease likely to impair drug metabolism or excretion, drug dosage must be reduced appropriately.

ABUSE OF OLDER PEOPLE

Elder abuse occurs when an older person is harmed, mistreated or neglected (see also Ch. 24). There are five types of elder abuse: psychological abuse, physical abuse, financial abuse, sexual abuse and neglect (Box 25.3).

People who are being abused are often scared that they will not be believed. Those who witness or suspect abuse may not want to be seen as 'interfering' or may be scared of 'getting it wrong'. If abuse is suspected, always talk to the 'victim' first and tell them what you want to do. The main charitable and government-sponsored organizations that can offer support to those affected include police, hospitals, general medical practitioners, carer organizations, social services/social work departments, and social care inspection bodies. Be clear about whether the person knows you are reporting your concerns; whether the older person is confused or lacks the capacity to make informed decisions about their life; who you think is being abused (name, address, age); and what you think is happening to that person. Give reasons/examples to illustrate why you think abuse is occurring. It helps if you can provide dates and times of incidents; what has been said; who you believe is responsible; and the relationship of that person with the older person.

See <http://www.ageuk.org.uk/> (accessed 30 September 2013).

FACIAL COSMETIC PROCEDURES

Cosmetic facial procedures are increasingly used by both genders and include injections of botulinum toxoid (Ch. 13); removal of unsightly skin lesions; laser resurfacing; chemical peeling; or orthognathic

Table 25.11 Facial cosmetic procedures other than use of orthognathic surgery or botulinum toxoid

Common terminology	Alternative terminology	Intended outcomes	Comments
Brow lift	Forehead lift	Eliminate stern or furrowed brows	Multiple incisions within hairline or single incision in upper eyelids. Alternatively a wide incision across top of scalp
Ear surgery	Ear pinning or otoplasty	Correct protruding or deformed ears	–
Eyelid surgery	Blepharoplasty	Eliminate tired or droopy eyelids	Incision within upper eyelid
Face lift	Rhytidectomy	Eliminate facial signs of ageing, including wrinkles and sagging skin	Incisions within hairline, above temple and continued along or just inside ear, ending behind ear. A second incision beneath chin is sometimes necessary
Facial augmentation	Injectable fillers (see Table 25.12)	Change facial contours, lines and creases	Pharmaceutical filler or patient’s own fat is injected below skin
Facial implants	–	Used most commonly in the cheek, chin, jaw or nasal region to change facial contours	Polyethylene ^a , e- polytetrafluoroethylene (PTFE) ^a , silicone ^a , hydroxyapatite ^a , collagen or injectables used. Incisions, if needed, are placed inside mouth or discreetly externally
Rhinoplasty	Nasal reshaping or nose job	Correct deviated septum, bump on the bridge, wide nostrils, bulbous tip or hooked nose	Incisions at nostril base and/or inside nose

^aUsually non-resorbable.

surgery – and a range of other procedures, some of which are shown in Table 25.11. These are often performed as outpatient procedures under local anesthesia with or without sedation but general anaesthesia may be used. Outcomes may include pain, swelling, bleeding and bruising and infection. The resultant changes in appearance typically persist for months or sometimes years, notably where non-resorbable materials have been used. More worrying are the do-it-yourself “cosmetic” procedures becoming popular for example in Korea.

Fillers

Injectable fillers are an increasingly popular cosmetic procedure. Results are temporary, lasting a few months with natural products to several years when synthetic materials are used. Complications may include temporary pain, bleeding, bruising, swelling, seromas (fluid collections), infection or allergy; mainly with synthetic materials such as silicone, long-term granulomas/disfigurement are also possible. However, the existence of a so-called silicone immune toxicity syndrome is controversial.

The US Food and Drug Administration (FDA) reviews and approves pharmaceutical fillers in the same manner as medical devices. However, some fillers may be used on an off-label basis and injection of permanent substances (e.g. silicone) in particular poses safety issues such as granuloma formation (Table 25.12).

MEN’S HEALTH

The male genitals include the testes, vas deferens, epididymis and penis, together with accessory structures – the prostate and bulbourethral glands. The testes, located in the scrotum, produce sperm cells and the hormone testosterone, which influences development of body shape and hair, and regulates spermatogenesis. The anatomy of the male genital system is shown in Figure 25.9. Disorders of the gonads are outside the remit of this text.

There are some conditions that affect only men and there are gender differences in regard to patterns of many diseases (Box 25.4). Men generally also access and use health care differently from women (typically less); generally, they are less likely to react to health promotion and are more likely to have lifestyle habits that are detrimental to their health (e.g. alcohol or drug abuse).

Table 25.12 Some fillers

Origin	Material	Source
Natural	Collagen	Human or bovine natural skin protein
	Fat (free fat transfer, autologous fat transfer/transplantation, liposculpture, lipostructure micro-lipoinjection)	Human – typically from inner thigh or abdomen
	Hyaluronic acid	Human or animal
	Hydroxyapatite	Mineral suspended in a gel-like formulation
Synthetic ^a	Polyacrylamide	Hydrophilic polyacrylamide gel (HPG)
	Poly-L-lactic acid	
	Polymethylmethacrylate (PMMA)	20–25% PMMA microspheres in collagen gel
	Silicone	Dimethylsiloxane

^aUsually non-resorbable.

Fig. 25.9 Male genital anatomy.

BALANITIS (BALANOPOSTHITIS)

Balanitis is inflammation of the skin covering the glans penis. The most common cause is neglected hygiene and tight foreskin (phimosis), leading to irritation by smegma, but less common causes are shown in Box 25.5. Treatment depends on the underlying cause.

Box 25.4 Health problems that are generally more common in men

- Alcoholism
- Balanitis
- Bladder:
 - Stones
 - Cancer
- Drug abuse and addiction
- Hydrocoele and varicocele
- Orchitis and epididymitis
- Peyronie disease
- Phimosis and paraphimosis
- Prostate:
 - Prostatitis
 - Benign prostatic hyperplasia
 - Cancer
- Snoring and obstructive sleep apnoea
- Testicular:
 - Torsion
 - Cancer
- Tinea
- Trauma

Box 25.5 Causes of balanitis

- Balanitis circinata (Reiter syndrome)
- Candidiasis
- Contact allergy (e.g. to latex)
- Diabetes
- Lichen sclerosis (balanitis xerotica obliterans; BXO)
- Seborrhoeic dermatitis and other skin diseases (e.g. lichen planus, psoriasis, erythema multiforme, erythroplasia of Queyrat – a rare, pre-cancerous skin condition)

BLADDER PROBLEMS

Urine passes from each kidney through the ureter to be stored in the bladder (Ch. 12). An outer muscle layer surrounds the bladder inner lining, which is made up of a uniform transitional epithelium resting on a thin basal lamina. When the bladder is full, the muscles can tighten to allow urination via the urethra.

Bladder stones**General aspects**

Bladder stones are common in men, especially in those over 45. They can form in healthy individuals for no apparent reason. Bladder stones can also develop in gout or urinary infections, or if urine stagnates in the bladder as in prostatic hypertrophy. Most are formed of calcium, from excess salt in the urine (or too little water). Most bladder stones form within the bladder, but a few form in the kidneys and then travel to the bladder, causing acute pain or colic *en route* in the ureter.

Clinical features

Bladder stones may be symptomless, or cause frequency and urgency of micturition, pain when urinating or blood in the urine (haematuria). Problems arise when stones become too large to be flushed out during urination, particularly if they become trapped in the urethra, when they cause pain (dysuria) and difficulty passing urine. If left

untreated, bladder stones can irritate the muscles of the bladder wall and lead to incontinence.

General management

Diagnosis is confirmed by ultrasound, intravenous urography or cystoscopy. Bladder stones usually need to be broken down during cystoscopy or by lithotripsy in order to flush them out.

Bladder cancer**General aspects**

Bladder cancer is the fourth most common cancer in males and incidence is increasing; 90% are transitional cell and 8% are squamous cell carcinomas. Risk factors for bladder cancer include older age, male sex (men are 2–3 times more predisposed than women), a positive family history, and race (Caucasians are twice as frequently affected as Africans, with lowest rates in Asians). Important causes are carcinogens concentrated in the bladder – from cigarette smoking (raises risk by 2–3 times) or occupation (e.g. workers in rubber, chemical, leather, metal, print and textile industries, or hairdressers, machinists, painters or truck drivers), or from treatment with cyclophosphamide or arsenic. Infections – particularly schistosomiasis – may occasionally be implicated (Ch. 21). Factors *not proven* to play a role in the aetiology include coffee, chlorine in drinking water and saccharine, the sweetener that, in large doses, causes bladder cancer in animals.

Clinical features

The most common presentation is painless haematuria, but dysuria, urgency, polyuria and/or urinary obstruction may be seen. Such symptoms are also common in prostatic hyperplasia and carcinoma. Bladder cancer can invade to involve nearby organs such as the prostate (or uterus/vagina) and can metastasize to regional lymph nodes and to lungs, liver or bones.

General management

Malignant cells may be seen on urine cytology; intravenous urography may show a filling defect but cystoscopy and biopsy give the definitive diagnosis. Surgery is the common treatment; other options include transurethral resection (TUR) for superficial cancer, segmental cystectomy for localized cancer and radical cystectomy for more widespread disease. Radiation, intravesical chemotherapy or immunotherapy using intravesical bacille Calmette–Guérin (BCG) may also be used.

Dental aspects

Metastases may involve the jaws. Chemotherapy may cause mucositis.

CIRCUMCISION

Circumcision, a surgical procedure that involves partial or complete removal of the foreskin (prepuce), is a feature of both Judaism and Islam, and many African and New World cultures. About one-fifth of men worldwide have been circumcised, commonly soon after birth or at puberty. Circumcision may also be carried out for medical reasons, such as balanitis, phimosis or paraphimosis (when the foreskin forms a tight tourniquet around the glans, causing pain). Sexually transmitted infections that cause genital ulcers (syphilis, chancroid, herpes simplex) are more common in uncircumcised men. However, penile warts and urethritis are more common in circumcised men. Poor personal hygiene,

smoking and exposure to human papillomavirus (HPV) are risk factors for penile cancer and that risk is not reduced by circumcision, but it does appear to reduce the risk of cervical cancer in women. Candidosis is equally common in circumcised and uncircumcised men. Views conflict as to whether circumcision can significantly reduce HIV transmission.

HYDROCOELE

A hydrocoele is an accumulation of fluid around the testis. Diagnosis is confirmed by transillumination and ultrasound. Most hydrocoeles in children resolve spontaneously and rarely cause discomfort. Most hydrocoeles in adults are persistent and therefore are usually managed by draining the fluid under LA, introducing a sclerosing agent to prevent recurrence. Alternatively, the hydrocoele can be removed surgically.

IRRITABLE MALE SYNDROME

Irritable male syndrome (IMS), sometimes called Padam or Del syndrome or late-onset hypogonadism (LOH), is a state of hypersensitivity, anxiety, frustration, and anger that occurs in older males ("grumpy old men"). It appears to be associated with changes in biochemistry, endocrines ("andropause"), stress, and identity. Testosterone substitution may be indicated but lacks controlled clinical trials on efficacy and safety.

ORCHITIS AND EPIDIDYMITIS

Sperm and hormones are produced in the testes and stored in the epididymis before being conveyed to the spermatic ducts (see Fig. 25.9).

Orchitis is an inflammation of testicular tissue. The mumps virus is a common cause. Orchitis causes pain in the scrotum (which may become hot and swollen) and fever; it can also result in infertility. Treatment is bed rest, a suspensory bandage and analgesics. All children are offered mumps vaccination when they are 12–15 months old.

Epididymitis is far more common than orchitis and usually arises from a bacterial urinary infection. Coliforms, pyogenic staphylococci and faecal streptococci are most often responsible, but infection may also be caused by *Chlamydia* or gonorrhoea; in many cases, no organism is identifiable. Symptoms may include fever and a hot, red and painful scrotal swelling; dysuria and frequency may be present. Bed rest, analgesics and antibiotics are indicated.

PEYRONIE DISEASE

This is the slowly progressive development of fibrous plaques around the corpora cavernosa of the penis, which mainly affects young adults and is of unknown aetiology. It causes bending to the affected side on erection. The condition may resolve but otherwise may require surgery.

PROSTATE DISORDERS

Prostatitis

Prostatitis is the most common prostate disease and accounts for up to 25% of all visits to general practitioners by young and middle-aged men with genitourinary symptoms. The types are shown in Table 25.13.

Prostatic hyperplasia

General aspects

The prostate almost invariably enlarges with age (benign prostatic hyperplasia or hypertrophy; BPH), possibly related to oestrogen or dihydrotestosterone (DHT) production, so that at least 50% of men in their sixties and as many as 90% in their seventies and above have symptoms.

Table 25.13 Prostatitis

Type	Comments	Therapy
Acute bacterial prostatitis	Fever, pain in the lower back and genital area, urinary frequency and urgency – often at night, burning or painful urination, and urinary infection	Antibiotics
Chronic bacterial prostatitis	Uncommon. Associated with an underlying prostatic defect, forming a focus for infection	Removal of the defect and use of antibiotics
Chronic prostatitis/chronic pelvic pain syndrome	In the inflammatory form, urine and semen contain leukocytes but no bacteria; in the non-inflammatory form, no evidence of inflammation is found	Antibiotics
Asymptomatic inflammatory prostatitis	Semen contains leukocytes	–

Clinical features

An enlarging prostate constricts the urethra, causing a hesitant, interrupted or weak urine stream. The bladder hypertrophies and then begins to contract, even when it contains little urine, causing urgency, frequency, nocturia and leaking or dribbling. Urinary infections are also more common. The bladder may become distended and atonic, leading to overflow incontinence. Sustained raised intravesical pressure can cause hydronephrosis and renal damage. Acute urinary retention can be precipitated by alcohol, cold temperatures or immobility, and is an emergency.

General management

Investigations indicated may include a prostate-specific antigen (PSA) blood test and digital rectal examination (DRE), mid-stream urine (MSU), urine flow study, and blood urea and electrolytes. Cystoscopy should identify the location and degree of any obstruction and rectal ultrasound with biopsies may be indicated.

The level of PSA can rise in BPH, infection or prostate cancer, so the result should be interpreted with caution, as there is also a high rate of false positives and false negatives. Prostate cancer gene 3 (*PCA3*) is probably a more specific marker for prostate cancer (Ch. 22).

The symptoms of BPH may resolve without treatment in as many as one-third of mild cases, but if BPH causes major inconvenience or complications, treatment is recommended. Drug therapy includes finasteride or dutasteride (5-alpha-reductase inhibitors inhibit DHT production and shrink the prostate), saw palmetto (a herbal remedy possibly as effective as finasteride) or alpha-blockers (e.g. alfuzosin, doxazosin, indoramin, prazosin, tamsulosin or terazosin, which relax the prostate and bladder neck smooth muscle). Surgical treatment includes: transurethral resection of the prostate (TURP); transurethral microwave thermotherapy (TUMT); transurethral needle ablation (TUNA; delivers low-level radiofrequency energy with fewer side-effects compared with TURP); transurethral laser surgery (Nd:YAG lasers); transurethral incision of the prostate (TUIP); or open excisional surgery (prostatectomy).

Prostatic cancer

General aspects

Risk factors for prostate cancer include age (it mainly affects those over 55), family history of prostate cancer, ethnicity (more common in those of African descent), and diet and dietary factors (animal fat may

possibly increase the risk, and diets high in fruits and vegetables may lower it; Ch. 22). BPH does *not* seem to raise the chances of contracting prostate cancer.

Clinical features

Early prostate cancer usually causes no symptoms but later features can mimic BPH or infection. These can include: urinary frequency, especially at night; difficulty starting urination or holding back urine; inability to urinate; weak or interrupted urine flow; painful or burning urination; difficulty in having an erection; painful ejaculation; blood in urine or semen; or frequent pain or stiffness in the lower back, hips or upper thighs.

General management

Investigations may include PSA, urinalysis for blood or infection, and a DRE. In some cases, blood prostatic acid phosphatase or PCA3 is helpful, especially if PSA results are positive. All men over 40 should have a DRE once a year to screen for prostate cancer. If results suggest cancer, a prostate biopsy is needed.

Prostate cancer can be managed by watchful waiting, surgery, radiation, chemotherapy or hormone therapy (androgen deprivation therapy [ADT] or androgen suppression therapy). ADT aims to reduce androgens (testosterone and DHT) by: orchidectomy (removal of the testes – the main androgen source); luteinizing hormone-releasing hormone (LHRH) agonists (leuprolerin [leuprolide], goserelin, buserelin, triptorelin), which prevent the testicles from producing testosterone; LHRH antagonists (abarelix); anti-androgens (e.g. flutamide, nilutamide or bicalutamide); or drugs to inhibit adrenal androgen production (e.g. ketoconazole and aminoglutethimide).

Dental aspects

Metastases occasionally involve the jaws and are typically osteosclerotic. Cancer chemotherapy may cause mucositis and immunosuppression.

TESTICULAR PROBLEMS

Torsion

Testicular torsion usually appears in teenage boys. The testicles hang loose in the scrotum and in rare cases they are twisted, obstructing their blood flow. Torsion presents with sudden pain and swelling of the scrotum. Urgent surgery is indicated and, to prevent recurrence, testicular fixation is performed.

Testicular cancer

Testicular cancer affects younger men, particularly those between ages 20 and 40, and is more common in Caucasians than those of African heritage. Most are seminoma, others are non-seminoma – a group which includes choriocarcinoma, embryonal carcinoma, teratoma and yolk sac tumours. Risk factors may include undescended testicle and age.

Clinical features

Testicular cancer usually affects only one testicle, presenting as a swelling, discomfort or feeling of heaviness in the scrotum/testicle, dull ache in the abdomen or groin, sudden collection of fluid in the scrotum, breast enlargement or tenderness, or unexplained fatigue.

General management

Diagnosis is confirmed with ultrasound and biopsy, and staging by computed tomography (CT) scanning. Treatments include radical inguinal orchidectomy, radiotherapy (seminomas respond well) or chemotherapy (the treatment of choice for widespread disease). Chemotherapy may affect sperm production but sperm can be frozen and preserved (cryopreservation) beforehand.

Varicocoele

A varicocoele is enlargement of the veins in the scrotum. It is most common on the left-hand side and may result in scrotal heaviness or pain and impaired fertility. In some cases, an operation can increase fertility.

WOMEN'S HEALTH

The ovaries are a pair of female reproductive organs located in the pelvis, alongside the uterus. They produce ova (eggs) and female hormones (oestrogen and progesterone), which influence the development of breasts, body shape and body hair, and regulate the menstrual cycle and pregnancy. Oestrogen stimulates uterine growth and development at puberty, thickens the endometrium during the first half of the menstrual cycle, and stimulates changes in breast tissue at puberty and childbirth. Progesterone, produced during the last half of the menstrual cycle, prepares the endometrium to receive the ovum. Every month, during the menstrual cycle, an ovum is released from one ovary (ovulation) and travels through the Fallopian tube to the uterus. If the egg is fertilized, progesterone secretion continues, preventing release of additional eggs.

Women generally live longer than men; there are gender differences with regard to patterns of many diseases and some conditions that affect only women (Box 25.6).

Women generally access and use health care differently from men (typically more) and generally react positively to health promotion. There has also been discrimination against women across cultures, and subordination and compromised dignity, and women more frequently suffer the consequences of domestic violence and/or sexual abuse than men.

Certain diseases that can have orofacial manifestations are especially common in women (e.g. anorexia nervosa/bulimia, atypical facial pain, burning mouth syndrome, facial arthromyalgia [temporomandibular joint dysfunction], pemphigus and pemphigoid, rheumatoid arthritis and Sjögren syndrome).

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is a common condition due to an imbalance in the normal vaginal bacteria and is not usually a sexually transmitted infection. BV may be symptomless or characterized by a discharge with a fishy smell. It is diagnosed by microbiology and treated with oral metronidazole or with clindamycin vaginal cream.

CANCER

Breast cancer

General aspects

Other than skin cancer, breast cancer is the most common cancer among women and is more frequently found in white women than in those of African or Asian descent. The causes are not clear but most cases are seen over the age of 50, and the risk is especially high over age 60. Risk factors are shown in Box 25.7.

Box 25.6 Some of the more common problems in women

- Bacterial vaginosis
- Cancer:
 - Breast
 - Cervical
 - Ovarian
- Cystitis
- Eating disorders
- Endometriosis
- Female genital cutting
- Fibroids
- Osteoporosis
- Pregnancy-related disorders
- Menopausal disorders
- Sexual abuse

Box 25.7 Risk factors for breast cancer

- Personal history of breast cancer
- A positive family history: the risk doubles if a woman's mother or sister has had breast cancer, especially at a young age. Genes changes (*BRCA1*, *BRCA2*) increase risk (see Ch. 22)
- A diagnosis of atypical hyperplasia or lobular carcinoma *in situ* (LCIS)
- Oestrogen exposure
- Late childbearing (after about age 30)
- Early menarche
- Breast density
- Radiation therapy
- Alcohol
- A fatty diet
- Long-term use of combined oral contraceptives or hormone replacement therapy (HRT)
- High body mass index (BMI) and taller stature
- Higher social class

Clinical features

Early breast cancer rarely causes pain; more commonly, it may be detected on self-examination as a lump or thickening. Later, cancer may result in a change in breast size or shape, nipple discharge, tenderness or inversion, ridging or pitting (the skin looks like orange skin – *peau d'orange*), or a change in the way the skin of the breast, areola or nipple looks or feels (e.g. warm, swollen, red or scaly; Fig. 25.10).

General management

The current recommendation is 3-yearly screening from the age of 50 but, in cases of increased risk such as positive family history, screening may start earlier, with mammograms (Fig. 25.11). If an area of the breast looks suspicious on screening mammogram, diagnostic mammograms may be needed. Ultrasonography can then often help. Biopsy is generally needed – by needle or open biopsy.

Lobular carcinoma in situ (LCIS) refers to abnormal cells in the lining of a lobule, which seldom become invasive cancer. Tamoxifen, a hormone receptor blocker, is the usual therapy. Occasionally, women with LCIS may decide to have bilateral mastectomy to try to prevent cancer but most just have regular screening.

Ductal carcinoma in situ (DCIS or intraductal carcinoma) refers to abnormal cells in the lining of a duct, which are at greater risk of

Fig. 25.10 Advanced cancer of the breast.

Fig. 25.11 Breast self-awareness.

invasive breast cancer. An association between >10 years of calcium-channel blockers use and a higher risk of ductal breast cancer has been reported. Treatments include breast-sparing surgery followed by radiation therapy or mastectomy, with or without breast reconstruction. Tamoxifen may reduce the risk of developing invasive breast cancer.

Breast carcinoma treatment most commonly involves surgery – usually a wide local excision with axillary node sampling or sentinel node biopsy. Histopathology results then dictate further treatment, which may be more radical surgery, or adjuvant radiotherapy plus or minus chemotherapy. Radiation therapy may lead to ischaemic heart disease and other cardiac conditions, including pericardial disease, peripheral vascular disease, cardiomyopathy, valvular dysfunction and arrhythmias. Treatment may include biological therapy. Hormone (oestrogen and progesterone) receptor tests can help determine whether a tumour is hormone-dependent. Oestrogen receptor (ER) and progesterone receptor (PR) tests help predict response to hormone therapy after surgery. Tamoxifen is the most common hormonal treatment used, usually for 5 years following the main treatment, and may cause hot flushes, vaginal discharge or irritation, nausea and irregular periods. Serious adverse effects are rare but tamoxifen can cause deep vein thrombosis and, in a few women, can increase the risk of uterine cancer or stroke. Anastrozole is a safer alternative in respect of stroke risk.

Human epidermal growth factor receptor-2 or *HER-2* may be associated with a higher risk for cancer recurrence. Trastuzumab – a monoclonal antibody that targets breast cancer cells having excess *HER-2* – may be given alone or along with chemotherapy. *HER-2* test results help predict response to trastuzumab, other anti-*HER-2* treatments and

Table 25.14 Oestrogen receptors/progesterone receptors and breast cancer

Breast cancer	Receptor relevance
Newly diagnosed invasive	The cancer is classified as ER-positive (if the tumour has oestrogen receptors) or ER-negative (if the tumour does <i>not</i> have oestrogen receptors); PR-positive (if the tumour has progesterone receptors) or PR-negative (if the tumour does <i>not</i> have progesterone receptors); and HER-2-positive (if the tumour does have HER-2) or HER-2-negative (if the tumour does <i>not</i> have HER-2)
Node-negative	Patients with tumours that do not have urokinase plasminogen activator (uPA) and plasminogen activator inhibitor 1 (PAI-1) have a good prognosis and may not need chemotherapy
Node-negative and ER-positive and/or PR-positive	Oncotype DX test identifies patients who may be successfully treated with tamoxifen alone and may not need chemotherapy
Metastatic	ER and PR tests help predict response to hormone therapy. HER-2 test helps predict response to trastuzumab and other anti-HER-2 treatments. Cancer antigen (CA) 15-3, CA 27.29 and carcinoembryonic antigen (CEA) help monitor patients; these should be used along with the patient's health history, a physical examination, and diagnostic imaging tests such as radiography, bone scans, magnetic resonance imaging and computed tomography
Recurrent	HER-2 test helps predict the response to trastuzumab and other anti-HER-2 treatments, and guides the use of specific chemotherapy

some types of chemotherapy (Table 25.14). Such therapy may include anthracyclines, and this and therapies targeting HER-2 can have a cardiotoxic effect. Advanced breast cancer may be treated with vinorelbine; capecitabine may be used for locally advanced or metastatic cancer.

Dental aspects

Metastases occasionally affect the jaws.

Cervical cancer

General aspects

Cancer of the uterine cervix is the most common genitourinary neoplasm and most often affects women over 40 years. It is most frequently found in sexually active persons and recognized to be associated with human papillomaviruses, particularly HPV-16 and HPV-18. Smoking, lower socioeconomic class and HIV disease increase the risk.

A vaccine for HPV-16 and HPV-18 has now been added to the immunization schedule and is given to girls of 12–13 years of age; there will be a catch-up programme for older girls.

Screening for pre-cancerous cells is carried out by a 'cervical smear' test – 3-yearly on women aged 25–50 and then 5-yearly until 64 years of age. The cells from the squamocolumnar junction in the cervical canal are then described as normal; mild dyskaryosis (cervical intraepithelial neoplasia 1 [CIN 1]; this may resolve spontaneously), moderate dyskaryosis (CIN 2) or severe dyskaryosis (CIN 3), sometimes referred to as carcinoma *in situ*.

Clinical features

Pre-cancerous changes of the cervix rarely cause pain. When cancer develops and invades, the most common manifestations are abnormal vaginal bleeding or abnormal vaginal discharge.

Box 25.8 Risk factors for ovarian cancer

- Family history of ovarian, breast or colon cancer (see Ch. 22)
- Personal history of breast or colon cancer
- Age: risk grows as a woman gets older, with the highest risk over 60
- Fertility drugs
- Talc
- Hormone replacement therapy (HRT)
- Endometriosis

General management

Following pelvic examination and liquid-based cytology from brushings at routine screening, women with CIN 2 or 3 then undergo colposcopy and biopsy. Large loop excision of the transformation zone (LLETZ) may be carried out using diathermy, laser ablation or cold coagulation. A cone biopsy removing the entire transformation zone may be carried out and often the entire pre-cancerous area is removed in this way. Staging for cervical cancer includes a pelvic examination, cystoscopy and proctosigmoidoscopy. Other investigations include intravenous pyelography, barium enema, CT scan, ultrasonography and magnetic resonance imaging (MRI). Treatment for a pre-cancerous lesion depends on several factors, such as whether the lesion is low- or high-grade, whether the woman wants to have children, her age and general health, and her preferences. Treatment may be surgery, radiotherapy or chemotherapy, or a combination, depending on the stage. Simple local excision may be all that is required for early disease, whereas for more advanced disease a radical hysterectomy and excision of other involved tissues may be necessary. Radiotherapy may be given alone or with concurrent chemotherapy (e.g. cisplatin).

Dental aspects

Other than the fact that sexual partners and sometimes the patient can have a higher risk of oral cancer, cervical cancer is rarely of direct relevance to oral health. Metastases occasionally involve the jaws and cancer chemotherapy may cause mucositis.

Ovarian cancer

Most ovarian cancer is carcinoma but there are rare germ-cell tumours and cancers that begin in the stroma. The causes are unclear but risk factors are shown in Box 25.8.

Factors that reduce the risk include breast-feeding, use of combined oral contraceptives, a low-fat diet and childbearing (the more children a woman has had, the less likely she is to develop ovarian cancer).

Clinical features

Ovarian cancer often causes no symptoms or only mild symptoms until the disease is advanced but may include abdominal discomfort and/or pain; nausea, diarrhoea, constipation or frequent urination; anorexia; weight gain or loss; and abnormal vaginal bleeding. Fluid in the abdomen (ascites) may be seen when the cancer metastasizes to the peritoneum.

General management

Diagnosis is from pelvic examination together with ultrasound, CA-125 assay, radiography of the lower gastrointestinal tract, or barium enema, CT or MRI and biopsy.

Women at high risk due to a positive family history may consider prophylactic oophorectomy. Treatments for ovarian cancer include

surgery (hysterectomy with bilateral salpingo-oophorectomy), chemotherapy, or external or intraperitoneal radiation therapy.

Dental aspects

Metastases occasionally affect the jaws.

CYSTITIS

Genitourinary tract infections are particularly common in females, often ascending the short urethra from the vulva, frequently as a consequence of intercourse ('honeymoon cystitis'). Cystitis can ascend the ureter to cause pyelonephritis.

Bladder infections usually have little relevance for dental care, although the symptoms of cystitis may cause the patient to defer treatment for a few days. Such infections often suggest that the patient is sexually active and at risk from sexually transmitted diseases (Ch. 32). Cranberry juice (*Vaccinium macrocarpon*), popularly used to prevent cystitis, may enhance warfarin activity.

ENDOMETRIOSIS

General aspects and clinical features

Endometriosis is an enigmatic disease that affects women in their reproductive years, in which endometrium-like tissue is found outside the uterus, where it develops into nodules. Like the endometrium, the nodules usually respond to the menstrual cycle hormones. Tissue accumulates each month, breaks down, and causes bleeding, pain, infertility and other problems. Prostaglandins may cause many of the symptoms. Pregnancy often causes a temporary remission of symptoms, and mild or moderate endometriosis generally ceases after the menopause. About one-third of women with endometriosis are infertile and there is an increased frequency of malignancy in people with endometriosis.

Endometrial nodules occur typically in the abdomen, usually involving the ovaries, Fallopian tubes, outer uterine surface and pelvic lining.

General management

Diagnosis is generally confirmed by laparoscopy. Treatment has varied, with no certain cure. Hormonal treatments for endometriosis aim to suppress ovulation (oestrogen and progestogen, progestogen alone, a testosterone derivative [danazol] and gonadotropin-releasing hormone [GnRH]). Hysterectomy with oophorectomy has been considered a cure but there can be continuation/recurrence. Conservative surgery, either major or laparoscopic, involving removal or destruction of the nodules, can relieve symptoms and allow pregnancy to occur in some cases. Again, recurrences are common.

FEMALE GENITAL CUTTING (CIRCUMCISION)

Female genital cutting (FGC) is the collective name given to traditional practices involving the partial or total cutting away of, or other injury to, female external genitalia, whether for cultural or other non-therapeutic reasons. FGC is practised predominantly in African, and also in some Middle Eastern cultures, typically being performed on girls between 4 and 12 years old.

FIBROIDS

Fibroids are benign tumours of uterine muscle fibres. Probably 20–50% of women have, or will have, fibroids but they are rare below 20 years

Fig. 25.12 Menstrual cycle, with hormonal and other changes.

of age. Fibroids occur up to nine times more often in black than in white women. The cause is unknown but fibroids seem to be influenced by oestrogen (which might explain why they appear during a woman's middle years, when oestrogen levels are high, and stop growing after the menopause, when oestrogen levels fall). Fibroids are often symptomless but the most common feature is heavy menstrual bleeding. Other symptoms include abdominal pain or pressure, changes in bladder and bowel function, and, in some cases, infertility.

MENSTRUATION AND PREMENSTRUAL ISSUES

Menstruation is the shedding of the endometrium that occurs on a regular basis in females of reproductive age (Fig. 25.12). Plasmin in the endometrium tends to inhibit blood clotting. Normal, regular menstruation lasts for about 3–5 days. The average blood loss during menstruation ranges from 10 to 80 mL and many women experience cramps (dysmenorrhoea) during this time. Premenstrual syndrome (PMS) is a symptom or collection of symptoms that occurs regularly in relation to the menstrual cycle. Usually, symptoms start five to eleven days before the onset of menses and resolve with menses or shortly after. Features may include mood swings, tender breasts, food cravings, fatigue, irritability and depression but can range from bloating to severe cramping and headaches. PMS tends to peak during the late 20s and early 30s and it can affect 75% of women. Treatments and lifestyle adjustments that can help include stress reduction, exercise and:

- Antidepressants
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Diuretics
- Oral contraceptives or
- Medroxyprogesterone acetate (<http://www.mayoclinic.com/health/premenstrual-syndrome/DS00134>).

Table 25.15 Common complaints in pregnancy

Main trimester in which complaint occurs		
First	Second	Third
Breast tenderness	Aches and pains	Haemorrhoids
Dizziness	Stretch marks	Heartburn
Frequency of urination	Weight gain	Swelling
Haemorrhoids		Varicose veins
Leg cramps		Dizziness/fainting
Nausea and vomiting		Itching (pruritus of pregnancy or cholestasis of pregnancy)
Nosebleeds, nasal stuffiness		Shortness of breath
Tiredness		Urinary incontinence
Deepened pigmentation, particularly of the nipples and sometimes the face (chloasma)		Backache
		Pubic symphysis dysfunction

PREGNANCY

Pregnancy is extremely important to most mothers and families, and this is typically more so if it is the first pregnancy; if there have been previous pregnancy mishaps; if there have been conception difficulties; or if the mother is over about 35 years of age. Pregnancy is often associated with changes in cardiovascular, endocrine, haematological, respiratory, gastrointestinal and genitourinary systems, and can cause features such as nausea, vomiting, nasal congestion, heartburn, changes in taste and food craving, hyperventilation, shortness of breath, fatigue and tiredness. Sex hormones, prolactin and thyroid hormones rise but levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) fall. Consequences may include deepened pigmentation, particularly of the nipples and sometimes the face (chloasma), and a rise in both blood volume and cardiac output, associated with tachycardia. Endocrine, cardiovascular, haematological and often mental (attitude, mood or behaviour) changes can be seen.

Variations in hormone levels result in changes that may include those shown in Figure 25.12. Pregnancy may be accompanied by a range of complaints (Table 25.15).

Cardiovascular disorders

Maternal cardiac output increases by 30–50%, with a heart rate increase of 20–30%. Women with high blood pressure values before the 20th week of gestation are assumed to have pre-existing hypertension, but any pregnant woman with a raised blood pressure should be referred to exclude development of pre-eclampsia (hypertension, proteinuria and oedema). Pre-eclampsia affects 5% of all pregnancies.

Blood pressure decreases while the patient is supine, especially in the second and third trimesters, due to decreased venous return to the heart from the compression of the abdominal aorta and inferior vena cava by the gravid uterus; hypotension, bradycardia and syncope characterize this supine hypotension syndrome. It can be relieved by tilting the patient 5–15° on to her left side. If this manoeuvre does not work, a full lateral position should be taken.

Hypertension may be asymptomatic but, when associated with oedema and proteinuria (pre-eclampsia), may culminate in eclampsia (hypertension, oedema, proteinuria and convulsions); this, in turn, leads to greater morbidity and mortality in both fetus and mother. Pre-eclampsia or pre-eclamptic toxæmia (PET) may cause intrauterine growth retardation (IUGR), fetal death and extreme prematurity. It rarely occurs before 28 weeks but affects 5–10% of pregnancies. In the mother it can cause haemorrhagic stroke, eclamptic fits, renal or liver

failure, or abruption, where the placenta separates from the uterus; this can result in intrauterine death of the fetus. Treatment involves bed rest, antihypertensives, close monitoring of both the mother and fetus, and possible early delivery.

In later pregnancy, up to 10% of patients may become hypotensive if laid supine, when the gravid uterus compresses the inferior vena cava and impedes venous return to the heart (supine hypotension syndrome).

Haematological disorders

Blood hypercoagulability can lead to venous thrombosis, particularly postoperatively, or occasionally to disseminated intravascular coagulopathy. The plasma volume increases significantly, without a corresponding increase in the red cell volume, thereby manifesting as anaemia. The number of white blood cells, erythrocyte sedimentation rate (ESR) and blood coagulation factors VII–X increase, and anti-clotting factors (XI and XIII) decrease, raising the risk of thrombo-embolism. Thus subcutaneous low-molecular-weight heparin may be indicated; this does not cross the placenta.

Pregnancy may worsen pre-existing anaemias, especially sickle cell anaemia. Deficiency anaemias may develop in about 20%, mainly because of fetal demands for iron and folate. Most pregnant patients are given both of these haematinics. Expansion of the blood volume may cause an apparent anaemia.

Gastrointestinal disorders

Progesterone increases cause nausea and vomiting in about two-thirds of pregnant women, beginning approximately 5 weeks after the last menstrual period and peaking between 8 and 12 weeks. Morning sickness occurs in most pregnant women, and it is best for them to avoid morning dental appointments. Decreased oesophageal sphincter tone, raised gastric pressure and slower gastric emptying may cause gastric reflux, heartburn and regurgitation. The patient should be advised to avoid citrus drinks or fatty foods and to prevent dehydration; frequent sipping of small volumes of liquid may help. Antacids and H₂ antagonists like ranitidine may ease symptoms. If vomiting occurs, procedures should be stopped and the patient repositioned upright.

Gestational glucose metabolism (GDM) disorder

Medical complications can include glycosuria and impaired glucose tolerance, which occasionally cause gestational diabetes. Disturbances of carbohydrate metabolism usually resolve after pregnancy. Diabetic control can be difficult, since insulin requirements rise; pregnant diabetics need specialist monitoring and care.

Gestational diabetes is similar to type 2 diabetes mellitus, in that it involves insulin resistance; oestrogens and progesterone, the hormones of pregnancy, cause insulin resistance in genetically predisposed women. Gestational diabetes occurs in nearly half of these women when pregnant and typically resolves with delivery of the child.

Two criteria, based on a 2-hour 75 g oral glucose tolerance test (OGTT), are used for the diagnosis of GDM: those recommended by the World Health Organization (WHO) and those recommended by the International Association for Diabetes in Pregnancy Study Group (IADPSG). They both identify women at a small increased risk for adverse pregnancy outcomes. Pregnancy hyperglycaemia that does not meet GDM diagnostic criteria affects a significant proportion of pregnant women and is also associated with a range of adverse pregnancy outcomes.

Interventions, including the provision of dietary advice and blood glucose level monitoring for women with pregnancy hyperglycaemia

not meeting diagnostic criteria for GDM and type 2 diabetes mellitus, helped reduce the number of macrosomic and large-for-gestational age (LGA) babies without increasing caesarean section and operative vaginal birth rates.

Fetal issues

Fetal development during the first 3 months (trimester) of pregnancy is a complex process of organogenesis and the fetus is then especially at risk from developmental defects. The most critical period is that between the third and eighth weeks (mainly between 18 and 45 days of gestation). All pregnant women have a 3–5% chance of having a baby with a birth defect.

Most fetal developmental defects are of unknown aetiology but, in addition to hereditary influences, infections, alcohol, smoking, drugs (Table 25.16), deficiencies and irradiation can be implicated in some

cases. Folic acid supplements taken pre-conception and for the first trimester may minimize the risk of neural tube defects, such as spina bifida, and of facial clefts.

All drugs should be avoided in pregnancy unless potential benefit outweighs potential risks. Any woman of childbearing age is a potential candidate for pregnancy and may not be aware of pregnancy for 2 months or more, when the fetus is most vulnerable to damage. A total of 10–20% of all pregnancies abort at this time, often because of fetal defects. Alcohol, anticonvulsants, thalidomide and isotretinoin can be teratogenic. Even a single exposure to high alcohol intake can cause significant brain damage; more than 10% of children have been exposed to high levels of alcohol *in utero* and many suffer effects ranging from mild learning disabilities to major physical, mental and intellectual impairment (fetal alcohol syndrome [FAS]; Box 25.9). Nevertheless, very few therapeutic drugs have been proved to be teratogenic.

Table 25.16 Known risks to the fetus of some drugs used in oral health care^a

Category ^b	No risk to fetus in animal model or human studies	Either safe to fetus in animal models without human data, or risk in animal models but safe in human studies	Risk to fetus in animal models but no human studies available, or no human studies support safety	Definitive human data demonstrating risk to fetus
<i>Use systemically unless otherwise stated</i>	<i>When desired (completely safe)</i>	<i>When necessary</i>	<i>Only if really essential and after consulting physician</i>	<i>Never</i>
Analgesics	–	Paracetamol (acetaminophen) Pethidine (meperidine)	Codeine Diflunisal Mefenamic acid	Aspirin Non-steroidal anti-inflammatory drugs (NSAIDs) ^c Opioids Pentazocine
Antimicrobials	–	Azithromycin Cefadroxil Cefalexin Cefuroxime Clindamycin Erythromycin Loracarbef Metronidazole Penciclovir (cream) Penicillins	Aciclovir Ciprofloxacin Clarithromycin Fluconazole Itraconazole Ketoconazole Miconazole (unless topical)	Dapsone Doxycycline Minocycline Tetracyclines
Local anaesthetic and vasoconstrictors	–	Lidocaine Felypressin Prilocaine ^d	Articaine ^e Bupivacaine Mepivacaine	–
Sedatives	–	Promethazine		Benzodiazepines ^e Nitrous oxide ^f
Others	–	–	Corticosteroids (even topical) Epsilon aminocaproic acid Tranexamic acid	Antidepressants Carbamazepine Colchicine Danazol Gabapentin Oxcarbazepine Phenytoin Povidone–iodine Retinoids Thalidomide Warfarin

^aIt is advisable to restrict use to the second or third trimester; see also Appendix 25.1.

^bUS Federal Drug Agency (FDA) pregnancy categories.

^cMay be safer in first and second trimesters.

^dPrilocaine can cause methaemoglobinaemia.

^eSometimes categorized as either safe to fetus in animal models without human data, or risk in animal models but safe in human studies.

^fNitrous oxide, though able to interfere with vitamin B₁₂ and folate metabolism, does not appear to be teratogenic in normal use, though it is advisable to restrict use to the second or third trimester.

- Night terrors
- Poor judgment
- Precocious puberty
- Reactive outbursts
- Renal failure
- Rigidity
- Serious maxillofacial deformities
- Severe loss of intellectual potential
- Sleep disorder
- Social problems
- Sociopathic behaviour
- Suicide
- Tourette's traits
- Tremors

Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) may cause closure of the ductus arteriosus *in utero* and fetal pulmonary hypertension, as well as delaying or prolonging labour, and therefore are contraindicated in the third trimester. Aspirin, in addition, causes a platelet defect and may induce abortion; it is best avoided throughout pregnancy. Corticosteroids can suppress the fetal adrenals and, if given, steroid cover is needed for labour. Tetracyclines stain developing teeth.

Serious damage to the fetus or child can also be caused by maternal tobacco-smoking during or after pregnancy. Smoking increases the risk of stillbirth, low birth weight and impaired mental and physical development. Smoking by either parent after the child's birth increases the child's risk of respiratory tract infection, asthma and sudden death.

Oral disease

In some pregnant women, gingivitis is aggravated (pregnancy gingivitis) or may even result in a pyogenic granuloma at the gingival margin (pregnancy epulis). These conditions typically arise after the second month and resolve on parturition. Pyogenic granulomas elsewhere may grow rapidly during pregnancy. Chronic periodontal disease in the mother has been linked with babies of low birth weight. About half of pregnant women experience gingivitis due to increased oestrogen and progesterone, which can progress to periodontitis. This typically begins in the second or third month of pregnancy.

In a few women subject to recurrent aphthae, ulcers may stop (or occasionally become more severe) during pregnancy.

Oral health care in pregnancy

There are concerns on the part of patients and health professionals about oral health care in pregnancy but pregnant patients are not medically compromised and should not be denied dental treatment simply because they are pregnant. Performing oral health interventions has not been found to be associated with an increased risk to the developing fetus. A study of 823 pregnant women at 13–21 weeks' gestation found that scaling and root planing for periodontitis, using local anaesthetics as needed, did not increase adverse fetal outcomes; however, it did lower preterm birth rates. Additionally, a randomized controlled trial of 870 women with pregnancy-associated gingivitis found that treatment (i.e. plaque control, scaling, and daily rinsing with chlorhexidine) and maintenance (i.e. oral hygiene instruction and manual supragingival plaque removal every 2–3 weeks until delivery) significantly reduced the rate of preterm births or low birth weight (LBW). Conversely, adverse pregnancy outcomes, such as LBW, preterm birth and pre-eclampsia, may occur in women who have not received oral health care.

Good oral health during pregnancy is important to the overall health of both mothers and their babies. Pregnancy is the ideal opportunity to begin preventive dental education and to advise on fluoride administration to the infant. Prenatal fluorides are not indicated, as there is little evidence of benefit to the fetus. The teeth do not, of course, lose calcium as a result of fetal demands and there is no reason to expect caries to become more active unless the mother develops a capricious desire for sweets.

As much treatment as possible should be postponed until after parturition in those with a history of abortions and those who have achieved pregnancy after years of failure to conceive. During the first trimester, the only safe course of action is to protect the patient as far as possible from infections and to avoid the use of drugs (particularly GA) and radiography. In the second and third trimesters, the fetus is growing and maturing but can still be affected by infections, drugs and possibly other factors. Nevertheless, dental treatment is best carried out during the second trimester, though advanced restorative procedures are probably best postponed until the periodontal state improves after parturition and prolonged sessions of treatment are better tolerated. In the third trimester, the supine hypotension syndrome may result if the patient is laid flat. She should therefore be put on one side to allow venous return to recover. Some pregnant women also have a hypersensitive gag reflex.

Elective dental care should be avoided in the last month of pregnancy, as it is often uncomfortable for the patient. Moreover, premature labour or even abortion may also be ascribed, without justification, to dental treatment. Oral health care under any circumstance should take account of the following cautions.

Table 25.17 Drug use in pregnancy in dentistry

Drug	Safe	Unsafe/caution
Anxiolytics	None	Alprazolam Diazepam
Local anaesthetics	Articaine Lidocaine Prilocaine	Bupivacaine
Analgesics	Ibuprofen (first and second trimesters) Paracetamol (acetaminophen; all trimesters)	Aspirin Diclofenac Ibuprofen (third trimester) Mefenamic acid Naproxen
Antifungals	Fluconazole Miconazole Nystatin	Ketoconazole
Antibacterials	Azithromycin Cephalosporins Clindamycin Erythromycin Penicillin group	Aminoglycosides Co-trimoxazole Metronidazole Sulphonamides Tetracyclines

Anaesthesia and sedation

Unnecessary drugs should be avoided (Tables 25.16 and 25.17; Appendix 25.1) and, because of the risk of coincidental mishaps, it is wise to try to avoid giving any potent drugs. LA is probably overall safe, though all LAs cross the placenta to some degree. Highest concentrations in the fetal circulation follow prilocaine injection and the lowest follow bupivacaine, while lidocaine gives intermediate levels. Lidocaine and prilocaine are safe for use in most pregnant women. The vasoconstrictor adrenaline (epinephrine), when used in low concentration in LA, does not cause fetal harm. Felypressin is a vasopressin derivative related to oxytocin and may have the potential to cause uterine contractions, although this is highly unlikely; nevertheless, felypressin is best avoided.

GA, and sedation with midazolam or diazepam, should be avoided in the first trimester and in the last month of the third trimester of pregnancy. Nitrous oxide, though able to interfere with vitamin B₁₂ and folate metabolism, does not appear to be teratogenic, though it is advisable to restrict use to the second or third trimester, limit the duration of exposure to below 30 minutes, use 50% oxygen, avoid repeated exposures, and use scavenging in the dental surgery to minimize staff exposure.

When GA is unavoidable and there is a mishap to the fetus, the mother is likely to blame the anaesthetist, even though this may be quite unjustifiable. Yet another hazard is a greater tendency to vomit during induction in the third trimester. Despite such considerations, there is scanty evidence of teratogenic effects in humans from exposure to GA agents. The greater risk is late in pregnancy, when GA may induce respiratory depression in the fetus. As always, GA must be given in hospital. Anxiolytics, such as alprazolam and diazepam, are contraindicated in pregnancy owing to reports of fetal developmental anomalies.

Drugs

Certain drugs can cause miscarriage, teratogenicity and babies of low birth weight. The decision to administer a specific drug requires the benefits to outweigh the potential risks of the drug therapy. As far as

analgesics are concerned, paracetamol (acetaminophen) is considered safe in all three trimesters of pregnancy but for short-term usage only. Some NSAIDs are to be avoided in all trimesters of pregnancy, while some are contraindicated in specific trimesters. NSAIDs can also cause gastrointestinal complications in the mother. Ibuprofen is considered a risk in the first trimester and is definitely contraindicated in the last trimester, as it may cause prolonged labour, haemorrhage, premature closure of ductus arteriosus and fetal pulmonary hypertension. Aspirin is safe but there is a risk associated with use of higher doses in the first and third trimesters, and it may cause constriction of ductus arteriosus, prolong gestation and delay labour.

Infections in pregnancy should be treated at the earliest opportunity. Preferred antibacterials are penicillins (amoxicillin and ampicillin) and cephalosporins (oral – cefalexin; parenteral – cefotaxime and ceftriaxone). If the patient is allergic to penicillin, then erythromycin (stearate salt only), azithromycin or clindamycin can be used. Tetracyclines are contraindicated, as they can cause bone and dental staining and anomalies in the fetus, as well as occasional maternal liver toxicity. Metronidazole is contraindicated in the first trimester.

Topical antifungals – nystatin and miconazole – are considered safe in pregnancy, but ketoconazole may cause adrenal insufficiency and hepatotoxicity, and therefore should be avoided. Fluconazole is an alternative but is not safe in the first trimester.

Amalgams

Dental amalgam restorations release mercury vapour when teeth are chewed on or brushed, or the restorations are removed; some of this is inhaled, and some may dissolve in saliva and be swallowed. Most mercury entering the body is excreted, although a small amount accumulates in the kidneys and, to a very much lesser extent, in brain, lungs, liver and gastrointestinal tract. Mercury can cross the placenta to the fetus and the number and surface areas of amalgam fillings in the mother increase mercury concentrations in amniotic fluid; levels are low, however, and there are no proven adverse outcomes in pregnancies or newborns. Mercury can also be detected in breast milk. However, there is no evidence of any link between amalgam use and birth defects or stillbirths. A case-control study of 1117 LBW infants found no association between low birth weight and placement of amalgam during pregnancy. In a database study, there was no association of cumulative amalgam exposure in 1062 births categorized as having ‘complications of pregnancy and childbirth’. Study of dental personnel in Norway, a group with possible previous exposure to mercury vapour, showed they had no excess risk of having children with congenital malformations or other adverse pregnancy outcomes compared to the general population.

Hydrogen peroxide, a common bleaching agent, can increase mercury release, so avoidance should be considered.

Generally, it is wise to minimize any health interventions during pregnancy. Although there is no reason to think that the placement or removal of amalgam during pregnancy is harmful, under ideal circumstances amalgams should not, if possible, be placed or removed during pregnancy. This is in spite of the fact that studies and case reports of amalgam exposure during pregnancy have not documented toxicity, including birth defects, neurological sequelae, spontaneous abortions or reduction in fertility.

Imaging

Ultrasound appears to be safe in pregnancy. MRI is probably best avoided during the first trimester. Radiography should also be

avoided, especially in the first trimester, even though dental radiography is unlikely to pose a significant risk. Ionizing radiation (X-ray) is composed of high-energy photons that are capable of damaging DNA and generating free radicals. A patient's dose of photons is measured in grays (Gy) and the rem, or in the older and more commonly recognized unit, the rad. The estimated fetal dose from dental radiograph is about 0.0001 rad for about 50 000 examinations. Fetal risk is considered to be negligible at 5 rad or less when compared to the other risks of pregnancy, and the risk of malformations is significantly increased above control levels only at doses above 15 rad. Radiation exposures of greater than 500 mGy are known to cause fetal damage.

Radiation (X-ray) doses of less than 5 rad are not associated with increased congenital malformations; therefore, dental X-rays, which give a fetal dose in a single dental exposure of 0.01 mrad, should not be cause for concern. A UK epidemiological study of a cohort of 7375 mothers did not find a significant association between the use of dental X-ray scans and LBW or preterm delivery. A case-control study found no overall increased risk of childhood brain tumour after exposure to prenatal abdominal X-rays, which produce many times higher radiation exposure than dental X-rays.

The most sensitive period for inducing developmental abnormalities is in the first trimester, and the most vulnerable period for radiation-induced central nervous system damage is 8–15 weeks after conception. Adverse fetal effects associated with radiation exposure include small head size, intellectual deficits or induction of childhood malignancies. Therefore, the radiation risk depends upon gestational age at the time of exposure, fetal cellular repair mechanisms and the absorbed radiation dose level. Even though the exposure dose for full-mouth dental radiographs (0.25 microGy) is negligible and unlikely to cause any abnormalities to the fetus, it is absolutely essential for the dentist to ensure that the pregnant patient avoids the smallest unnecessary dose of radiation.

Dental professionals should have a clear perception of the risks and benefits of performing radiographic studies during pregnancy; radiographs must not be requisitioned unless absolutely necessary and retakes must be avoided. Protective measures, such as high-speed films (E/F speed) and rectangular collimation, should help keep the dose to a minimum. Current guidelines are that exposure must be minimal but a lead apron is unnecessary, unless the beam is directed at the fetus, such as in vertex-occlusal radiography. It has been estimated that two periapical dental X-rays give an exposure less than that which can be ascribed to natural radiation for 1 day.

Hazards to pregnant dental staff

Exposure to infections such as rubella or herpesviruses should be minimized or avoided.

Nitrous oxide scavenging must always be used and some pregnant staff exempt themselves from work involving GA or sedation.

Concern has been expressed, particularly in Sweden, about the risk of placental transfer of mercury as a result of exposure to the metal during pregnancy. However, measurements on female dental personnel, their newborn babies and non-exposed controls have shown no significant differences in plasma mercury levels or in fetal/maternal ratios of mercury levels. Female dental personnel had no observed increased occurrence of:

- congenital malformations (including malformations of the CNS)
- dysplasia of the hip, clubfoot, or malformations of the heart and great vessels

- low birth weight, preterm birth, babies that were small for gestational age, or changed gender ratio
- multiple birth, stillbirth or prenatal death.

On a group level, there was no excess risk of congenital malformations or other adverse pregnancy outcomes among female dental personnel in Norway during 1967–2006 compared to the general population. Experimental and clinical data do not suggest that there should be any restriction on use of amalgams by or work restriction of pregnant dental professionals, provided that work practices are up to accepted standards.

Lactation and breast-feeding

The two main contraindications to breast-feeding are mothers who are HIV-positive or have AIDS, or who are taking drugs/medicines that are contraindicated. Drugs may pass from mother to fetus in the breast milk, and thus care should be taken in their use (see [Box 25.9](#) and [Table 25.17](#)). Various drugs can affect infants (see Appendix 25.2).

The National Institute for Health and Care Excellence (NICE) states (2008, www.nice.org.uk/nicemedia/pdf/ph011guidance.pdf; accessed 30 September 2013) that health-care professionals who prescribe or dispense drugs to a breast-feeding mother should consult supplementary sources (e.g. the Drugs and Lactation Database [known as LactMed; <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>; accessed 30 September 2013]) or seek guidance from the UK Drugs in Lactation Advisory Service (www.ukmicentral.nhs.uk/drugpreg/guide.htm; accessed 30 September 2013). They should discuss the benefits and risks associated with the prescribed medication and encourage the mother to continue breast-feeding, if it is reasonable to do so. If drugs are essential, they should preferably be taken by the mother immediately after breast-feeding, so the milk levels of the drug are as low as possible at the next feed. Cefalexin is a useful antimicrobial, as it is not secreted in the milk.

Fluoride passes into breast milk and, if the local water supply contains more than 1 mg/L fluoride, supplements are not indicated for the breast-fed infant.

Drugs contraindicated in breast-feeding

These are shown in [Table 25.18](#).

Infertility

Around one couple in six in the UK is affected by infertility. Main treatments include;

- Artificial insemination (Intrauterine insemination [IUI]); involves directly inserting sperm into a woman's uterus (womb).
- In vitro fertilisation (IVF); an egg is fertilised by sperm outside the body.
- Intra cytoplasmic sperm injection (ICSI); a single sperm is injected into an egg.

However, there are many treatment options as shown in [Box 25.10](#).

THE MENOPAUSE

General aspects and clinical features

The menopause – marked by cessation of menstrual periods – can start at any age between 40 and 55 years. Menopause is the permanent end of menstruation and fertility, defined as occurring 12 months after the last menstrual period, and may give rise to physical and emotional

Table 25.18 Drugs that may be used in dentistry but are contraindicated in breast-feeding mothers, with alternatives

Drug group	May be contraindicated	Possible alternatives
Analgesics	Aspirin (high-dose)	Aspirin (low-dose) or paracetamol (acetaminophen)
	Dextropropoxyphene	Codeine or paracetamol (acetaminophen)
	Diflunisal	Diclofenac or paracetamol (acetaminophen)
	Indometacin	Mefenamic acid or paracetamol (acetaminophen)
Antimicrobials	Tetracyclines	Erythromycin
	Aminoglycosides	Cephalosporins
	Co-trimoxazole	Penicillins
	Fluconazole	Nystatin or miconazole topically
	Itraconazole	Nystatin or miconazole topically Ganciclovir
Pre-medication	Metronidazole	
	Sulphonamides	
	Atropine	Benzodiazepines (low-dose)
Others	Chloral hydrate	Phenothiazines (low-dose)
		Beta-blockers
	Antidepressants	
	Barbiturates	
	Etretinate	
	Carbamazepine	
	Corticosteroids (high-dose)	
	Povidone-iodine	

Box 25.10 Fertility treatment options

Assisted hatching
 Cycle monitoring
 Donor insemination
 Egg donation
 Embryo cryopreservation
 Frozen embryo replacement cycle
 Gamete intra fallopian transfer (GIFT)
 In-vitro fertilisation (IVF)
 Intra cytoplasmic sperm injection (ICSI)
 Intra-uterine insemination
 Micro epididymal sperm aspiration
 Open testicular biopsy with microsurgical techniques
 Ovulation Induction – Clomifene Citrate
 Parental induction of ovulation
 Percutaneous epididymal sperm aspiration
 Testicular epididymal sperm extraction
 Zygote intra-fallopian transfer (ZIFT)

symptoms. Menopause is a natural process but may be premature if there is hysterectomy/oophorectomy/ovariectomy; radiotherapy; chemotherapy; or primary ovarian dysfunction. Although rarely associated with serious physical or other complications, some women in the menopause gain weight, lose muscle tone, develop a few hairs on

Table 25.19 Marketed herbal alternatives to hormone replacement therapy

Reported possible benefit		No reported benefit
<i>Herbal alternatives</i>	<i>Comments</i>	
Soy and isoflavones (plant oestrogens in beans, particularly soybeans)	Helpful short-term to relieve hot flushes and night sweats. May be harmful to women with oestrogen-dependent breast cancer	Chasteberry (monk's pepper, Indian spice, sage tree hemp or tree wild pepper), dong quai, evening primrose, ginseng, valerian root, wild and Mexican yam
Black cohosh	Helpful short-term (6 months or less) for hot flushes and night sweats	

the chin or upper lip or have hot flushes. These appear to be caused by vasomotor instability, and may sometimes be controlled by hormone replacement therapy (HRT) typically with oestrogens. The menopause is frequently associated with emotional disturbances and stresses, often due to the changes in the pattern of family life around that time. Psychological disorders are not uncommon but are usually mild (e.g. dizziness and insomnia); however, depression or paranoia may develop. CBT and antidepressants may be called for (Ch. 10).

Osteoporosis is more common (Ch. 16); HRT slows its development and reduces the risk of fractures.

General management

HRT is replacement of reduced oestrogen secretion after menopause or oophorectomy, with oestrogens taken orally, via a patch on the skin or implanted; or with oestrogens plus progestogens (progestin). Tibolone, a steroid with oestrogenic, progestogenic and androgenic activities, has the same licensed applications. HRT is used mainly for the benefits it confers for short-term relief of menopausal symptoms and prevention of osteoporosis. There may also be benefits from reduced colorectal cancer. Adverse effects of HRT may include a predisposition to deep vein thrombosis, stroke and coronary heart disease, and an increase in breast, and possibly ovarian and endometrial cancers.

Consideration of the risks and benefits of HRT has concluded that it is beneficial but that the combined HRT involving oestrogen plus progestogen may cause more harm than good. Alternatives to HRT are shown in Table 25.19. Bisphosphonates, along with calcium and vitamin D supplements, can also be used to minimize osteoporosis (Ch. 16).

Dental aspects

LA is satisfactory. CS can be given if required. GA must, as always, be carried out in hospital.

HRT appears to lessen alveolar bone and tooth loss, as well as gingival bleeding, in older women, and improves salivary flow and buffering capacity. Overall, however, HRT appears not to improve complaints such as oral discomfort. Adverse effects from bisphosphonates are discussed in Chapter 16.

Atypical facial pain and oral dysaesthesias are particularly common but there is little evidence of benefit from use of steroid sex hormones.

Dryness of the mouth and desquamative gingivitis are more common in middle-aged or older people, and particularly in females, but are not hormonal – rather immunological – in origin. Sjögren syndrome, lichen planus and mucous membrane pemphigoid are simply more common at this age.

TRANSGENDER

Transgender is the state of gender identity (self-identification) not matching one's 'assigned sex' (identification by others as male or female, based on physical features or genetic make-up) and does not imply any specific form of sexual orientation (<http://en.wikipedia.org/wiki/Transgender>; accessed 30 September 2013).

IMPLANTS

Antimicrobial prophylaxis for dental treatment is usually unwarranted for people having breast or penile implants/augmentations (<http://www.cda-adc.ca/jcda/vol-72/issue-7/619.pdf>; accessed 30 September 2013).

APPENDIX 25.1 DRUGS CONTRAINDICATED IN PREGNANCY

This chart represents information on select drugs that are contraindicated (pregnancy category X) for women who are pregnant. This is not an inclusive list of products that carry that pregnancy category. Those drugs that are contraindicated at a certain phase of the pregnancy are listed next to the product name. For more information on specific drug monographs, see product entries or consult the manufacturer.

Allergic disorders

Vistaril (hydroxyzine) *Early pregnancy*

Cardiovascular system

Advicor (niacin ext-rel/lovastatin)
 Aggrenox (dipyridamole/aspirin) *3rd trimester*
 Altoprev (lovastatin)
 Bayer (aspirin) *3rd trimester*
 Caduet (amlodipine/atorvastatin)
 Coumadin (warfarin sodium)
 Crestor (rosuvastatin)
 Ecotrin (aspirin) *3rd trimester*
 Juvisync (sitagliptin/simvastatin)
 Lescol (fluvastatin)
 Lescol XL (fluvastatin)
 Letairis (ambrisentan)
 Lipitor (atorvastatin)
 Livalo (pitavastatin)
 Mevacor (lovastatin)
 Multaq (dronedarone)
 Pravachol (pravastatin)
 Simcor (niacin ext-rel/simvastatin)
 Tracleer (bosentan)
 Vytorin (ezetimibe/simvastatin)
 Zocor (simvastatin)

Central nervous system

Beyaz (drospirenone/ethinyl estradiol)
 Doral (quazepam)
 Estazolam
 Flurazepam
 Halcion (triazolam)
 Restoril (temazepam)
 Vistaril (hydroxyzine) *Early pregnancy*
 Yaz (drospirenone/ethinyl estradiol)

Dermatological disorders

Amnesteem (isotretinoin)
 Avage (tazarotene)
 Beyaz (drospirenone/ethinyl estradiol)
 Carac (fluorouracil)
 Claravis (isotretinoin)
 Efudex (fluorouracil)
 Estrostep Fe (norethindrone acetate/ethinyl estradiol)
 Fluoroplex (fluorouracil)
 Loryna (drospirenone/ethinyl estradiol)
 Ortho Tri-Cyclen 28 (norgestimate/ethinyl estradiol)
 Propecia (finasteride)
 Silvadene (silver sulfadiazine) *Late pregnancy*
 Solage (mequinol/tretinoin)
 Solaraze (diclofenac sodium) *3rd trimester*

Soriatane (acitretin)
 Sotret (isotretinoin)
 SSD (silver sulfadiazine) *Late pregnancy*
 SSD AF (silver sulfadiazine) *Late pregnancy*
 Tazorac (tazarotene)
 Tilia Fe (norethindrone acetate/ethinyl estradiol)
 Tri-Legest 21 (norethindrone acetate/ethinyl estradiol)
 Tri-Legest Fe (norethindrone acetate/ethinyl estradiol)
 Tri-previfem (norgestimate/ethinyl estradiol)
 Tri-sprintec (norgestimate/ethinyl estradiol)
 Yaz (drospirenone/ethinyl estradiol)

Endocrine disorders

Androderm (testosterone)
 Androgel (testosterone)
 Android (methyltestosterone)
 Axiron (testosterone)
 Delatestryl (testosterone enanthate)
 Depo-testosterone (testosterone cypionate)
 Egrifta (tesamorelin)
 Fluoxymesterone
 Fortesta (testosterone)
 Juvisync (sitagliptin/simvastatin)
 Lupron (leuprolide acetate)
 Methitest (methyltestosterone)
 Oxandrin (oxandrolone)
 Striant (testosterone)
 Supprelin LA (histrelin acetate)
 Synarel (nafarelin)
 Testim (testosterone)
 Testred (methyltestosterone)
 Virilon (methyltestosterone)

Gastrointestinal tract

Bellergal-S (phenobarbital/ergotamine tartrate)
 Cytotec (misoprostol)

Infections and infestations

Bactrim (sulfamethoxazole/trimethoprim) *3rd trimester*
 Copegus (ribavirin)
 Flagyl (metronidazole) *1st trimester for trichomoniasis*
 Furadantin (nitrofurantoin) *Pregnancy at term*
 Gantrisin (sulfisoxazole) *3rd trimester*
 Grifulvin V (griseofulvin)
 Gris-Peg (griseofulvin)
 Macrobid (nitrofurantoin as macrocrystals and monohydrate) *Pregnancy at term*
 Macrochantin (nitrofurantoin macrocrystals) *Pregnancy at term*
 Rebetol (ribavirin)
 Rebetron (ribavirin/interferon alfa-2b)
 Septra (sulfamethoxazole/trimethoprim) *3rd trimester*
 Sulfadiazine *Pregnancy at term*
 Tindamax (tinidazole) *1st trimester*
 Urobiotic-250 (oxytetracycline HCl/sulfamethizole/phenazopyridine) *Late pregnancy*
 Virazole (ribavirin)

Metabolic disorders

Zavesca (miglustat)

Musculoskeletal disorders

Advil (ibuprofen) *3rd trimester*
 Aleve (naproxen sodium) *3rd trimester*
 Ansaid (flurbiprofen) *Late pregnancy*

(Continued)

Arava (leflunomide)
 Arthrotec (diclofenac sodium/misoprostol)
 Bayer (aspirin) *3rd trimester*
 BC Arthritis Strength (aspirin/caffeine/salicylamide) *3rd trimester*
 Cataflam (diclofenac potassium) *Late pregnancy*
 Celebrex (celecoxib) *3rd trimester*
 Choline magnesium trisilicylate *Pregnancy at term*
 Dantrium (dantrolene)
 Daypro (oxaprozin) *3rd trimester*
 Diflunisal *3rd trimester*
 Duexis (ibuprofen/famotidine) *Late pregnancy (≥30 wks)*
 Ecotrin (aspirin) *3rd trimester*
 Etodolac *Late pregnancy*
 Evista (raloxifene HCl)
 Feldene (piroxicam) *Late pregnancy*
 Ketoprofen *Late pregnancy*
 Mobic (meloxicam) *3rd trimester*
 Motrin (ibuprofen) *3rd trimester*
 Nabumetone *3rd trimester*
 Nalfon (fenoprofen calcium) *3rd trimester*
 Naprelan (naproxen) *3rd trimester*
 Prevacid Naprapac (lansoprazole/naproxen) *3rd trimester*
 Probenecid + Colchicine
 Prolia (denosumab)
 Rheumatrex (methotrexate sodium)
 Salsalate *3rd trimester*
 Soma Compound w. Codeine (carisoprodol/aspirin/codeine) *3rd trimester*
 Vimovo (naproxen/esomeprazole) *Late pregnancy (≥ 30 wks)*
 Voltaren (diclofenac sodium) *Late pregnancy*
 Zipsor (diclofenac potassium) *Late pregnancy*

Neoplasms

Bexxar (tositumomab)
 Casodex (bicalutamide)
 Delestrogen (estradiol valerate)
 Efudex (fluorouracil)
 Eligard (leuprolide acetate)
 Estrace (estradiol)
 Evista (raloxifene HCl)
 Firmagon (degarelix)
 Fluoxymesterone
 Menest (esterified estrogens)
 Revlimid (lenalidomide)
 Targretin (bexarotene)
 Thalomid (thalidomide)
 Trelstar (triptorelan pamoate)
 Trexall (methotrexate)
 Vantas (histrelin acetate)
 Zytiga (abiraterone acetate)

Nutrition

Didrex (benzphetamine)

Pregnancy categories

When pregnancy appears as a contraindication or precaution to the use of a drug, it is usually qualified by a category.

Cat. A: Adequate studies in pregnant women have failed to show a risk to the fetus in the first trimester and there is no evidence of risk in later trimesters.**Cat. B:** Animal studies have failed to show a risk to the fetus but there are no adequate studies in pregnant women; or animal studies have shown an adverse effect but human studies have not shown a risk to the fetus in the first trimester and there is no evidence of risk in later trimesters.**Cat. C:** Animal studies have shown an adverse effect on the fetus but there are no adequate studies in humans, but the benefits may outweigh the risks; or there are no adequate human studies.**Cat. D:** Positive evidence of human fetal risk but the benefits may outweigh the risks.**Cat. X:** Animal or human studies have shown fetal abnormalities or toxicity and the risk outweighs the benefit<http://www.empr.com/drugs-contraindicated-in-pregnancy/article/125914/> (accessed 30 September 2013).**APPENDIX 25.2 DRUG EFFECTS ON BREAST-FEEDING INFANTS**

Drug	Reported outcomes of use
Alcohol (ethanol)	With large amounts, drowsiness, weakness, decrease in linear growth, abnormal weight gain
Aspirin (salicylates)	Metabolic acidosis (rare)
Atenolol	Cyanosis; bradycardia
Bendroflumethiazide	Suppression of lactation
Caffeine	Irritability, poor sleeping pattern, excreted slowly; no effect with moderate intake of caffeinated beverages (2–3 cups per day)
Carbimazole	Goitre
Chloral hydrate	Sleepiness
Contraceptive pill with oestrogen/progestogen	Rare breast enlargement; decrease in milk production and protein content
Danthron	Increased bowel activity
Dexbrompheniramine maleate with <i>D</i> -isoephedrine	Crying, poor sleeping patterns, irritability
Ethosuximide	Appearance of drug in infant blood
Indometacin	Seizure (rare)
Iodides	May affect thyroid activity; goitre
Iodine	Goitre
Iodine (povidone–iodine)	Elevated iodine levels in breast milk, odour of iodine on infant's skin
Nalidixic acid	Haemolysis in glucose-6-phosphate dehydrogenase (G6PD) deficiency
Nitrofurantoin	Haemolysis in infant with G6PD deficiency
Phenobarbital	Sedation; infantile spasms after weaning, methaemoglobinaemia (rare)
Phenytoin	Methaemoglobinaemia (rare)
Sulfapyridine	Caution in jaundice or G6PD deficiency and ill, stressed or premature infant
Sulfisoxazole	Caution in jaundice or G6PD deficiency and ill, stressed or premature infant
Tetracyclines	Tooth discolouration
Theophylline	Irritability
Tolbutamide	Possible jaundice

Traditional medicine is widely practised across the world, particularly in Asian and African cultures. In the developed world, therapies that are not currently considered an integral part of conventional allopathic medical practice are termed *complementary* (when used in addition to conventional treatments) and *alternative* (when used instead of conventional treatments). Such therapies (complementary and alternative medicine – or CAM) include, but are not limited to, acupuncture, aromatherapy, chiropractic, colonic irrigation, diet fads (Ch. 27), faith healing, folk medicine, herbal (natural) medicine, homoeopathy, meditation, naturopathy, new-age healing, massage and music therapy.

During 2007, almost 40% of adults in the USA used CAM, the most commonly used therapies being non-vitamin, non-mineral, natural products and deep breathing exercises (<http://www.cdc.gov/nchs/data/nhsr/nhsr012.pdf>; accessed 30 September 2013). Over the preceding 5 years, there was increased use of acupuncture, deep breathing exercises, hypnotherapy, massage therapy, meditation, naturopathy and yoga, but use for colds showed a marked decrease. However, there is only limited evidence of efficacy for many CAM therapies. For instance, PubMed, the National Library of Medicine journal database, identified 40 systematic reviews involving acupuncture, massage therapy, naturopathy or yoga, only 10 of which (25%) provided sufficient evidence to conclude that a given therapy was effective for a given condition. These were acupuncture for knee pain, insomnia and nausea or vomiting, and acupuncture and yoga for back pain; both acupuncture and massage therapy are included among recommended therapies for back pain. CAM is taken increasingly seriously in the West and there is a National Centre for Complementary and Alternative Medicine (NCCAM) in the USA.

Since there is some evidence of increasing use by the public and of efficacy, this chapter focuses on forms of traditional medicine, acupuncture, herbal medicines and probiotics. Herbal alternatives to hormone replacement therapy are discussed in Chapter 25; omega-3 and omega-6 are discussed in Chapter 27.

TRADITIONAL CHINESE MEDICINE

Traditional Chinese medicine (TCM; <http://nccam.nih.gov/health/whatiscam/chinesemed.htm>, accessed 30 September 2013) views how the body works, what causes illness and how to treat illness, differently from Western views. TCM is typically delivered by a practitioner who uses acupuncture, herbs and other methods to treat a wide range of conditions. Other TCM practices include cupping, dietary therapy, massage, mind–body therapy and moxibustion (the burning of mugwort, a small herb). Acupuncture has the largest body of evidence and is considered safe if practised correctly. Some Chinese herbal remedies may be safe; others may not be.

ACUPUNCTURE

A limited number of randomized controlled trials (RCTs) support acupuncture as a possible treatment for a range of conditions that include anxiety, cancer and chemotherapy-induced nausea, depression, insomnia, migraine, musculoskeletal pain and postoperative pain. However,

Table 26.1 *Acupuncture in orofacial conditions (benefit proved)*

Probably	Possibly	Inconclusive
Dental pain	Dental local anaesthesia – reduced time to onset	Bell palsy
Postoperative or chemotherapy-induced nausea/vomiting	Gag reflex	Burning mouth sensation
Postoperative pain	Hyposalivation	Mouth ulceration
Temporomandibular joint pain	Neck pain	Sensory loss
		Sinusitis

there is inadequate evidence of benefit in conditions such as asthma, dysphagia, epilepsy, schizophrenia, smoking cessation or stroke.

Dental aspects

There are several publications but few RCTs on acupuncture used for orofacial conditions (Table 26.1). Efforts have been made to clarify mechanisms but consensus has yet to be reached. Any efficacy may be explained by possible release of endogenous opiates (beta-endorphin, enkephalin, endomorphin and dynorphin; Ch. 10) during acupuncture. The serotonergic descending inhibitory pathway is an alternative suggested mechanism. The autonomic nervous system and resultant inflammatory reflex might be part of antihyperalgesia elicited by acupuncture.

AYURVEDIC MEDICINE

Ayurvedic medicine (Ayurveda; <http://nccam.nih.gov/health/ayurveda/introduction.htm>; accessed 30 September 2013) originated in India. Its aim is to integrate and balance the body, mind and spirit because it is believed that this helps prevent illness and promote wellness. Many therapies employed in Ayurvedic medicine are also used on their own as CAM – for example, herbs, massage and specialized diets. Some of the products may be harmful (causing adverse effects or interacting with conventional medicines). Different systems used to treat oral diseases, individually or in combinations, include *Acacia chundra* Willd., *Adhatoda vasica* Nees, *Mimusops elengi* L., *Piper nigrum* L., *Pongamia pinnata* (L.) Pierre, *Quercus infectoria* Olivier, *Syzygium aromaticum* L., *Terminalia chebula* Retz and *Zingiber officinale* Roscoe.

CAM IN OTHER CULTURES

Details of African, American Indian, Latin American, Caribbean and other important CAM can be found at: <http://www.ncbi.nlm.nih.gov/pmc/journals/970/> and <http://americanindianhealth.nlm.nih.gov/> (both accessed 30 September 2013).

HERBAL MEDICINES

Many conventional drugs that have been proven to be effective originated from plant sources. Examples include aspirin (from willow bark), digoxin (foxglove), morphine (opium poppy) and quinine (cinchona bark). However, natural does not signify safe. Some plant products (e.g. opioids, cocaine and peyote) are addictive (Ch. 34) and many are highly toxic; for example, some Chinese weight-loss herbs are nephrotoxic, and kava-kava (*Piper methysticum*) is hepatotoxic. Chamomile, liquorice root, quassia and red clover all contain coumarin derivatives and can provoke a bleeding tendency. Some other herbal products may impair platelet aggregation, thus prolonging bleeding (Table 26.2). Herbs that pose a risk for cardiac patients are shown in Box 26.1.

Some herbal drugs appear to be effective and fairly safe, and there are reliable published data supporting a potential medicinal role for aloe vera, melatonin, saw palmetto and St John's wort (Table 26.3). Reliable published data on efficacy are weaker for ginkgo biloba and alpha-lipoic acid, and are contradictory for valerian and echinacea. Research into the safety and efficacy of most herbals has been limited

because of product variability, lack of controlled studies and few legal controls (Appendices 26.1 and 26.2).

ALOE VERA

Aloe vera, derived from *Aloe barbadensis* Miller, contains many constituents, some of which purportedly have anti-inflammatory, anti-septic and/or analgesic properties. These include:

- vitamins: A (beta-carotene), C, E, B₁₂, folic acid and choline
- enzymes: alkaline phosphatase, amylase, bradykinase, carboxypeptidase, catalase, cellulase, lipase and peroxidase
- minerals: calcium, chromium, copper, selenium, magnesium, manganese, potassium, sodium and zinc
- sugars: monosaccharides (glucose and fructose) and polysaccharides (glucomannans/polymannose)
- anthraquinones
- fatty acids: cholesterol, campesterol, beta-sitosterol and lupeol
- hormones: auxins and gibberellins
- others: amino acids, salicylic acid, lignin and saponins.

Aloe may have healing and protective effects against radiation damage, and anti-inflammatory, antiviral and antiseptic properties. There

Table 26.2 Herbal products that may inhibit haemostasis

Herbal	Source
Bilberry	<i>Vaccinium myrtillus</i>
Bromelain	<i>Anas comosus</i>
Cat's claw	<i>Uncaria tomentosa</i>
Devil's claw	<i>Harpagophytum procumbens</i>
Dong quai	<i>Angelica sinensis</i>
Evening primrose	<i>Oenothera biennis</i>
Feverfew	<i>Tanacetum parthenium</i>
Garlic	<i>Allium sativum</i>
Ginger	<i>Zingiber officinale</i>
Ginkgo biloba	<i>Ginkgo biloba</i>
Ginseng	<i>Panax ginseng</i>
Grape seed	<i>Vitis vinifera</i>
Green tea	<i>Camellia sinensis</i>
Horse chestnut	<i>Aesculus hippocastanum</i>
Turmeric	<i>Curcuma longa</i>

Box 26.1 Herbs that may interact with cardiovascular drugs

- Liquorice root – contains glycyrrhetic acid and can increase blood pressure
- Ma huang – contains ephedrine
- Foxglove – source of digitalis
- Hawthorn – contains oligomeric procyanins, with hypocholesterolaemic action, and can enhance digoxin
- Tan shen – may inhibit platelet aggregation and potentiate warfarin
- Willow bark – contains salicin (a source of acetylsalicylic acid [ASA])
- Garlic – antiplatelet activity; high doses may reduce serum thromboxane levels
- Ginkgo (maidenhair tree) – ginkgolides inhibit platelet-activating factor, decrease vascular resistance and improve circulatory flow
- Hellebore – contains alkaloids that may cause bradycardia and hypotension
- Wu-chu-yu (*Evodia rutaecarpa*) – contains rutaecarpine, a vasorelaxant

Table 26.3 Herbal preparations and supplements of proven efficacy

Herbal preparation	Effective for treating	Derived from	Possible interactions	Possible adverse effects
Saw palmetto	Benign prostatic hyperplasia	<i>Serenoa repens</i>	–	Minimal
Melatonin	Jet lag	Synthetic	Warfarin	–
Aloe vera	Chronic skin issues Lichen planus	<i>Aloe vera</i> Linne or <i>Aloe barbadensis</i>	Digoxin Hypoglycaemics	Dermatitis In animals – colon cancer
St John's wort	Mild to moderate depression	A yellow-flowered weed, <i>Hypericum perforatum</i>	Induces cytochrome P450 hepatic enzyme system, specifically CYP3A4 isoform, and thus interacts with many drugs (see Box 26.2) May also intensify or prolong the effects of some narcotic drugs and anaesthetic agents	Dry mouth, dizziness, gastrointestinal symptoms, increased sensitivity to sunlight and fatigue
Ginkgo biloba	Improved memory; stable or slowed deterioration in Alzheimer disease	A flowering tree native to China	Anticoagulant and antiplatelet medicines	Minimal
Echinacea	Increases the 'non-specific' activity of immune system Contradictory reports of efficacy in prevention of upper respiratory infections	<i>Echinacea purpurea</i>	Anabolic steroids	Should not be used in progressive systemic and autoimmune disorders such as tuberculosis, or connective tissue disorders

are reports of efficacy in seborrhoeic dermatitis, psoriasis, herpes, burns, wound healing, pressure ulcers, mucositis, radiation dermatitis, acne, lichen planus and aphthous stomatitis.

Aloe may cause redness, burning, a stinging sensation and, rarely, dermatitis. Abdominal cramps, diarrhoea, red urine, hepatitis, dependency or worsening of constipation are also possible. Its laxative effect may cause electrolyte imbalances (low potassium levels). Prolonged use (in animals) has reportedly increased the risk of colorectal cancer.

Oral aloe is not recommended during pregnancy due to theoretical stimulation of uterine contractions, and if taken by breast-feeding mothers it may sometime causes gastrointestinal distress in the nursing infant. Aloe reduces the effectiveness and may increase the adverse effects of digoxin and digitoxin, due to its potassium-lowering effect. It decreases blood sugar levels and thus may interact with hypoglycaemic drugs and insulin. Aloe should not be taken for 2 weeks prior to any surgical procedure, as it may cause increased bleeding.

Further information on aloe is available at: <http://umm.edu/health/medical/altmed/> (under 'Herb' and 'Herb Interaction') and <http://nccam.nih.gov/health/aloevera> (both accessed 30 September 2013).

GINGKO BILOBA

The flavonoids found in ginkgo may help prevent or reduce retinal problems and age-related macular degeneration; they may also enhance neuropsychological/memory processes, and possibly are effective in Alzheimer disease, improving cognitive performance, global function and activities of daily living, and, at least *in vitro*, inhibiting amyloid-beta aggregation and caspase-3 activation (Ch. 13). Meta-analyses comparing ginkgo with acetylcholinesterase inhibitors in Alzheimer disease have shown similar clinical efficacy, with an additional safety benefit for ginkgo. Ginkgo might cause early labour; it might also interfere with diabetes management, provoke seizures or cause a bleeding disorder.

Ginkgo can interact with some medications, including anticonvulsants, antidepressants (SSRIs – may increase the risk of serotonin syndrome), antihypertensives, and drugs such as warfarin, clopidogrel, aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). It is recommended that ginkgo be stopped at least 2 weeks before surgery.

More information is available at: <http://umm.edu/health/medical/altmed/herb/ginkgo-biloba> and <http://www.nlm.nih.gov/medlineplus/druginformation.html> (both accessed 30 September 2013).

MELATONIN

Melatonin taken in the evening in the new time zone will reset the biological clock and alleviate (or prevent) symptoms of jet lag. Melatonin helps determine when a woman starts to menstruate, the frequency and duration of menstrual cycles, and when a woman stops menstruating (menopause). The incidence of adverse effects to melatonin is low. Interactions are possible with anticoagulants, antidepressants, antihypertensives, antipsychotics, benzodiazepines, beta-blockers, corticosteroids or other immunosuppressants, interleukin-2, NSAIDs and tamoxifen.

More information is available at: <http://umm.edu/health/medical/altmed/supplement/melatonin> (accessed 30 September 2013).

SAW PALMETTO

Saw palmetto, from *Serenoa repens* fruit, can be effective treatment for benign prostatic hypertrophy (BPH), producing similar improvements in urinary symptoms and flow to finasteride – and with fewer adverse effects. However, the long-term effectiveness, safety and ability to

prevent BPH complications are unknown. Saw palmetto may interact with anticoagulants, antiplatelets, finasteride, hormonal contraceptives and hormone replacement therapy (HRT).

More information is available at: <http://umm.edu/health/medical/altmed/herb/saw-palmetto> (accessed 30 September 2013).

ST JOHN'S WORT

St John's wort (*Hypericum perforatum*; SJW) is beneficial in mild to moderate depression. It also induces various drug-metabolizing enzymes (cytochrome P450 isoenzymes, CYP3A4, CYP2C9, CYP1A2, and the transport protein P-glycoprotein), which lowers blood levels and therapeutic effects of some drugs (Box 26.2). It is important also to note that, when patients stop taking SJW, blood levels of interacting

Box 26.2 Drugs to be avoided with St John's wort

- Anthracycline
- Anticoagulants
- Anticonvulsants
- Antidepressants
- Antiretrovirals
- Azole antifungals
- Benzodiazepines
- Calcium-channel blockers
- Carbamazepine
- Cardiovascular drugs
- Ciclosporin
- Cytotoxic drugs
- Dextromethorphan
- Digoxin
- Docetaxel
- Eszopiclone
- Etoposide
- Hormonal contraceptives
- HRT
- Imatinib
- Immunosuppressants
- Indinavir
- Irinotecan
- Lithium
- Loperamide
- Monoamine oxidase inhibitors (MAOIs)
- Oral contraceptives
- Paclitaxel
- Phenprocoumon
- Protease inhibitors (PIs)
- Ramelteon
- Selective serotonin reuptake inhibitors (SSRIs)
- Statins
- Tamoxifen
- Teniposide
- Theophylline
- Thyroxine
- Tricyclic antidepressants
- Triptans
- Vinca alkaloids
- Warfarin
- Zaleplon
- Zolpidem

medicines may rise, resulting in toxicity. SJW should be stopped at least 5 days or more before surgery.

SJW may worsen symptoms of attention deficit disorder (ADD) and attention deficit hyperactivity disorder (ADHD), increase the risk of psychosis in schizophrenia, and may contribute to dementia in Alzheimer disease.

More information is available at: <http://umm.edu/health/medical/altmed/> (under 'Herb' and 'Herb Interaction') and <http://nccam.nih.gov/health/stjohnswort> (both accessed 30 September 2013).

ALPHA-LIPOIC ACID

Alpha-lipoic acid is found in red meat, liver and yeast, as well as being made by the body, where it is changed into dihydrolipoic acid. Alpha-lipoic acid appears to help lower blood sugar levels and may help people with diabetic peripheral neuropathy. It has been used to treat burning mouth syndrome. Alpha-lipoic acid may interact with hypoglycaemics, chemotherapy or thyroid hormone.

More information is available at: <http://umm.edu/health/medical/altmed/> (under 'Supplement' and 'Supplement Interaction'; accessed 30 September 2013).

ECHINACEA

Echinacea was promoted as an immunostimulator, especially for reducing the common cold; however, three of four published studies concluded that taking echinacea to prevent a cold was ineffective. It is also ineffective in combating cancers. People with tuberculosis, leukaemia, diabetes, connective tissue disorders, multiple sclerosis, HIV/AIDS, autoimmune diseases or, possibly, liver disorders should not take echinacea. Echinacea may interact with immunosuppressants. People with asthma and allergies may be at an increased risk for developing adverse reactions. When taken by mouth, echinacea may cause temporary numbing and a tingling tongue. Its safety in pregnancy or breast-feeding is unclear.

More information is available at: <http://umm.edu/health/medical/altmed/herb/echinacea> (accessed 30 September 2013).

DENTAL ASPECTS OF HERBALS

There are weak data on the possible effects of aloe extracts, berries, chamomile, cocoa, coffee, grapes, honey/propolis, myrtle, polyphenols (stilbenes, flavonoids and proanthocyanidins) and tea on various oral diseases (caries, gingivitis, periodontal disease, candidiasis, aphthae, mucositis, lichen planus, leukoplakia and oral cancer) but no strong evidence (Table 26.4).

Herbals may influence treatment, especially in that they may interact with other drugs (e.g. when benzodiazepine sedation is used; Table 26.5) or produce a bleeding tendency.

PROBIOTICS

Probiotics are live microorganisms, added to food with the intention of benefitting the host by changing intestinal microbial balance. The main probiotics used include *Lactobacillus rhamnosus* GG, *L. reuteri*, bifidobacteria, certain strains of *L. casei* or the *L. acidophilus* group, *Escherichia coli* strain Nissle 1917, certain enterococci (*Enterococcus faecium* SF68) and *Saccharomyces boulardii*.

The underlying mechanisms of probiotic action are unclear but may include strengthening of the non-immunological gut barrier, pathogen

Table 26.4 Herbs and other preparations and oral disease

Preparation	Purported effects
Pilocarpine in Brazilian 'slobber plant' (<i>Pilocarpus jaborandi</i>)	Helps hyposalivation
Aloe vera	See Table 26.3
Acemannan (an aloe polysaccharide)	Relief in aphthae
B vitamins	
<i>Eupatorium laevigatum</i> Lam.	
<i>Lactobacillus acidophilus</i> and <i>L. bulgaricus</i>	
Liquorice with glycyrrhizic acid removed (deglycyrrhized liquorice; DGL)	
LongoVital	
Tannins (in agrimony, cranesbill, tormentil, oak, periwinkle and witch hazel)	
Zinc	
Capsaicin	May help in burning mouth syndrome
Lipoic acid	
Zinc	May help in taste disturbances

Table 26.5 Potential interactions of herbal preparations with benzodiazepines

Herbal preparation	Potential effect on sedation
Dong quai	Increased
Houpu	Increased
Kava kava	Increased
Passion flower	Increased
St John's wort	Reduced
Tan shen	Increased
Valerian	Reduced

growth inhibition and interference with adhesion, and enhancement of mucosal immune systems, as well as the systemic immune response. Probiotics appear effective in preventing and reducing the severity of a number of conditions, as shown in Box 26.3, but there is insufficient evidence with respect to any suggested benefits from probiotics in prevention or therapy of ischaemic heart diseases, autoimmune disease or cancer.

RCTs on probiotics in oral health are few. Lactic acid-producing bacteria can generate antimicrobial factors (e.g. organic acids, hydrogen peroxide, carbon peroxide, diacetyl, antimicrobial substances, bacteriocins and adhesion inhibitors). *Lactobacillus* and *Bifidobacterium* may inhibit cariogenic streptococci and *Candida* species. Six of seven placebo-controlled studies on the effect of probiotics reported reduced salivary *Streptococcus mutans* and/or yeasts. A study carried out in 3–4-year-old children reported significant caries reduction after 7 months of daily consumption of probiotic milk. The bacteriocin producer *Streptococcus salivarius* K12 may reduce halitosis.

A prebiotic is a selectively fermented ingredient that allows specific changes in the composition and/or activity of the gastrointestinal microflora. Only bifidogenic, non-digestible oligosaccharides (particularly inulin, its hydrolysis product oligofructose, and [trans]galacto-oligosaccharides) fulfil criteria for classification as prebiotic; some may help prevent diarrhoea or constipation, and modulate intestinal flora metabolism, and may have positive effects on cancer prevention, lipid metabolism, mineral adsorption and immunity.

Synergistic combinations of probiotics and prebiotics are called synbiotics.

Box 26.3 *Conditions that may benefit from use of probiotics*

- Acute diarrhoea in children
- Antibiotic-associated diarrhoea
- Inflammatory bowel disease, especially ulcerative colitis
- Prevention of urogenital tract infection
- Reduction of atopy in children
- Reduction of lactose intolerance
- Reduction of cancer-promoting enzymes and/or gut putrefactive (bacterial) metabolites
- Normalization of passing stool and stool consistency in irritable bowel syndrome
- Prevention of respiratory tract infections (common cold, influenza)

More information on *L. acidophilus* is available at: <http://umm.edu/health/medical/altmed/supplement/lactobacillus-acidophilus> (accessed 30 September 2013).

HYPNOTHERAPY

Hypnotherapy is a complementary therapy that uses hypnosis, an altered state of consciousness and, despite there being no strong evidence, is widely promoted as a treatment for breaking certain habits, such as smoking, bruxism, or thumb-sucking, or for various long-term conditions such as anxiety, eczema, gagging, idiopathic facial pain, temporomandibular pain-dysfunction or irritable bowel syndrome.

APPENDIX 26.1 HERBAL PREPARATIONS AND SUPPLEMENTS OF UNPROVEN EFFICACY

Herbal preparation	Purported use for 'treating'	Interactions possible with	Comments
<i>Agnus castus</i> fruit extract	Premenstrual syndrome	–	–
Butterbur (<i>Petasites hybridus</i>)	Allergic rhinitis	–	–
Coenzyme Q ₁₀ (CoQ ₁₀ , Q ₁₀ , vitamin Q10, ubiquinone or ubiquinone)	Breast and other cancer control	Warfarin	–
	Periodontal disease (no proven benefit)	Insulin	–
Cranberry–lingonberry juice	Recurrent urinary tract infections	–	Possibly effective
Feverfew (<i>Chrysanthemum parthenium</i>)	Migraine prophylaxis	Anticoagulants	–
Garlic	Mildly elevated cholesterol and blood pressure and to help arteries remain elastic. Also has antibacterial properties	Anticoagulants	Has antiplatelet activity
		Saquinavir	
Ginger	Nausea and vomiting	–	May impair platelet activity
Ginseng	Aphrodisiac, antidepressant, increases resistance, and improves both physical and mental performance	–	Possibly effective. Can cause bleeding, hypertension and tachycardia
Glucosamine	Pain control and for improving function in osteoarthritis	–	Possibly effective
Senna	Constipation	–	Possibly effective
Valerian (<i>Valeriana officinalis</i>)	Sleep disturbance	Barbiturates	–

APPENDIX 26.2 HERBAL PREPARATIONS AND SUPPLEMENTS OF UNPROVEN EFFICACY HAVING POSSIBLE ADVERSE EFFECTS

Herbal medicine	May also contain	Possible health hazard
<i>Aristolochia</i> plantain	<i>Digitalis lanata</i>	Cardiac
Arthrin	Indometacin and alprazolam	Sedation
Chaparral (a traditional American Indian medicine)	–	Liver disease
Comfrey (<i>Symphytum</i> species)	–	Hepatic blood flow obstruction
Ephedra, ma huang, Chinese ephedra and epitonin	–	Hypertension, arrhythmia. Nerve damage, insomnia, tremors, headaches, seizures, stroke and death
Germander (<i>Teucrium</i> species)	–	Liver disease
Germanium	–	Kidney damage, possibly death
Green leaf tobacco	–	Nicotine poisoning

(Continued)

Herbal medicine	May also contain	Possible health hazard
Hepastat, neutralis, poena, osporo	Indometacin	–
Hua fo	Sildenafil	–
Jin bu huan	–	Liver disease
Kava kava	–	Liver damage
Lobelia (also known as Indian tobacco)	–	Breathing problems. Sweating, hypotension, tachycardia, and possibly coma and death at higher doses
L-Tryptophan	–	Eosinophilia myalgia syndrome
<i>Magnolia–Stephania</i>	–	Renal disease
Neo-melubrina	Metamizole (dipyrone)	–
Niacin	–	Stomach pain, vomiting, bloating, nausea, cramping, diarrhoea, liver disease, muscle disease, cardiac and eye damage
PC-SPES (a formula consisting of a combination of eight herbs that contain a range of plant chemicals including flavonoids, alkanoids, polysaccharides)	Warfarin	Bleeding
Pennyroyal	–	Liver disease
RA Spes	Alprazolam	Sedation
SOA Plus	Indometacin	–
Selenium	–	Tissue damage
Slimming/dieter's teas	–	Nausea, diarrhoea, vomiting, stomach cramps, constipation, fainting
SPES	Alprazolam	Sedation
Vitamin A	–	Birth defects, bone abnormalities, severe liver disease
Vitamin B ₆	–	Ataxia, nerve injury
Willow bark	Salicylates	Reye syndrome
Wormwood	–	Hypoaesthesia of legs and arms, loss of intellect, delirium and paralyses

DIET AND HEALTH

Dietary factors have been implicated as influencing a range of conditions (Box 27.1; see also Ch. 36).

Minimizing intake of saturated fat (especially from dairy sources) and partially hydrogenated vegetable fats lowers the risk of coronary artery disease and some cancers (Chs 5 and 22). In contrast, consumption of monounsaturated fats, such as olive oil, and omega oils may be beneficial. Generous amounts of vegetables and fruit daily appear to offer some protection against cancers of the stomach, colon and lung, and possibly against cancers of the mouth, larynx, cervix, bladder and breast (Ch. 22). Citrus fruits and juices in excess, however, may cause tooth erosion.

Carbohydrates as wholegrain, unrefined products may offer some protection against colon cancer, diverticulitis and dental caries. A high-fibre diet may offer some protection against hypertension and coronary heart disease (Ch. 5).

MALNUTRITION

Malnutrition is mainly a consequence of lack of resources and education, and results from imbalance between people's needs and their intake of nutrients, which can lead to obesity or to syndromes of deficiency, dependency or toxicity. Overnutrition develops over time from overeating; insufficient exercise; overprescription of therapeutic diets, including parenteral nutrition; excess intake of vitamins, particularly pyridoxine (vitamin B₆), niacin and vitamins A and D; and excess intake of trace minerals. Undernutrition (starvation) usually results from inadequate intake; malabsorption; abnormal systemic loss due to diarrhoea, haemorrhage, renal failure, cancer or excessive sweating; infection; or addiction to drugs. Undernutrition can develop rapidly.

OBESITY

General aspects

To most people, the term 'obesity' means the state of being very overweight; however, 'overweight' is sometimes defined as an excess amount of body weight that includes muscle, bone, fat and water, while 'obesity' specifically refers to excessive body fat. Some people, such as bodybuilders or other athletes with a lot of muscle, can be overweight without being obese. Obesity is the main nutritional problem in developed countries (Fig. 27.1), though some body fat is needed for energy, heat insulation, shock absorption and other functions. As a rule, women have more body fat than men. Men with more than 25% body fat and women with more than 30% body fat are obese.

Almost 25% of North American adults are now clinically obese and obesity is increasing in children. More than 60% of Americans aged 20 years and older are overweight. Europe and Japan follow similar patterns. In 2012 in England, 16% of children and 26% of adults were obese. The prevalence of obesity in England has more than tripled in the last 25 years.

Obesity results from eating more than the body needs – an imbalance between calories in and calories out. Control of eating and weight regulation is complex and involves a range of endocrine and nervous

Box 27.1 Conditions that may be influenced by diet

- Alzheimer disease
- Birth defects such as facial clefts and spina bifida
- Cancer
- Cardiovascular disease (arteriosclerosis, hypertension and coronary artery disease)
- Dental caries and erosion
- Diabetes and the 'metabolic syndrome'
- Drug absorption and metabolism

Fig. 27.1 Obesity – the main nutritional problem today.

signals, especially peptide YY, ghrelin, insulin, cholecystokinin and leptin (Table 27.1). The body monitors blood glucose concentration, which contributes to the overall regulation of food intake, via GLUT2 transporters, which mediate glucose entry to the cells, and the glucokinase enzyme. This makes their intracellular adenosine triphosphate (ATP) supply exquisitely sensitive to glucose availability, and forms the basis for their signalling systems by pancreatic beta-cells; portal vein glucose sensor; carotid bodies; the nucleus of the solitary tract; and the hypothalamus – which triggers a massive sympathetic response to hypoglycaemia, with pounding heart, trembling, anxiety, sweating and hunger. However, the effects of hyperglycaemia on feeding and satiation are less obvious, and may even lead to paradoxical overeating. Leptin (from the Greek *leptos*, meaning thin) is a protein hormone released by fat cells that counteracts the effects of neuropeptide Y, a potent feeding stimulant secreted by cells in the gut; it has important effects in regulating metabolism, reproductive function and body weight, acting on the hypothalamic arcuate nucleus to suppress eating behaviour and also to increase energy expenditure. Leptin also acts directly on the liver and skeletal muscle, where it stimulates the oxidation of fatty acids in the mitochondria, reducing the storage of fat in those tissues (but not in adipose tissue). The absence of functional leptin (or its receptor) leads to uncontrolled food intake and resulting

Table 27.1 Complications of obesity (plus various cancers)

Cardiovascular	Orthopaedic	Psychosocial	Gastrointestinal	Respiratory	Metabolic and endocrine	Gynaecological
Hypertension	Accidents	Depression	Diverticulitis	Cor pulmonale	Diabetes mellitus	Amenorrhoea
Ischaemic heart disease	Gout	Social effects	Gallstones	Sleep apnoea	Hyperlipoproteinaemias (types II, III and IV)	Menstrual irregularities and infertility
Stroke	Osteoarthritis		Hiatus hernia (and other hernias)			Polycystic ovaries
Varicose veins			Liver disease			Uterine prolapse

obesity. Rarely, mutations in the leptin gene or its receptor are found in obese people but these are only a very uncommon cause of morbid obesity. Recombinant human leptin trials in the hope of reducing obesity in humans have so far had no great benefit.

Many other factors that appear to affect appetite, satiation and obesity include proinflammatory cytokines (tumour necrosis factor alpha [TNF α], interleukin-6 [IL-6] and IL-1); incretins (cholecystokinin, gastric inhibitory peptide [GIP], glucagon-like peptide 1 and glucagon-like peptide 2); the melanocortin receptor system (MCR); cocaine and amphetamine-regulated transcript (CART); thyrotropin-releasing hormone; corticosteroids; and growth hormone (for more information, see <http://www.bmb.leeds.ac.uk/teaching/icu3/lecture/26>; accessed 30 September 2013).

Environmental factors affecting body weight include lifestyle behaviours, such as what a person eats and their level of physical activity. Psychological factors may play a role; many people eat in response to negative emotions such as boredom, sadness or anger. Some anti-depressants can cause weight gain. Genetic factors, hormonal influences, hypothalamic disease (Frohlich, Laurence–Moon–Biedl or Prader–Willi syndromes), endocrinopathies (hypothyroidism, Cushing disease or insulinoma) or drugs (e.g. steroids) can rarely be implicated.

Clinical features

There is about a threefold increase in premature deaths in obese patients because of heart disease, type 2 diabetes, hypertension, stroke and cancer (see Table 27.1; Fig. 27.2). Obese men are more likely than non-obese men to die from cancer of the colon, rectum or prostate. Obese women are more likely to die from cancer of the gallbladder, breast, uterus, cervix or ovaries.

General management

Measuring body fat is not easy. A simple method is to measure the subcutaneous fat thickness in several parts of the body with skin callipers. The most accurate methods are to weigh the person under water or to use dual-energy X-ray absorptiometry (DEXA). Body mass index (BMI), the standard for measuring overweight and obesity, uses a formula based on height and weight: BMI equals weight in kilograms divided by height in metres squared (BMI = kg/m²; Table 27.2). Because measuring body fat is difficult, health-care providers often rely on weight-for-height tables – a range of acceptable weights for a person of a given height. However, these tables do not distinguish between muscle and excess fat.

Bariatric medicine (from the Greek *baros* [weight] and *-iatrics* [medical treatment]) is the term used for the specialty of caring for obese patients. Weight loss is recommended, particularly if there are two or more of the following:

- Family history of heart disease or diabetes
- Pre-existing disorders, such as hypertension, hyperglycaemia or hypercholesterolaemia
- ‘Apple’ body shape.

Fig. 27.2 Obesity outcomes.

Table 27.2 Body mass index (BMI)

BMI (kg/m ²)	Classification
<18.5	Underweight
18.5–24.9	Normal
25.0–29.9	Overweight
30.0–34.9	Obesity class I
35.0–39.9	Obesity class II
≥40	Obesity class III

The method of treatment depends on the degree of obesity, overall health condition and motivation to lose weight. It may include a combination of diet, exercise, behaviour modification and sometimes weight-loss drugs (Table 27.3) or surgery. People who have a BMI of 30 or more can improve their health by weight loss – especially if they are severely obese. A weight loss of 5–10% can do much to improve health by lowering blood pressure and cholesterol levels, and preventing type 2 diabetes in people at high risk for it. Sympathomimetic appetite suppressants are used only in the short-term treatment of obesity since their effect tends to decrease after a few weeks. Tesofensine is a new agent of possible benefit.

Table 27.3 *Drugs used in treatment of obesity*

Drug	Mechanism	Possible adverse effects	Comments
Butabindide	Blocks cholecystokinin breakdown	Not yet in clinical use	Inhibits tripeptidylpeptidase
Cholecystokinin promoters	Increase cholecystokinin receptors	–	–
Glucagon-like peptide 1	Delays gastric emptying, more insulin	–	Used in type 2 diabetes
Orlistat	Blocks pancreatic lipase	Anal leakage	Fatty stools
Sibutramine	Blocks 5-hydroxytryptamine (5HT) uptake/sympathomimetic	Dry mouth, headache	May cause hypertension and tachycardia
(Dex)fenfluramine	Blocks 5HT uptake	Cardiac valve defects	Withdrawn because of adverse effects
Troglitazone	Activates peroxisome proliferator-activated receptor gamma (PPAR γ)	Liver damage	Withdrawn because of adverse effects
Topiramate	Central nervous system (CNS) effects	CNS effects	Poor compliance

In severe obesity, bariatric surgery may rarely be recommended. It aims at:

- reducing stomach size:
 - vertical banded gastroplasty (Mason procedure, stomach stapling)
 - laparoscopic adjustable gastric band (LAGB; REALIZE[®] band – lap band)
 - sleeve gastrectomy
 - transoral gastroplasty
- reducing food absorption:
 - biliopancreatic diversion (Scopinaro procedure – rare)
- or mixed procedures:
 - gastric bypass
 - sleeve gastrectomy with duodenal switch
 - implantable gastric stimulation.

Severely obese people can encounter many problems relating to health-care access.

Dental aspects

Bariatric surgeries may be associated with an increased risk for gastro-oesophageal reflux and taking a more cariogenic diet, which in turn might account for the higher amount of carious and erosive tooth surface loss seen in bariatric patients. Jaw wiring of obese patients appears to be an effective and safe way of substantially reducing weight in those in whom simpler methods fail, but relapse frequently follows.

Dental treatment of obese patients may be complicated mainly by the sheer size of the patient and difficulties in accessing the dental chair. Bariatric dental chairs suitable for all patient groups up to 454 kg (1000 lb; 71 st) are available, in which large, overweight, obese and bariatric patients can be safely treated (e.g. Diaco, Barico). Respiration is impaired if the patient is laid supine. The total work of breathing is greater and, even at rest, obese patients need to ventilate more than normal. Some 10% of the grossly obese have hypoventilation, cor pulmonale and episodic somnolence (Pickwickian syndrome).

Local anaesthesia (LA) is satisfactory but may prove more difficult because of the thickness of the tissues. Conscious sedation (CS) may be given if required. Cardiac arrhythmias may be produced by the interaction of halogenated anaesthetics and large doses of amphetamines or amphetamine-like appetite suppressants (all controlled drugs), which should be discontinued a week before general anaesthesia (GA).

Treatment may also be complicated by diabetes or, rarely, by an organic cause of the obesity. Sympathomimetic appetite suppressants may interact with a range of drugs (Box 27.2).

Appetite suppressants, including sibutramine and phentermine, and herbal supplements containing ephedrine alkaloids/caffeine (ma huang, kola nut) can produce dry mouth.

Box 27.2 *Drugs that can interact with sympathomimetic appetite suppressants*

- Antidepressants
- Amantadine
- Amphetamines
- Caffeine
- Clofedanol
- Cocaine
- Methylphenidate
- Nabilone
- Pemoline

Table 27.4 *Vegetarianism*

Type of vegetarianism	Dietary habits
Fruitarianism	Eat only fruit products
Veganism	Abstain from all foods from animals, including dairy products
Lacto-vegetarianism	Like vegans, but eat dairy products
Lacto-ovo-vegetarianism	Like vegans, but eat dairy products and eggs
Pesco-vegetarianism	Like vegans, but eat dairy products, eggs and fish
Semi-vegetarianism	Like vegans, but eat dairy products, eggs, fish and poultry

EATING HABITS

Vegetarianism

Vegetarianism includes a range of habits (Table 27.4). *Vegans* are strict vegetarians, avoiding all foods of animal origin, including meat, poultry, fish, dairy products and eggs. This can lead to vitamin B₁₂ deficiency (Ch. 8), though this is surprisingly uncommon – vegans typically use yeast extracts and oriental-style fermented foods to provide B₁₂. Calcium, iron and zinc intakes also tend to be low. *Lacto-vegetarians* include dairy products in their diet. *Lacto-ovo-vegetarianism* – whose adherents also eat dairy products and eggs – is the most common form of vegetarianism. *Pesco-vegetarians* eat fish, dairy products and eggs along with plant foods. *Semi-vegetarians* eat some poultry and fish, dairy products and eggs. *Fruitarianism* eat only fruit and their diet is thus deficient in protein, salt and many micronutrients; this diet is not recommended.

Vegetarians tend to live longer and develop fewer chronic disabling conditions than their meat-eating peers. However, their lifestyle usually also includes regular exercise and abstention from alcohol and

tobacco, which may contribute to their improved health. Vegetarians may have less caries. Disadvantages are few; iron deficiency is the main risk. A fruitarian or prolonged lacto-vegetarian diet may suffer from dental erosion; citrus fruits, vinegar and acidic berries are especially responsible, particularly if ingested just before retiring to sleep.

Fad diets

Many commercial diets claim to enhance well-being or reduce weight but some have resulted in vitamin, mineral and protein deficiency states. Cardiac, renal and metabolic disorders, as well as some deaths, have resulted.

EATING DISORDERS

Eating is controlled by many factors, including appetite; food availability; family, peer and cultural practices; and attempts at voluntary control. Dieting is a common practice in the developed world and heavily promoted by fashion trends, sales campaigns and in some activities (e.g. fashion models). Food fads, selective eating (extreme fussiness) and food avoidance (without any fear of weight gain) are relatively common and usually fairly inconsequential in medical terms. Eating disorders, however, are of concern and are frequent among models, elite performers of certain sports or physical activities, ballet dancers, gymnasium users and bodybuilders.

Dieting to a body weight lower than is needed for health is common; eating disorders are also common and spotting the borderline between the two can be difficult. Eating disorders usually develop during adolescence or early adulthood, most often in females. They often coexist with other mental health issues, such as depression, substance abuse and anxiety disorders; they can disturb growth, lead to endocrine, cardiac and renal disease, and may be fatal. There are probably 90 000 people in UK receiving treatment.

Most people are concerned about their weight, so the early signs of eating disorders may easily be overlooked (Box 27.3). Eating disorders include anorexia nervosa (self-imposed starvation), bulimia nervosa (binge-eating and dieting), binge-eating disorder, and eating disorder not otherwise specified (EDNOS) (Table 27.5). Night-eating syndrome (NES) is also reportedly common – especially in obese people. Nocturnal sleep-related eating disorder (NS-RED) is not strictly an

Box 27.3 Early signs of eating disorders

- Changes in habits or activities
- Secretive behaviour
- Withdrawal from family or friends
- Weight loss
- Irregular menstruation or amenorrhoea
- Signs of vomiting
- Sudden disappearance of food from kitchen
- Finding of laxatives or diuretics

Table 27.5 The eating disorders^a

Anorexia nervosa	Bulimia nervosa	Binge-eating disorder	Night-eating syndrome	Eating disorder not otherwise specified ^b
Food intake				
Refusal to maintain body weight over a minimal normal for age and height	Recurrent episodes of binge-eating, including eating more than most people in a discrete period of time, and sense of loss of control	Recurrent episodes of binge-eating, including eating more than most people in a discrete period of time, and sense of loss of control	Eating excessively (hyperphagia) at night after retiring to bed	
Behaviour				
Intense fear of gaining weight or of becoming fat, even though underweight	Regular engagement in inappropriate compensatory behaviours	At least three behavioural measures of loss of control during bingeing	Obesity	
Disturbance in body perception	Minimum of at least two bingeing episodes each week for at least 3 months	Rapid eating	Insomnia, anorexia in the mornings	
	Persistent overconcern about body shape and weight	Eating until uncomfortably full	Minimum of at least 2 months	
	May be abuse of medications in order to lose weight	Eating large amounts when not hungry	Eating produces guilt and shame, not enjoyment	
		Eating large amounts outside meal times	Mood lower in mornings	
		Eating alone because of embarrassment at quantities eaten	Depression common	
		Negative feelings about self because of eating		
		Minimum of at least two bingeing episodes each week for at least 6 months		
		Marked distress at bingeing		
		No abuse of medications in order to lose weight		
Others				
Amenorrhoea				

^aModified from Diagnostic and Statistical Manual of Disease version 4 (DSM-IV).

^bDisorders of eating that do not fit criteria for other categories.

eating disorder; rather it is a type of sleep disorder in which people eat while 'sleepwalking', seeming to be sound asleep.

The main disorders that can have life-threatening health complications are anorexia nervosa and bulimia nervosa; they affect mainly females.

Anorexia nervosa

Anorexia nervosa is failure to eat, in the absence of any physical cause, to the extent that more than 15% of body weight is lost. It has several complications and may become life-threatening (Fig. 27.3). Body image may be distorted, so the emaciated patients consider themselves normal or even fat. Intense fear of gaining weight or becoming fat, even though underweight, with resistance to maintaining body weight at or above a minimally normal for age and height, is prominent (Box 27.4). Disturbance in body image, the way in which the body weight or

Fig. 27.3 Anorexia nervosa.

Box 27.4 Features of anorexia nervosa

- Low body weight
- Intense fear of gaining weight
- Disturbance in body image
- Attempts to control weight
- Peripheral cyanosis and coldness with bradycardia
- Females under 25 years, mainly
- Severe anorexia overriding hunger
- Sometimes self-induced vomiting (especially after orgies of eating)
- No other causal organic or mental disease
- Amenorrhoea

shape is perceived, undue influences of body weight or shape on self-evaluation, denial of the seriousness of the current low body weight, obsession in the process of eating and development of unusual habits are common. Examples include avoiding food and meals, picking out a few foods and eating these in small amounts, pushing food around the plate instead of eating, or carefully weighing and portioning food. Anorectics may repeatedly check their body weight, despite severe weight loss (Fig. 27.4). Engaging in techniques to control weight, such as intense and compulsive exercise, purging by means of vomiting, or abuse of laxatives, enemas, appetite suppressants, diuretics and thyroid hormones, is common.

Girls with anorexia often experience a delayed onset of the first menstrual period, since gonadotropin release is impaired. In others, periods may become infrequent or cease. Depression, anxiety, obsessive-compulsive disorder and self-harming are common. Growth may be impaired. Anorexia nervosa may be complicated by anaemia, endocrine disturbances, peripheral oedema and electrolyte depletion (hypokalaemia), peripheral cyanosis and coldness with bradycardia (see Table 27.5).

The course and outcome of anorexia nervosa vary. Some sufferers recover fully after a single episode; some have a fluctuating pattern of weight gain and relapse; and others experience a chronically deteriorating course over many years. The morbidity is high (Table 27.6) and mortality rate is about 12 times increased, cardiac arrest, electrolyte imbalance or suicide being the main causes.

Bulimia nervosa

Bulimia nervosa is recurrent episodes of binge-eating, which may be associated with compensatory behaviours such as self-induced vomiting and purgative abuse. The binge-eating and inappropriate compensatory behaviours are practised, on average, at least twice a week for 3 months. Features include irresistible craving for food, characterized by eating an excessive amount within a discrete period of time and by a sense of lack of control over eating during the episode. Recurrent inappropriate compensatory behaviour in order to prevent weight gain is common, and may include self-induced vomiting or misuse of laxatives, diuretics, enemas or other medications (purgings), fasting or excessive exercise. Bulimics often perform their behaviours in secrecy, feeling disgusted and ashamed when bingeing, and relieved once they purge.

Fig. 27.4 Anorexia nervosa. Severely thin limbs.

Table 27.6 Medical and oral complications of anorexia nervosa

Type	Complication
Cardiovascular	Bradycardia
	Hypotension
	Arrhythmias
	Cardiac failure
Endocrinological	Raised cortisol
	Reduced gonadotropins, thyroid and sex hormones
Gastrointestinal	Oesophagitis
	Oesophageal rupture
	Duodenal dilatation
	Constipation
Haematological	Bone marrow hypoplasia
	Pancytopenia
	Lowered plasma protein levels
Metabolic	Dehydration
	Hypothermia
	Hypokalaemia
	Hypercholesterolaemia
	Hypoglycaemia
Musculoskeletal	Abnormal liver function
	Osteoporosis
	Pathological fractures
	Impaired growth
	Myopathies
Neurological	Tetany
	Brain atrophy
	Seizures
Oral	Mucosal atrophy, glossitis and glossodynia
	Dental erosion
	Sialosis
	Hyposalivation
Renal	Low glomerular filtration rate (GFR)
	Hypokalaemic nephropathy

Box 27.5 Features of bulimia nervosa

- Recurrent episodes of binge-eating
- Recurrent inappropriate compensatory behaviour in order to prevent weight gain, e.g. self-induced vomiting or misuse of laxatives, diuretics, enemas or other medications (purging)

Bulimics usually weigh within the normal range for their age and height but, like individuals with anorexia, may fear gaining weight, desire to lose weight and feel intensely dissatisfied with their bodies (Box 27.5).

General management of eating disorders

Eating disorders are serious conditions with a high co-morbidity and a poor prognosis: only 30–50% make a full recovery. Acute management of severe weight loss (BMI <13) is usually provided in hospital, where medical care and monitoring are needed to try to restore healthy eating and deal with the underlying emotional/psychological issues (by cognitive behavioural or interpersonal psychotherapy, nutritional counselling and, when appropriate, medication). Selective serotonin reuptake inhibitors (SSRIs) may be helpful for weight maintenance and for resolving mood and anxiety symptoms.

Table 27.7 Management of patients with tooth erosion

Minimize tooth exposure to dietary acids	Increase oral pH	Caries protection
Reduce carbonated drinks, fruit juices, vinegar, alcohol	Mouth rinses of water, milk or bicarbonate	Non-cariogenic diet
Use a straw to drink low-pH fluids where feasible	Chewing gum	Fluorides
		Plaque control

Dental aspects of eating disorders

Repeated doses of paracetamol (acetaminophen) may be hepatotoxic in anorexia nervosa; doses should be kept to the minimum. Anaemia and the possibility of hypokalaemia and consequent arrhythmias must be kept in mind if GA is considered necessary.

Oral manifestations (see Table 27.6) can include erosion of teeth (perimylolysis) after repeated vomiting, usually most severe on lingual, palatal and occlusal surfaces. The patient should be counselled about diet and oral hygiene, what drinks and foods to avoid (Table 27.7) and how to reduce further erosion (e.g. by drinking colas and fruit juices through a straw). There is no evidence that tooth-brushing is harmful to eroded teeth, even soon after taking a drink of low pH. Topical bicarbonate after each vomiting incident, combined with daily sodium fluoride gel applications or a 0.05% sodium fluoride mouthwash, may lessen dental damage. Desensitizing toothpaste may also be indicated. Full-coverage plastic splints may be needed to protect the teeth and it may help to fill these splints with magnesium hydroxide. Restorative care may include dentine-bonded resins or composites, crowns or use of a Dahl appliance.

Parotid enlargement (sialosis) and angular stomatitis may develop, as in other forms of starvation. The parotid swellings tend to subside if the patient resumes a normal diet. Oral ulcers or abrasions, particularly in the soft palate, may be caused by fingers or other objects used to induce vomiting.

Pica

Pica is a condition in which the appetite is perverted. It is seen mainly in persons with learning disability or mental health issues, but is sometimes due to pregnancy or iron deficiency. Many unusual objects and substances may be ingested, such as buttons, screws, pins, nails, etc., and some may cause gastrointestinal obstruction or perforation (Fig. 27.5). In the past, children sometimes chewed painted objects and succumbed to lead poisoning, which still occurs in the developing world.

UNDERNUTRITION

General aspects

Severe undernutrition results mainly from poverty, especially in children and older people in the developing world or in war zones. Other causes include eating disorders, abuse (food restriction), oral problems, obstruction to the pharynx or oesophagus, malabsorption and cachexia of malignant disease or HIV/AIDS. Undernutrition is the most common cause of immunodeficiency worldwide.

Infants and children are at particular risk of undernutrition because of a high demand for energy and essential nutrients. Protein-energy malnutrition in children consuming inadequate amounts of protein, calories and other nutrients is a particularly severe form of

Fig. 27.5 Pica showing intra-abdominal ingested radio-opacities.

undernutrition, which retards growth and development. Deficiencies of iron, folic acid, vitamin C, copper, zinc and vitamin A may develop in inadequately fed infants and children. An exclusively breast-fed infant can develop vitamin B₁₂ deficiency if the mother is a vegan.

Adolescents are at risk since nutritional requirements go up as the growth rate increases. Requirements for all nutrients rise during pregnancy and lactation. Anaemia due to folic acid deficiency is common in pregnant women, especially those who have taken oral contraceptives, so folic acid supplements are now recommended to prevent neural tube defects (spina bifida) in their children. Aberrations of diet (rarely including pica) are common in pregnancy. An alcoholic mother may have a handicapped and stunted child with fetal alcohol syndrome. Caffeine has been implicated in miscarriages and underweight babies.

Older people, despite a reduction in physical activity lowering their energy and protein requirements, are at risk of undernutrition because of poverty, apathy or dementia. Diminished senses of taste and smell, poverty (real or perceived), loneliness, physical and mental impairments, immobility and chronic illness can also contribute. Furthermore, absorption may be impaired, contributing to iron deficiency, osteoporosis (also related to calcium deficiency), and osteomalacia due to lack of vitamin D and sunshine exposure (Ch. 25).

Clinical features

Features of undernutrition may include listlessness, emaciation, skin dryness, scaliness, atrophy, petechiae, ecchymoses, spooned nails, depigmentation, loss of hair and orofacial problems (angular stomatitis, glossitis, ulcers and sialosis).

General management

The history may reveal food faddism, lack of variety, inadequate intake of energy-rich and essential nutrients, poor appetite, gastrointestinal disturbance and recent weight loss. Chronic use of alcohol, cocaine, heroin, immunosuppressants or some antibiotics and anticonvulsants raises questions about the adequacy of vitamin and mineral nutrition.

The musculature should be examined for size, strength and tenderness. Neurological examination may detect disorientation, an abnormal

gait, altered reflexes, and sensory or motor neuron abnormalities. Painful bones and joints, osteopenia and distortions in the shape or size of bones (e.g. rachitic rosary) may indicate current or past malnutrition.

Nutritional status can be classified on the basis of BMI. The triceps skinfold estimates the amount of body fat within 20% and is therefore useful in determining the body's energy stores. Based on the mid-arm muscle area, muscle mass may be classified as adequate, marginal, depleted or wasted. Imaging (radiography, computed tomography [CT] or magnetic resonance imaging [MRI]) may be needed.

A full blood count and measurement of plasma proteins reflect the adequacy of amino-acid nutrition (albumin, pre-albumin and transferrin). Electrolyte assays may point to a mineral deficiency. Lipids and related lipoproteins should be assayed.

The patient may need hospital treatment, including nasogastric feeding. Refeeding syndrome (see below) must be avoided.

Dental aspects

Undernutrition in children can result in retarded tooth eruption. Latent undernutrition may predispose to burning mouth syndrome, mouth ulcers, glossitis and angular stomatitis. Resulting immunodeficiencies predispose to oral ulceration, angular stomatitis, necrotizing gingivitis and, rarely, gangrenous stomatitis (noma; cancrum oris) or sialosis (Ch. 20).

Whether chronic undernutrition is a significant factor that underlies many oral cancers is unclear, but there is a protective effect of diets rich in fresh fruits and vegetables, and in vitamins A and C. Iron deficiency is seen in the Paterson–Brown–Kelly (Plummer–Vinson) syndrome.

Dental care can be provided under LA. CS may be given in hospital. GA should, as always, be given in hospital.

Protein-energy malnutrition

General aspects

Protein-energy malnutrition (PEM), or protein-calorie malnutrition, is seen mainly in infants and children in some developing nations. Characterized not only by an energy deficit due to a reduction in all macronutrients and a deficit in many micronutrients, PEM is an example of the inadequate protein and/or energy intake that lies between starvation (no food intake) and adequate nourishment.

Clinical features

Clinically, PEM has three forms, which depend on the balance of non-protein and protein sources of energy. Each form can be graded as mild, moderate or severe by calculating weight as a percentage of expected weight for length using international standards (normal, 90–110%; mild, 85–90%; moderate, 75–85%; severe, <75%).

Marasmus (dry, thin, desiccated) is the predominant form of PEM in developing countries, and results from near-starvation with deficiency of protein and non-protein nutrients. The consequence is emaciation due to loss of muscle and body fat. Marasmic infants have hunger, weight loss, growth retardation, and wasting of subcutaneous fat and muscle. Marasmus is associated with the early abandonment or failure of breast-feeding and with consequent infections, notably those causing infantile gastroenteritis.

Kwashiorkor (an African word for 'first child–second child') is characterized by protein deficiency more than energy deficiency, and by oedema. It refers to the observation that the first child develops PEM when the second child is born and takes over at the breast.

Kwashiorkor is confined to areas where staple and weaning foods – such as yam, cassava, sweet potato and green banana – are protein-deficient and excessively starchy (rural Africa, Caribbean and Pacific islands). Generalized oedema, ‘flaky paint’ skin, thinning, decolouration and reddening of the hair, enlarged fatty liver and apathy are seen, in addition to retarded growth. Pneumonia, diarrhoea, otitis media, genitourinary disease and sepsis are almost invariable.

Marasmic kwashiorkor is a combined form of undernutrition between the two extremes.

General management

Differential diagnosis includes consideration of secondary growth failure due to malabsorption, congenital defects, renal failure, endocrine disease, infections or emotional deprivation.

Fluid and electrolyte abnormalities (hypokalaemia, hypocalcaemia, hypophosphataemia and hypomagnesaemia) must be corrected and infections treated. Macronutrients should be supplied by milk-based formulas. A full-fat desiccated milk product can be fortified with additional corn oil and maltodextrin. After 4 weeks, the formula can be replaced with whole milk plus solid foods, including eggs, fruit, meats, cod liver oil and yeast. In children, mortality varies between 5% and 40%, the lower mortality rates being seen in those receiving intensive care.

Dental aspects

Noma (maxillofacial gangrene; cancrum oris) is a severe, potentially fatal infection common in starving children, particularly in Africa.

Starvation

General aspects

Starvation is the most severe form of malnutrition and may result from famine, fasting, anorexia nervosa, gastrointestinal disease, stroke, cancer or coma. The metabolic response to starvation is conservation of energy and body tissues, but the body mobilizes its tissues, resulting in destruction of organs and muscle, and extreme shrinkage of adipose tissue. Loss of organ weight is greatest in liver and intestines, moderate in heart and kidneys, and least in the nervous system.

Clinical features

Emaciation is most obvious in areas where fat normally deposits. Muscle mass shrinks and bones protrude. The skin becomes thin, dry, inelastic, pale and cold. The hair is dry and sparse, and falls out easily. Most body systems are affected (Box 27.6). Total starvation is fatal in 8–12 weeks.

General management

At first, food repletion must be limited until gastrointestinal function is restored. Food intake is then gradually increased until it is about 5000 kcal/day and weekly weight gain is 1.5–2.0 kg. Non-responsive patients may require nasogastric feeding, and parenteral nutrition is indicated if malabsorption is severe.

Alcohol or drug dependency

Patients with alcohol or drug dependency often have lifestyles in which nourishment is neglected. Nutrient absorption and metabolism are also impaired. For example, alcoholics who consume 1 litre or more

Box 27.6 Features of emaciation

- Achlorhydria and diarrhoea
- Anaemia
- Apathy and irritability
- Body temperature fall
- Cell-mediated immunity compromised
- Wound-healing impaired
- Fat and muscle loss
- Gonadal atrophy, loss of libido and amenorrhoea
- Heart size and cardiac output fall
- Respiratory rate and vital capacity fall
- Weakness

of spirits per day usually lose weight and become undernourished. Alcoholism is the most common cause of thiamine deficiency in the developed world and may also lead to deficiencies of magnesium, zinc, folic acid and other vitamins.

Cachexia

Cachexia is the weakness and emaciation commonly associated with serious illness, such as cancer, HIV/AIDS (‘slim disease’) and tuberculosis, and seen after burns, major surgery or trauma. Cachexia is mediated by proinflammatory cytokines, such as TNF α (originally termed cachexin), IL-6 and IL-1.

Carnitine deficiency

Carnitine is an amino acid required for the transport of long-chain fatty acyl coenzyme A (CoA) esters into mitochondria. Requirements are met by a combination of dietary intake (mainly animal products) and endogenous biosynthesis. Carnitine deficiency can result from inadequate intake during long-term total parenteral nutrition (TPN), impaired biosynthesis in liver disease, increased requirements in states of ketosis, and high demand for fat oxidation or excess loss of carnitine due to diarrhoea, diuresis or haemodialysis. Although uncommon, carnitine deficiency may cause muscle necrosis, myoglobinuria, lipid-storage myopathy, hypoglycaemia, fatty liver and hyperammonaemia – with muscle aches, fatigue and confusion.

Chronic diseases

In patients with chronic diseases (including those who have undergone major surgery), there may be impaired absorption of fat-soluble vitamins, vitamin B₁₂, calcium and iron. Liver disease impairs the storage of vitamins A and B₁₂, and interferes with protein and energy metabolism. Chronic kidney disease and dialysis lead to deficiencies of protein, iron and vitamin D. Patients receiving long-term home parenteral nutrition, most commonly after total or near-total resection of the gut, tend to develop vitamin and trace mineral deficiencies. Biotin, vitamin K, selenium, molybdenum, manganese and zinc must be adequately supplied.

Essential fatty acid deficiency

Essential fatty acids (EFAs) are those that must be taken in the diet. EFAs are needed for many physiological processes, including maintenance of cell membrane structure, synthesis of prostaglandins and

leukotrienes, and skin integrity. EFAs include linolenic acid, eicosapentaenoic acid and docosahexaenoic acid (omega-3 fatty acids – largely from fish oils), and linoleic acid and arachidonic acid (omega-6 fatty acids – largely from vegetable oils, such as corn oil, cottonseed oil and soybean oil).

Omega-3 fatty acids are needed for synthesis of prostaglandins and leukotrienes, and tend to reduce inflammation. Eicosapentaenoic acid and docosahexaenoic acid are important components of the brain and retina. Omega-6 fatty acids tend to promote inflammation and cancer, and autoimmune and inflammatory disease. A diet with a high omega-3:omega-6 ratio appears to be the most healthy (Ch. 5).

Deficiency in EFAs may occur in patients with fat malabsorption, serious trauma and burns. EFA deficiency used to be a hazard of long-term fat-free TPN, but fat emulsions prevent this.

Lipodystrophy

Lipodystrophy is a rare condition in which adipose tissue cannot be produced and, in the absence of fat cells, leptin is not produced; as a result, patients cannot become obese but often develop type 2 diabetes. Treatment with recombinant leptin helps.

A rare form of lipodystrophy is facial hemiatrophy of Romberg, starting typically in adolescence and in females; there is progressive disappearance of facial fat unilaterally, mimicking facial paralysis. Patients appear to be otherwise well. Plastic surgery is the only treatment.

Lipodystrophy may also follow active antiretroviral therapy (ART) with protease inhibitors for HIV/AIDS. Clinically, there may be peripheral fat-wasting but central adiposity, with expanding abdominal girth ('protease paunch' or 'Crix belly'), growing dorsicervical fat pads ('buffalo hump'), loss of subcutaneous fat over cheeks and temples (facial thinning), arm, buttock and leg wasting, and growing prominence of leg veins.

Persons with raised blood cholesterol are at greater risk of developing lipodystrophy. Age, use of anabolic steroids and use of psychotropic medications (including antidepressants and benzodiazepines) are also associated with lipodystrophy. Associated adverse metabolic effects include hyperlipidaemia, hypercholesterolaemia, hypertriglyceridaemia, hyperglycaemia, insulin resistance and late-onset diabetes, increasing the risk of cardiovascular and other complications. Parotid lipomatosis can be a complication of ART.

VITAMINS AND THEIR DISORDERS

Vitamins are essential organic dietary factors that cannot be synthesized within the body (Table 27.8). They are required in only small amounts but their deficiency can result in disease (Table 27.9).

Sometimes, vitamin excess can be dangerous (Table 27.10). Vitamin A supplementation has been linked to birth defects and irreversible bone and liver damage. Vitamin D supplementation can cause hypercalcaemia. Other adverse effects include diarrhoea (from vitamin C), neuropathies (long-term use of high doses of vitamin B₆) and flushing (niacin).

VITAMIN A (RETINOL)

Vitamin A is fat-soluble and found in animal fats, milk and liver. It can also be derived from precursors (carotenes or carotenoids) found in plants, particularly green leafy vegetables. Vitamin A is stored in the liver; reserves can last about 1 year.

Table 27.8 Vitamins

Fat-soluble	Water-soluble
Vitamin A	Vitamin B ₁ (thiamine)
Vitamin D	Vitamin B ₂ (riboflavin)
Vitamin E	Vitamin B ₆ (pyridoxine)
Vitamin K	Vitamin B ₁₂
	Vitamin C (ascorbic acid)
	Folic acid
	Pantothenic acid
	Biotin
	Nicotinic acid (niacin)

Table 27.9 Vitamin deficiency syndromes

Vitamin	Deficiency syndrome	Usual causes
A	Night blindness, xerophthalmia	Malabsorption, inadequate diet, protein-energy malnutrition (PEM)
B ₁ (thiamine)	Beri-beri, Wernicke encephalopathy	Inadequate diet, alcoholism
B ₂ (riboflavin)	Mucosal lesions, corneal opacities	Inadequate diet, drugs, alcoholism
Nicotinic acid (niacin)	Pellagra (dementia, dermatitis, diarrhoea)	Alcoholism, inadequate diet, carcinoid syndrome
B ₆ (pyridoxine)	Glossitis, neuropathy, dermatitis	Inadequate diet, drugs (isoniazid, hydralazine)
Folate	Megaloblastosis, villous atrophy, mucosal lesions	Inadequate diet, alcoholism, pregnancy, haemolytic anaemia, drugs
B ₁₂	Megaloblastosis, villous atrophy, neuropathies, mucosal lesions	Inadequate diet, pernicious anaemia, Crohn disease
C (ascorbic acid)	Scurvy	Inadequate diet
D	Rickets, osteomalacia	Inadequate exposure to sunlight, malabsorption
E	Spinocerebellar degeneration	Severe fat malabsorption, abetalipoproteinaemia
K	Hypoprothrombinaemia, bleeding	Warfarin, oral antibiotics, biliary obstruction

Table 27.10 Main consequences of vitamin overdose

Vitamin	Toxicity
A	Headache, convulsions, hepatotoxicity, bone damage, teratogenicity
B ₁ (thiamine)	?
B ₂ (riboflavin)	?
Nicotinic acid (niacin)	Vasodilatation, neuropathy
B ₆ (pyridoxine)	Peripheral neuropathy
Folate	?
B ₁₂	?
C (ascorbic acid)	Increased urinary oxalate
D	Hypercalcaemia, renal failure
E	Nausea, bleeding
K	Hyperbilirubinaemia

Vitamin A deficiency is usually dietary in origin and the eyes are first affected, with night blindness, xerophthalmia and conjunctival ulceration. The skin becomes dry and scaly (follicular hyperkeratosis) and the oral mucosa becomes hyperkeratinized.

Natural derivatives of vitamin A (carotenoids) and synthetic analogues of vitamin A (retinoids) can modulate epithelial cell

differentiation, possibly by regulating gene expression, and may have some protective effect against cancers.

In hypervitaminosis A there is alopecia, peeling of the skin, coarsening of the hair and bone pain.

VITAMIN B

There are several B vitamins; all are water-soluble. The most widely recognized deficiencies are of vitamin B₁₂ and folic acid.

Vitamin B₁₂

Vitamin B₁₂ is found mainly in liver, eggs, meat and milk. Liver stores last for up to 3 years and thus deficiency is rarely of dietary origin, except in vegans.

Vitamin B₁₂ deficiency is typically seen in pernicious anaemia, where there is deficiency of the gastric intrinsic factor required for its absorption. Vitamin B₁₂ deficiency causes defective cellular uptake of 5-methyltetrahydrofolate and its impaired conversion by the homocysteine methyl transferase reaction, and thus vitamin B₁₂ deficiency interferes with development of rapidly dividing cells, including mucosae, erythrocytes, granulocytes and platelets. Impaired erythrocyte production leads to a macrocytic anaemia; haemoglobin synthesis continues relatively normally but cell size remains large, and condensation and extrusion of the nucleus are delayed (megaloblastosis).

Neuropathies (subacute combined degeneration of the cord), glossitis and stomatitis may result from vitamin B₁₂ deficiency.

Vitamin B₁ (thiamine, aneurine)

Vitamin B₁ is widely distributed in foods and is necessary in the formation of the coenzyme thiamine pyrophosphate, required for oxidative decarboxylation of pyruvate and alpha-ketoglutarate, and utilization of pentoses.

In vitamin B₁ deficiency, therefore, there is a build-up of lactate and pyruvate that interferes with carbohydrate metabolism. Deficiency of vitamin B₁ is common in alcoholism and leads to beri-beri. This is characterized by polyneuritis, muscular weakness, cardiac failure, mental changes and, in children, growth retardation. Thiamine given intravenously may precipitate anaphylaxis, so caution is advised.

Vitamin B₂ (riboflavin)

Riboflavin is found in leafy vegetables, meat, milk and fish. It acts in the formation of two coenzymes, flavine-adenine dinucleotide and flavine mononucleotide, involved in oxidative metabolism.

Deficiency of vitamin B₂ is commonly dietary and is seen especially in alcoholics. This leads to seborrhoeic dermatitis, corneal vascularization and anaemia, and oral mucosal manifestations similar to those of vitamin B₁₂ deficiency.

Vitamin B₆ (pyridoxine)

Vitamin B₆ is found in meat and vegetables. It is involved in the formation of pyridoxal phosphate and pyridoxamine phosphate, coenzymes in amino acid metabolism.

Vitamin B₆ deficiency is found particularly in alcoholism, pregnancy and the use of some drugs (e.g. isoniazid). Deficiency of vitamin B₆ leads to dermatitis and peripheral neuropathy, and oral mucosal manifestations similar to those of vitamin B₁₂ deficiency.

Pantothenic acid

Pantothenic acid is needed for the synthesis of coenzyme A, which is necessary for several metabolic pathways.

Biotin

Biotin is a coenzyme in carboxylation reactions. Deficiency is rare.

Nicotinic acid (niacin; nicotinamide)

The active derivative of nicotinic acid, nicotinamide, is necessary for the production of nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) for oxidative metabolism. Wheat, nuts, meat and fish are rich sources of nicotinic acid.

Deficiency of nicotinic acid is seen mainly in alcoholics, and causes pellagra (dermatitis and neurological disturbances), oral mucosal erythema and papillary atrophy of the tongue.

Folic acid

Folic acid (pteroylglutamic acid) is biologically inactive; folates are the active forms. Folate, present in green vegetables, liver and yeast, is converted, after small intestinal absorption, to the active tetrahydrofolate, which is involved in synthesis of purine and pyrimidine bases.

Folate deficiency typically results from a diet deficient in green vegetables and can arise within a relatively short period of time, since body stores last less than 3 months. Alcoholism, phenytoin and some cytotoxic drugs (e.g. methotrexate), are other relatively common causes of folate deficiency.

Folate deficiency leads to impaired synthesis and repair of DNA with megaloblastic change in haemopoietic and other cells. The oral effects of folate deficiency in humans are virtually indistinguishable from those of vitamin B₁₂ deficiency.

VITAMIN C (ASCORBIC ACID)

Vitamin C is water-soluble, and found especially in fresh fruits (mainly in citrus fruits) and vegetables, including potatoes. It is involved in the hydroxylation of proline in collagen synthesis.

Deficiency results from a dietary lack of vitamin C, and leads to defective collagen with capillary fragility, a haemorrhagic state, anaemia, and follicular hyperkeratosis and gingival changes (scurvy) of swelling and haemorrhage.

VITAMIN D

Vitamin D is the general name for a group of fat-soluble sterols (cholecalciferol) found in fish, eggs and milk products. Cholecalciferol from the diet is converted into 25-hydroxycholecalciferol in the liver and this is converted in the kidneys to the active form, 1,25-dihydroxycholecalciferol. Ultraviolet light converts a skin precursor, 7-dehydrocholesterol, to vitamin D.

Vitamin D affects immunity, and calcium and phosphate metabolism; deficiency leads to rickets or osteomalacia. This is increasing in communities where sun exposure is limited. Vitamin D can modulate both innate and adaptive immune responses and deficiency in vitamin D is associated with increased susceptibility to infection and increased autoimmunity. The vitamin D receptor is expressed on immunocytes such as antigen presenting cells and B and T lymphocytes, cells also capable of synthesizing active vitamin D. The extrarenal

1- α -hydroxylase enzyme in macrophages differs from the renal enzyme as it is not regulated by PTH, but is dependent upon circulating levels of active vitamin D or it may be induced by proinflammatory cytokines such as IFN- γ , IL-1 or TNF- α .

VITAMIN E

Vitamin E is the general name for a group of fat-soluble tocopherols that are found particularly in asparagus, avocado, nuts, olives and vegetable oils. Vitamin E is important in erythropoiesis and helps the body to use vitamin K. It has been claimed that alpha-tocopherol is the most important lipid-soluble antioxidant. It may have some protective effect against some leukoplakias and carcinomas.

Deficiency is rare, except in premature infants, people with fat malabsorption and rare genetic abnormalities in the alpha-tocopherol transfer protein (ataxia and vitamin E deficiency;AVED). Neuropathies may result. There is no good evidence that vitamin E is cardioprotective.

VITAMIN K

Vitamin K is a fat-soluble naphthaquinone derivative found in green vegetables.

Malabsorption, parenteral nutrition and warfarin cause deficiency, the manifestations of which can include gingival bleeding and postoperative haemorrhage.

OXIDATIVE DAMAGE AND ANTIOXIDANTS

In humans, oxidation by oxides and peroxides from atmospheric pollution, cigarette smoke and some normal bodily processes can cause DNA mutations (and hence cancer risk), oxidize polyunsaturated fatty acids (and thus contribute towards heart disease and strokes), and damage proteins (e.g. eye proteins are particularly vulnerable because light also assists oxidation). Considerable evidence indicates that oxidative damage is associated with and may contribute to most major age-related degenerative diseases (e.g. cancer, heart disease, strokes, diabetes, cataracts, Parkinson disease and Alzheimer disease). In fats and oils, oxidation is the prime cause of rancidity, causing them to become unpleasant to eat and potentially dangerous.

Antioxidants are chemicals that slow oxidation reactions, which can otherwise produce the damaging 'free radicals' or 'reactive oxygen species'. All fats and oils will become rancid, given enough exposure to air, sunlight and heat, but antioxidants will combat this, and offer huge economic and environmental benefits in preventing wastage of food. It is not clear which antioxidants are the most effective. Many foods, particularly pecan nuts, walnuts and various beans, contain high levels of various antioxidants (Table 27.11). Flavonoids, typical examples of which are quercetin in onions and apples, and epigallocatechin in tea, are other antioxidants. Fruits are high in antioxidants, the purple, blue, red and orange fruits being the most antioxidant-rich. Good sources of flavonoids include citrus fruits (hesperidin, quercetin, rutin) and berries (due to their dark colour, purple berries are as much as 50% higher in antioxidants than some of the more common berry varieties). Both red and white wine contain flavonoids but, since red wine is produced by fermentation in the presence of grape skins, red wine has higher levels of flavonoids and other polyphenolics, such as resveratrol. Green plants or herbs contain antioxidants, as do green tea (contains catechins), jiaogulan (southern ginseng or xiancao – the 'immortality

Table 27.11 Antioxidant-containing foods

Food	High in antioxidants	Very high in antioxidants
Beans	Various beans	Cacao (including chocolate)
Beverages	Beer, cider, coffee, tea	Green tea, red wine
Cereals	Barley, hops, maize, millet	–
Fruits	Apples, cherries, lemons, mangos, melons, oranges, peaches, pineapples, plums, tangerines	Blackberries, blackcurrants, blueberries, cranberries, elderberries, pomegranates, raspberries, strawberries
Nuts	Almonds, pistachios	Hazelnuts, pecans, walnuts
Vegetables	Artichokes, mushrooms, onions, parsley, peppers, spinach	–

herb' – contains gypenosides), tomatoes (lycopene), chocolate (relatively high amounts of epicatechin) and grape seeds (resveratrol).

Vitamins A, C and E, and plant polyphenols (including flavonoids) and carotenoids (including beta-carotene and lycopene) are amongst the most powerful antioxidants. Vitamin C (E300) and vitamin E (E306) are found in fruit and vegetables, and are also widely used as supplementary additives. They are amongst the safest chemicals known; 'ACES' products contain pro-vitamin A (beta-carotene), vitamin C, vitamin E and selenium.

Heart disease, strokes, diabetes, cataracts, Parkinson disease and Alzheimer disease seem to occur less frequently in people who eat antioxidant-rich diets, but it is a moot point whether or not the effect is due to some other lifestyle factor. Some dietary antioxidant vitamins are required for good health, and antioxidant-containing foods are recommended. However, although some foods are high in antioxidants, not all are absorbed because of variable absorption or metabolism (bioavailability) in the gut. There is considerable doubt as to whether antioxidant *supplementation* is beneficial. Some studies have suggested that antioxidant supplementation benefits health, but several large clinical trials have failed to demonstrate definite benefit, and excess supplementation may even be harmful. The most common synthetic antioxidants are butylated hydroxyanisole (E320) and butylated hydroxytoluene (BHT; E321). BHT has been controversial; it has produced adverse reactions in dogs but, like all antioxidants, is anticarcinogenic.

POLYPHENOLS

Polyphenols (PPs) are derived from L-phenylalanine. The most important PP classes are phenolic acids, flavonoids, lignans and stilbenes. Flavonoids are divided into flavonols (e.g. quercetin and kaempferol, the most ubiquitous flavonoids in foods), flavones, isoflavones, flavanones, anthocyanidins (pigments responsible for the colour of fruits) and flavanols (catechins, monomers and proanthocyanidins). The PPs that are best absorbed are isoflavones and gallic acid (a phenolic acid), followed by flavanones, catechins and quercetin glucosides. The least well absorbed are proanthocyanidins, anthocyanins and galloylated catechins. All PPs are excreted chiefly in the urine and bile.

PPs have powerful antioxidant activities *in vitro* and are capable of scavenging a range of reactive oxygen, nitrogen and chlorine species, such as superoxide, hydroxyl radical, peroxy radicals, hypochlorous acid and peroxynitrous acid.

PPs have been proposed to have beneficial effects in cancers, cardiovascular diseases and neurodegenerative disorders but, although there are many epidemiological studies, comprehensive data are

Table 27.12 Food additives that may present health risks

Additive ^a	Possible associations	Possible carcinogenicity
Aluminium sulphide, aluminium phosphate, sodium phosphate, aluminium chloride – common leavening agents in baked goods	Possible link to Alzheimer disease	–
Artificial sweeteners (aspartame, acesulphame K and saccharin)	Behavioural problems, hyperactivity, allergies	+
Artificial food colours	Allergies, asthma, hyperactivity	+
Artificial flavours	Allergic or behavioural reactions	–
Bromates (usually potassium bromate)	?	Carcinogenic in animals
Caffeine	Promotes stomach acid secretion, temporarily raises blood pressure, and dilates some blood vessels while constricting others. Excessive caffeine intake results in 'caffeinism', with symptoms ranging from nervousness to insomnia	–
Carbonated beverages	Tooth erosion; obesity, metabolic syndrome, chronic kidney disease, pancreatic carcinoma; rarely, hyponatraemia	–
Food waxes (protective coating of produce, as in cucumbers, peppers and apples)	May trigger allergies, can contain pesticides, fungicide sprays or animal by-products	–
Hydrogenated fats	Cardiovascular disease, obesity	–
Monosodium glutamate (MSG)	Common allergic and behavioural reactions, including headaches, dizziness, chest pains, depression and mood swings; also a possible neurotoxin	–
Nitrites and nitrates	Headaches	Can develop into nitrosamines in body, which can be carcinogenic
Olestra (an artificial fat)	Diarrhoea and digestive disturbances. Olestra inhibits the absorption of some vitamins and other nutrients	–
Phosphorous compounds, which make soft drinks bubbly (phosphoric acid), as well as keeping canned vegetables firm (calcium phosphate) and dried instant oatmeal and soup mixes easy to hydrate (sodium phosphate)	Might possibly interfere with calcium absorption and predispose to osteoporosis	–
Plastic packaging	Immune reactions, lung shock	+ (vinyl chloride)
Preservatives – butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), etc.	Allergic reactions, hyperactivity; BHT may be toxic to the nervous system and the liver	+
Refined flour	Low-nutrient calories, carbohydrate imbalances, altered insulin production	–
Salt (excessive)	Fluid retention and blood pressure increases	–
Sugar and sweeteners	Obesity, dental caries, diabetes and hypoglycaemia, increased triglycerides or candidiasis	–
Sulphites (sulphur dioxide, metabisulphites and others) can keep cut fruits and vegetables looking fresh – they also prevent discolouration in apricots, raisins and other dried fruits; control 'black spot' in freshly caught shrimp; and prevent discolouration, bacterial growth and fermentation in wine	Allergic and asthmatic reactions	–

^aSome are naturally present in some foods.

available only for flavonoids, specifically flavonols, flavones and catechins – indicating that flavonoids reduce coronary artery disease risk. In contrast, the association between flavonoid intake and cancer protection is controversial.

There is also some alleged antimicrobial activity of PPs against some infectious diseases but high dietary PP intake could potentially be more of an oxidative risk than a benefit – a concern corroborated by an epidemiological study reporting an association between flavonoid intake and colon cancer. This suggests that dietary supplementation with large amounts of a single antioxidant might be *deleterious* to human health.

FOOD ADDITIVES

The main reasons for adding chemicals to foods include to improve shelf-life or storage time; make food convenient and easy to prepare; increase nutritional value (e.g. added vitamins); improve flavour and enhance attractiveness; and improve consumer acceptance. For decades,

the food industry has created new chemicals to manipulate, preserve and transform food, and has produced altered versions of breads, fruits, vegetables, meats, dairy products and many more commonly used foods; now there are even 'foods', such as coffee creamers, sugar substitutes and confectionery, that consist almost entirely of artificial ingredients.

Some additives have undoubted health benefits, such as antioxidants. Other food additives may actually cause disease – such as benzoates, tartrazine and cinnamonaldehyde, implicated, for example, in orofacial granulomatosis (Table 27.12). Some are dangerous; the recent adulteration of milk in China with melamine and the subsequent renal or bladder stones, or cancer, is a prime example. Appendix 27.1 outlines E numbers.

NUTRITIONAL INTERVENTIONS

Most conventional nutritional interventions ('diets') recommend recognized 'healthy' patterns of eating (reduction or elimination of fat,

sugar, alcohol and coffee, and an increase in fresh vegetables and fibre) that most people with normal digestion can tolerate without adverse effects. These are generally to be recommended.

Unconventional nutritional interventions include nutritional supplements, dietary modification and 'therapeutic' systems. Some supplements are taken to improve general health and performance, whereas others are purported to be for specific clinical indications, not always with evidence for efficacy. Vitamin D supplementation is discussed above. High doses of single minerals or amino acids may induce deficiencies in nutrients that share similar metabolic pathways. Some trace mineral supplements have had toxic effects; excessive doses of zinc and selenium can cause immune suppression, and evening primrose oil may exacerbate temporal lobe epilepsy.

Dietary modifications, such as many commercial fad diets, are claimed to enhance well-being or reduce weight but some have resulted in frank vitamin, mineral and protein deficiency states. Cardiac, renal and metabolic disorders, as well as some deaths, have resulted. Many diets, such as vegetarianism and veganism, originated as 'movements' characterized by political and/or ecological concerns, a moral stance toward food, and a view of diet as inseparable from lifestyle. Very low-calorie diets (below 400 kcal/day) cannot sustain health for long, and high-dose nutritional supplementation can sometimes lead to adverse effects. Many diets are based on theoretical considerations rather than empirical data. For example, the rationale for the Hay diet is that starch and protein should not be eaten together since each type of food requires a different pH for optimum digestion. The principle of the Stone Age diet is that humans are not adapted by evolution to eat grains and legumes. The Zone diet advocates consuming calories from carbohydrates, protein and fat in a balanced ratio.

'Therapeutic' systems include techniques such as elimination dieting and naturopathy. Elimination dieting is based on the principle that foods particular to each patient may contribute to chronic symptoms or disease when eaten in normal quantities. Exclusion dieting definitely appears to benefit conditions including coeliac disease, orofacial granulomatosis, rheumatoid arthritis, hyperactivity and migraine. Unlike classic allergies, these 'food intolerances' do not involve a conventionally understood immune mechanism or have a rapid onset. Diagnosis consists of eliminating all but a few foods from the diet and then reintroducing foods one by one to see if they provoke symptoms. After a period of complete exclusion, the problem substances can usually be reintroduced gradually without recurrence of symptoms. Although practitioners commonly diagnose wheat and dairy 'intolerance', each patient is said to be sensitive to a different set of foods.

Less evidence-based 'therapeutic' diets are also promoted. In 'Vega' or electrodermal testing, an electrical circuit is made that includes both the patient and the food suspected of causing disease. In applied kinesiology, practitioners claim to be able to diagnose allergy or deficiency on the basis of changes in muscle function. Naturopathy emphasizes the philosophy of 'nature cure' and incorporating dietary intervention among other practices such as hydrotherapy and exercise. For example, a naturopath might advise a patient with vaginal candidosis to undertake a fast, reduce foods containing sugar and yeast, and take herbal and probiotic preparations. Another therapeutic system tests patients for 'subclinical' nutritional deficiencies – thought to arise where systems of food intake, digestion or absorption are not fully functional – and gives appropriate supplementation. Tests include biochemical assays of the vitamin and mineral content of blood or hair. The evidence for the effectiveness of many of these unconventional nutritional interventions in treating disease is often doubtful.

Box 27.7 Foods that might influence drug absorption

- Antacids
- Citrus fruits (mainly grapefruit)
- Garlic
- Minerals (mainly calcium and iron)
- Phytates
- Vitamin K

Box 27.8 Drugs whose absorption is reduced by antacids

- Angiotensin-converting enzyme inhibitors (ACEIs)
- Antimicrobials – azithromycin, ciprofloxacin, isoniazid, nitrofurantoin, norfloxacin, pivampicillin, rifampicin, some tetracyclines (doxycycline, demeclocycline), antimalarials, itraconazole, ketoconazole
- Bisphosphonates
- Digoxin
- Gabapentin
- Lithium
- Penicillamine
- Phenothiazines
- Phenytoin

EFFECTS OF FOODS ON DRUG ABSORPTION

Foods and drugs can affect the absorption or activity of various drugs (Box 27.7). Monoamine oxidase inhibitors, such as phenelzine or tranylcypromine, and eating chocolate could be dangerous, causing a sharp rise in blood pressure. The caffeine in chocolate can also interact with stimulant drugs and increase the effect of methylphenidate, or decrease the effect of sedative-hypnotics such as zolpidem. Other foods that should be avoided when taking MAO inhibitors include bologna, aged cheese, pepperoni, salami and sausage. Licorice may cause digoxin toxicity or reduce the effects of antihypertensive drugs or diuretics, including hydrochlorothiazide and spironolactone.

Minerals may influence drug absorption. Iron can reduce absorption of quinolones (e.g. ciprofloxacin). Calcium in dairy foods and in supplements chelates tetracyclines. Avoiding high-calcium foods within 2 hours of taking the medication minimizes this problem.

Phytates in chapattis bind calcium and impair its absorption.

Antacids can cause early release of drugs from enteric-coated capsules, and can reduce absorption of antimicrobials and drugs, such as those listed in Box 27.8.

Citrus fruit acids may cause some medications to dissolve prematurely in the stomach rather than in the intestine and, therefore, taking drugs with acid fruit juices (and carbonated sodas) is usually not recommended. Citrus juice, however, improves the absorption of iron.

Grapefruit – fresh, canned or frozen, grapefruit juice or drinks that contain grapefruit juice can affect the metabolism of several drugs (Box 27.9 and Table 27.13), typically enhancing their activity. Sour orange juice (e.g. from Seville oranges), real lime juice, pomelos and tangelos (a hybrid of grapefruit) may possibly have this effect too. Furthermore, other fruits and juices, including cranberry, Goji berry and apple, contain other active moieties that can affect different P450 isoforms and transporters, and interact with different drugs. The effect appears to last for at least 3 days but may vary, depending on brand, juice fraction and time of year. It results from irreversible inhibition of certain intestinal drug-metabolizing cytochrome P450 enzymes

Box 27.9 Drugs whose action may be enhanced by grapefruit^a

- Antiarrhythmics (amiodarone, propafenone, dronedarone)
- Anticoagulants (apixaban, rivoraxaban)
- Artemether
- Astemizole
- Caffeine
- Calcium-channel blockers (verapamil, amlodipine, felodipine, nifedipine, nicardipine)
- Cisapride
- Colchicine
- Cytotoxics (nilotinib, sunitinib, lapatanib)
- Diazepam
- Dihydropyridine calcium antagonists
- Diltiazem
- Drugs that act on the central nervous system (buspirone, carbamazepine, pimozide, quetiapine, sertraline, triazolam)
- HIV-protease inhibitors (e.g. efavirenz, saquinavir)
- HMG-CoA reductase inhibitors
- Immunosuppressants (ciclosporin, tacrolimus, sirolimus)
- Ivabradine
- Lovastatin
- Methadone
- Midazolam
- Nisoldipine
- Ranolazine
- Rupatadine
- Sildenafil
- Statins (atorvastatin, simvastatin)
- Tadalafil
- Terfenadine
- Tolvaptan
- Vardenafil

^aActions of aliskiren and bilastine are reduced.

Table 27.13 Effects of grapefruit juice on some relevant drugs

Drug(s)	Effect of grapefruit juice	Implications
Benzodiazepines	Increases blood drug concentrations	Increased sedation. Clinical significance of effect on cognitive function unclear
Carbamazepine	Increases blood drug concentrations	Toxicity (e.g. dizziness, poor balance and coordination, drowsiness, nausea, vomiting, tremor and agitation)
Ciclosporin	Increases blood drug concentrations	Toxicity, such as kidney and liver damage, and immune suppression
Corticosteroids	Increases blood drug concentrations	Consumption of large amounts of grapefruit might increase the risk of adverse effects
Itraconazole	Impairs drug absorption	The clinical significance of this interaction is unclear; theoretically, it could decrease efficacy of itraconazole

(CYP3A4) by furanocoumarins (such as 6',7'-dihydroxybergamot-tin). CYP3A4 is involved in the metabolism of around 50% of drugs, so a wide variety of drugs can be affected by the consumption of grapefruit juice. The consequence is a large rise in the effects of these

drugs. Impaired metabolism of various cardiac drugs after ingestion of grapefruit juice has led to an increase in QT interval and torsades de pointes (Ch. 5). Statins are also affected, leading to rhabdomyolysis.

A second mechanism involves the inhibition by grapefruit of an influx transporter protein family (organic anion transporter poly-peptide; OATP) due to flavonoids such as naringin and hesperidin. The effect is reduced bioavailability of the drug and a decreased efficacy lasting about 4 hours. Drugs affected via this mechanism include aliskiren, celiprolol, ciprofloxacin, fexofenadine and talino-lol. Grapefruit juice constituents, including flavonoids (naringin and naringenin, along with the furanocoumarins, bergapten and 6',7'-dihydroxybergamottin), have also been implicated in activating P-glycoprotein, an intestinal-wall drug efflux mechanism.

Dental aspects

In dentistry, the main problem is with drugs that act on the central nervous system (benzodiazepines, buspirone, carbamazepine, pimo-zide, quetiapine). For example, one glass of grapefruit juice more than triples the bioavailability of diazepam, with more drowsiness. The bioavailability of oral midazolam and triazolam is also increased. Patients about to be given benzodiazepines, therefore, should avoid grapefruit (see Table 27.13). Anticoagulants, antiarrhythmics, calcium-channel blockers, cytotoxics immunosuppressants (ciclosporin, tacrolimus, sirolimus) and statins (atorvastatin, simvastatin) are the other main problems.

Most other citrus fruits, such as lemons, naturally sweet oranges and tangerines, are considered safe in this respect.

Cranberry juice (*Vaccinium macrocarpon*) may enhance warfarin.

Garlic supplements appear to enhance anticoagulants.

Pomegranate may inhibit cytochrome P450 and increase the effects and adverse effects of codeine, carbamazepine, diclofenac, midazolam, tramadol and other drugs (Box 27.10)

Vitamin K in foods (e.g. liver, cabbage, spinach, cauliflower, green tea and broccoli), in contrast, can substantially reduce the effectiveness of warfarin.

Medications such as itraconazole, ketoconazole, ciclosporin, diltiazem and erythromycin may inhibit both intestinal CYP3A4 and hepatic CYP3A4.

NUTRITIONAL SUPPORT

Methods to improve or maintain nutritional intake are known as nutri-tion support and include:

- oral nutrition support – e.g. fortified foods, additional snacks and/or sip feeds
- enteral tube feeding – delivery of a nutritionally complete feed into the gut directly via a tube (nasogastric [NG] or per-enteric gastrostomy [PEG])
- (total) parenteral nutrition ([T]PN) – delivery of nutrition intravenously.

Nutrition support should be considered in people who are malnour-ish, as defined by any of the following:

- a BMI of less than 18.5 kg/m²
- unintentional weight loss of more than 10% within the past 3–6 months
- a BMI of less than 20 kg/m² plus unintentional weight loss of more than 5% within the last 3–6 months.

Box 27.10 Drugs enhanced by pomegranate

- Alfentanil
- Amitriptyline
- Amlodipine
- Captopril
- Carbamazepine
- Celecoxib
- Codeine
- Desipramine
- Diclofenac
- Diltiazem
- Enalapril
- Fentanyl
- Flecainide
- Fluoxetine
- Fluvastatin
- Glipizide
- Ibuprofen
- Indinavir
- Irbesartan
- Lisinopril
- Losartan
- Midazolam
- Nelfinavir
- Ondansetron
- Phenytoin
- Piroxicam
- Propranolol
- Ramipril
- Ritonavir
- Rosuvastatin
- Saquinavir
- Tamoxifen
- Tolbutamide
- Torsemide
- Tramadol
- Verapamil
- Warfarin

Nutrition support should also be considered in people at risk of malnutrition, defined as those who have:

- eaten little or nothing for more than 5 days and/or are likely to eat little or nothing for 5 days or longer
- a poor absorptive capacity and/or high nutrient losses and/or increased catabolism.

ENTERAL TUBE FEEDING

Enteral tube feeding may be appropriate for people who are malnourished or at risk of malnutrition and if:

- they have an inadequate or unsafe oral intake
- they have a functional, accessible gastrointestinal tract
- they have been admitted to intensive care – these patients should be fed via a tube into the stomach, unless there is upper gastrointestinal dysfunction
- they have upper gastrointestinal dysfunction (or an inaccessible upper gastrointestinal tract) – these patients should be considered for post-pyloric (duodenal or jejunal) feeding

- they have long-term (4 weeks or more) needs – gastrostomy should be considered
- PEG tubes have been placed without apparent complications – these can be used for enteral tube feeding 4 hours after insertion)
- they have an inability to swallow safely or take sufficient energy and nutrients orally – these patients should have a 2–4-week trial of NG enteral tube feeding).

The position of all NG tubes should be confirmed after placement and before each use by aspiration and pH-graded paper (with X-ray if necessary), with repeat checks of the tube position. Enteral tube feeding should be stopped when the patient is established on adequate oral intake.

PARENTERAL NUTRITION

PN provides formulae that contain nutrients such as glucose, amino acids and lipids, plus vitamins and minerals. It is termed *total parenteral nutrition* (TPN) or *total nutrient admixture* (TNA) when no significant nutrition is obtained by other routes.

TPN is mainly used in gastrointestinal diseases that cause malabsorption, such as inflammatory bowel disease (Crohn disease), surgical bowel removal (short bowel syndrome) and abnormal bowel function (motility problems due to surgical adhesions, radiation enteritis, neurological disorders, etc.).

PN may be called *total peripheral nutrition* (also TPN) when administered through a limb vein rather than through a central vein. When PN is done at home, it is called *home parenteral nutrition* (HPN).

Two types of catheter can be used for TPN/HPN. Both are inserted into a large vein – most commonly, a soft silicone tube with a segment exiting the chest, or an implantable venous access device or port. Tunnelling subclavian lines is recommended for long-term use (more than 30 days). Catheters do not have to be tunnelled for short-term use (less than 30 days).

Continuous administration of PN is the preferred method of infusion in severely ill people. Cyclical delivery of PN should be considered when using peripheral venous cannulae with planned routine catheter change. A gradual change from continuous to cyclical delivery should be considered in patients requiring PN for more than 2 weeks.

Dental aspects

There are no indications for giving antimicrobial prophylaxis for dental care in people with central catheters (<http://www.cda-adc.ca/jcda/vol-72/issue-7/619.pdf>; accessed 30 September 2013).

Complications

PN may occasionally lead to complications related to catheter insertion, including pneumothorax, accidental arterial puncture and:

- infection – with a mortality rate of approximately 15% per infection
- blood clots
- hepatic steatosis and liver failure
- acute cholecystitis
- cholelithiasis
- hyperglycaemia
- refeeding syndrome (hypokalaemia, hypophosphataemia, hypomagnesaemia) (Box 27.11).

Box 27.11 Criteria for determining people at high risk of developing refeeding problems^a**Patient has one or more of the following**

- BMI <16 kg/m²
- Unintentional weight loss >15% within the last 3–6 months
- Little or no nutritional intake for >10 days
- Low levels of potassium, phosphate or magnesium prior to feeding

Or patient has two or more of the following

- BMI <18.5 kg/m²
- Unintentional weight loss >10% within the last 3–6 months
- Little or no nutritional intake for >5 days
- A history of alcohol abuse or drugs, including insulin, chemotherapy, antacids or diuretics

^aNICE. *Nutrition support in adults: oral nutrition support, enteral tube feeding and parenteral nutrition. Clinical Guideline 32.* February 2006.

Refeeding syndrome

Refeeding syndrome can be defined as the potentially fatal shifts in fluids and electrolytes that may occur in malnourished patients receiving artificial refeeding and that result from hormonal and metabolic changes. The main feature is hypophosphataemia but there can be abnormal sodium and fluid balance; changes in glucose, protein and fat metabolism; thiamine deficiency; hypokalaemia; and hypomagnesaemia. If the syndrome is detected, the feeding rate should be slowed down and essential electrolytes replenished, and the hospital specialist dietetics team should be involved.

For people at high risk of developing refeeding problems, consider:

- starting nutrition support at a maximum of 10 kcal/kg/day, increasing levels slowly to meet or exceed full needs by 4–7 days
- using only 5 kcal/kg/day in extreme cases (e.g. BMI less than 14 kg/m² or negligible intake for more than 15 days) and monitoring cardiac rhythm continually in these people and any others who already have or develop any cardiac arrhythmias
- restoring circulatory volume and monitoring fluid balance and overall clinical status closely
- providing immediately before and during the first 10 days of feeding: oral thiamine 200–300 mg daily, vitamin B compound strong 1 or 2 tablets, three times a day (or full-dose daily intravenous vitamin B preparation, if necessary), and a balanced multivitamin/trace element supplement once daily
- providing oral, enteral or intravenous supplements of potassium (likely requirement 2–4 mmol/kg/day), phosphate (likely requirement 0.3–0.6 mmol/kg/day) and magnesium (likely requirement 0.2 mmol/kg/day intravenous, 0.4 mmol/kg/day oral) unless pre-feeding plasma levels are high. Pre-feeding correction of low plasma levels is unnecessary.

APPENDIX 27.1 E-NUMBERS: REFERENCE NUMBERS USED BY THE EUROPEAN UNION TO HELP IDENTIFICATION OF FOOD ADDITIVES

- All food additives allowed and used in the European Union (EU) are identified by an E-number.
- ‘E’ stands for ‘Europe’ or ‘European Union’.
- Normally, each food additive is assigned a unique number, though occasionally, related additives are designated by an extension (e.g. a, b, i or ii, etc.) to another E-number.
- The Commission of the European Union assigns E-numbers after the additive is cleared by the Scientific Committee on Food

(SCF), the body responsible for the safety evaluation of food additives in the EU. A summary is given below:

- ◆ E100–199: food colours
- ◆ E200–299: preservatives
- ◆ E300–399: antioxidants, phosphates and complexing agents
- ◆ E400–499: thickeners, gelling agents, phosphates, emulsifiers
- ◆ E500–599: salts and related compounds
- ◆ E600–699: flavourings
- ◆ E700–899: not used for human food additives (used for animal feed additives!)
- ◆ E900–999: surface coating agents, gases, sweeteners
- ◆ E1000–1399: miscellaneous additives
- ◆ E1400–1499: starch derivatives.
- E-numbers are only used for substances added directly to food products, so contaminants, enzymes and processing aids, which may be classified as additives in the USA, are not included in the E-number system.
- There is an EU directive on food labelling that requires food additives to be listed in the product ingredients whenever they are added for technological purposes. This includes colouring, sweetening and flavour enhancement, as well as for preservation, thickening, emulsifying and the like.
- Ingredients must be listed in descending order of weight, which means that they are generally found close to the end of the list of ingredients.
- Substances used in the protection of plants and plant products, flavourings and substances added as nutrients (e.g. minerals, trace elements or vitamins) do not need to be included in the ingredient list. Because of this, some substances that are regulated as food additives in other countries may be exempt from the food additive definition in the EU.

The International Classification (ICIDH) system, distinguishes impairment (I) from disability (D) and handicap (H; Table 28.1). Terminology related to disability varies in different countries. For example, the term ‘mental retardation’, as used in the USA, is not used in UK, where ‘learning disability’ and ‘learning, intellectual or cognitive impairment’ are accepted terms. The UK Disability Discrimination Act 1995 (DDA) considers a person as disabled if they have a mental or physical impairment that interferes with their ability to carry out everyday activities. Barriers that can create disability from impairment are shown in Table 28.2. The DDA, the Americans with Disabilities Act 1990 and similar acts in other developed countries make it unlawful to treat disabled people less favourably for reasons related to their disability, and thus service providers need to ensure that the physical features of their premises overcome any barriers to access.

The main conditions causing disability are shown in Table 28.3. Only patients with physical or mental impairment and some specific conditions will be considered here. Patients with other important specific diseases that can prove disabling, such as haemophilia, neurological disorders and muscular dystrophies, as well as children and older people, are discussed in other chapters.

PHYSICAL IMPAIRMENTS

General aspects and clinical features

Physical disabilities include orthopaedic, neuromuscular, cardiovascular and pulmonary disorders. The disability may be either congenital or acquired – typically the result of injury or disease. People with disabilities often rely for mobility upon devices such as wheelchairs, crutches, frames (e.g. Zimmer), walking sticks and artificial limbs. Some people may have additional hidden (non-visible) disabilities, which include epilepsy or respiratory and other disorders.

General management

Limited access to transport and buildings or reluctance of staff to provide care are the major barriers to health care. Decreased physical stamina and endurance, impaired eye–hand coordination or impaired verbal communication may complicate care.

Accept the fact that a disability exists and approach the patient with sensitivity (Box 28.1). When it appears that a person needs assistance, ask if help can be given. Assistance, if requested, should be provided. If a person’s speech is difficult to understand, do not hesitate to ask them to repeat. Sensitivity to using words like ‘walking’ or ‘running’ is inappropriate; people who are handicapped use such words. Always ask first while facing a person who uses a wheelchair; never come up from behind and push them. Try to have conversations at the same eye level by sitting, kneeling or squatting where appropriate. However, a wheelchair is part of the person’s body space, so do not hang or lean on it.

Some who have to use wheelchairs can achieve amazing feats, such as in the Para-Olympic Games (Fig. 28.1), and can walk with the aid of canes, braces, crutches or walkers. Others cope with extraordinary impairments and perform amazing feats.

Table 28.1 *International Classification system*

Term	Definition
Impairment	The functional limitation caused by physical, mental or sensory impairment (i.e. it is organ-based)
Disability	The loss or limitations of opportunities to participate in the normal life of the community on an equal level with others, due to physical or social barriers (i.e. it is person-based)
Handicap	The disadvantage suffered as a consequence of impairment and disability (i.e. it is socially based)

Table 28.2 *Barriers that can create disability from impairment^a*

Barriers	Main problems	Possible consequences
Discrimination	Access to: premises facilities health care education employment recreation	Difficulties with stairs Inappropriate toilets Inadequately trained staff Often lower wages
Prejudice	Denial of anonymity Lack of respect Hostility Patronization Lowered expectations of achievements	Being stared at Being regarded as a ‘burden’ Intolerance
Ignorance	Fear of people with disabilities Inadequate education of carers or professionals	Fear of aggression or being bitten Lack or scarcity of undergraduate training

^aReproduced from Scully C, et al. (2007).

Table 28.3 *Important conditions with impairments*

	Visual defects and hearing defects	Physical disorders
Mental impairment		
Autism disorders	Various	Cardiac disease
Chromosomal anomalies, especially Down syndrome		Cerebral palsy
Dyslexia		Cleft deformities
Learning impairments		Cystic fibrosis
		Hydrocephalus
		Juvenile arthritis
		Muscle diseases
		Spinal cord damage (especially paraplegia) and spina bifida
		Thalidomide deformities

Dental aspects

Guidelines for care are available at <http://www.bsdh.org.uk/guidelines/physical.pdf> (accessed 30 September 2013).

Box 28.1 *How to interact with a person who uses a wheelchair*

- Avoid presumptions about a person's physical abilities
- Greet a wheelchair user in the same way as you would anyone
- Speak directly to the person who uses the wheelchair
- Don't feel shy about using expressions like 'running along' or 'let's go for a walk'
- Keep your observations to yourself
- Do not pat or touch the wheelchair user (or the wheelchair), unless you have permission
- Offer to help when appropriate
- Learn the location of 'accessible' ramps
- Respect wheelchair users, even when you're not interacting with them
- Don't compare a young wheelchair user to an old adult

Fig. 28.1 A person with paraplegia showing impressive independence.

CEREBRAL PALSY

Cerebral palsy (CP) is the most common congenital physical handicap. It is caused by brain damage early in development, either during fetal life, during the birth process or during the first few months of infancy. Brain damage is caused mainly by hypoxia, trauma, infection or hyperbilirubinaemia, but genetic or other biochemical factors may be involved. Risk factors are shown in [Box 28.2](#).

Clinical features

People with CP have abnormalities of motor control that can cause abnormalities of movement and posture in various parts of the body. CP shows no uniform pattern because of the many variations in brain damage ([Table 28.4](#)), but features may include delays in motor skills development, poor control over hand and arm movement, weakness, abnormal walking with one foot or leg dragging, and excessive drooling or difficulties in swallowing. Many patients are highly intelligent but may have such severely impaired speech as to *appear* to have learning impairment. Up to 50% do have additional challenges, such as epilepsy, defects of hearing, vision or speech, learning impairment or emotional disturbances.

Box 28.2 *Risk factors for cerebral palsy*

- Breech presentation
- Low birth weight
- Maternal infection
- Meconium staining of amniotic fluid – caused by stool passed by the fetus *in utero*
- Vaginal bleeding during pregnancy

Table 28.4 *Types of cerebral palsy*

Type	Subtype	Involves
Spastic	Monoplegic	Only one limb
	Paraplegic	Lower extremities
	Hemiplegic	One upper and lower limb on same side
	Double hemiplegic	All limbs but mainly the arms
	Diplegic	All limbs but mainly the legs
Athetoid	Quadriplegic (tetraplegic)	All limbs equally
	Athetosis	All limbs equally
	Chorea	
	Choreoathetosis	
Ataxic		
Rigid		
Mixed		

Fig. 28.2 Cerebral palsy showing contractures in spasticity.

Spastic cerebral palsy is the most common type, and CP patients were sometimes loosely referred to as 'spastics'. It is an upper motor neuron lesion that manifests with excessive muscle tone and contractures, pathological reflexes and hyperactive tendon reflexes ([Fig. 28.2](#)). Many people with CP may need to use wheelchairs ([Fig. 28.3](#)). Hemiplegia is a common subtype, often associated with neurological disorders such as epilepsy, or sensory or visual field defects. Quadriplegics may more frequently have learning impairment but are less often epileptic. Paraplegics and diplegics have an intelligence quotient (IQ) intermediate in level between quadriplegics and hemiplegics, but are the least likely to have epilepsy.

Fig. 28.3 Cerebral palsy – wheelchair user.

Athetoid cerebral palsy accounts for 15% of CP. It is caused by extra-pyramidal damage, usually in the basal ganglia, giving rise to smooth worm-like movements that become exaggerated under stress. There is excessive muscle tone of the 'lead-pipe' type: the limb, when flexed, moves like a lead pipe that is being bent, but there are normal tendon reflexes and no contractures. Athetoid CP is mainly caused by intrauterine rubella and by hyperbilirubinaemia (kernicterus as in rhesus incompatibility). It usually involves the arms especially but all four limbs are affected; it is often accompanied by high-tone deafness. Epilepsy can be associated but learning impairment is less common than in spastic CP.

Ataxic cerebral palsy, caused by a cerebellar lesion, accounts for about 10% of all CP, and is characterized by disturbed balance.

General management

CP brain damage is unfortunately irreversible, but muscle training and exercises help the child's strength, balance and mobility, and increase independence. Muscle relaxants ease stiffness and anticonvulsants reduce seizures. Support from occupational therapists, speech therapists, audiologists, ophthalmic specialists, orthopaedic specialists and dieticians is invaluable.

Dental aspects

Patients restricted to wheelchairs can sometimes be treated in their wheelchair or using a double-articulating headrest, but otherwise it is often better to transfer them to the dental chair by carrying them, using a hoist or sliding them across a 'banana' transfer board placed between the wheelchair and dental chair, or to tilt their wheelchair. Ataxic and some other patients may need the wheelchair to be tilted backwards. Many, however, become apprehensive when this is done. If not, some clinics provide a wheelchair-tilting device such as Versatilt®, Safari® or Diaco®.

Uncontrollable movements, especially in athetosis, bruxism, abnormal attrition and spontaneous dislocation or subluxation of the temporomandibular joint (TMJ), are common.

Communication difficulties, along with concentration, which is often poor, may give a misleading impression of low intelligence.

Epilepsy may be seen. Abnormal swallowing and drooling are common due to poor control of the oral tissues and head posture. Anxiety may worsen athetosis or spasticity, so that anxiolytic drugs such as diazepam are useful as pre-medication.

Preventive dental care is important. Parental counselling about diet, oral hygiene procedures and the use of fluorides should be started early. Manual dexterity is usually poor but favourable results are often achievable with an electric toothbrush or a modified handle on a normal brush. Most dental disease is more common when the arms are severely affected. Periodontal disease is frequently found, especially in the older child, because soft-tissue movement is abnormal and oral cleansing is impaired. Mouth-breathing worsens the periodontal state, and papillary hyperplastic gingivitis may be seen, even in the absence of treatment with phenytoin.

There may be delayed eruption of the primary dentition and enamel hypoplasia is common. Caries activity appears normal, unless there is overindulgence by carers or others, but lack of treatment frequently leads to premature loss of primary teeth and earlier eruption of premolars and permanent canines. Malocclusion is common, probably caused by abnormal muscle behaviour. The maxillary arch is frequently tapered or ovoid, with a high palate. The upper teeth are often labially inclined, due to the pressure of the tongue against the anterior teeth during abnormal swallowing. Most, however, have skeletal patterns within normal limits.

CLEFT LIP AND PALATE

See Chapter 14.

HYDROCEPHALUS

General aspects

Hydrocephalus (*hydro* from the Greek for water and *cephalus* from the Greek for head) is a neurological disorder that affects approximately 1 in 1000 children. It is caused by raised intracranial pressure (ICP), usually due to an abnormal accumulation of cerebrospinal fluid (CSF) within the ventricles and/or subarachnoid space. CSF is overproduced, its flow is obstructed, or there is a failure to reabsorb it. In *normal pressure* hydrocephalus, the ventricles are enlarged but there is little or no rise in ICP.

Hydrocephalus is considered *congenital* when X-linked, or its origin can be traced to a birth defect or brain malformation that impairs drainage of CSF. Congenital hydrocephalus can be caused by TORCH syndrome from intrauterine infection, usually with *toxoplasmosis*, other infections, rubella, cytomegalovirus or herpes. Congenital hydrocephalus may be seen in spina bifida with myelomeningocele, or as a part of other neurological conditions and congenital malformations (e.g. Dandy-Walker syndrome, neural tube defects, Chiari malformations, vein of Galen malformations, craniosynostosis, schizencephaly and tracheo-oesophageal fistula).

Hydrocephalus can be *acquired* later in life if there is a rise in resistance to CSF drainage, such as by obstruction from a brain tumour, arachnoid cyst, intracranial or intraventricular haemorrhage (IVH), trauma, or infection such as meningitis.

The term 'communicating hydrocephalus' means that the site of raised resistance to CSF drainage is outside the ventricular system in the subarachnoid space. Non-communicating, or *obstructive*, hydrocephalus is caused by a CSF obstruction within the ventricular system, especially in the aqueduct of Sylvius, at outlets of the fourth ventricle (foramina of Luschke and Magendie) or from the lateral ventricles into the third ventricle at the foramina of Monro.

Table 28.5 *Hydrocephalus*

Signs	Complications
Large head and bulging fontanelles in children	Epilepsy Spasticity
Headache, vomiting, mental changes, papilloedema	Learning impairment or dementia Visual impairment

**Fig. 28.4** Hydrocephalic shunt.

Clinical features

The main features of hydrocephalus are outlined in [Table 28.5](#).

General management

Hydrocephalus can be treated directly, by removing the cause of CSF obstruction or overproduction, or indirectly, by diverting the CSF build-up to somewhere else. Diuretics (acetazolamide and furosemide) may help reduce CSF production. Endoscopic third ventriculostomy (ETV) may relieve CSF pressure. However, in many cases, CSF has to be redirected. Initially, such 'shunts' were into the right atrium (Spitz–Holter shunt, ventriculo-atrial [VA] shunt; [Fig. 28.4](#)) but now they are typically into another body cavity (usually the peritoneal cavity – ventriculo-peritoneal [VP] shunt) via an implanted silastic device ([Fig. 28.5](#)). Shunt-lengthening surgery may be needed as the child grows.

Dental aspects

The weight of the hydrocephalic head may cause difficulties, especially in the anaesthetized patient, and there may be other management challenges, including shunt infection, or frequently associated spina bifida, latex allergy, epilepsy, or learning or visual impairment.

The consequences of infection can be so devastating that antibiotic cover may occasionally need to be given before oral procedures that might produce bacteraemia in patients with a VA shunt. There is probably no indication for antimicrobial prophylaxis for patients with a VP shunt. The risk of CSF shunt infection following dental procedures appears to be almost negligible and there are no reported cases. There is no evidence that *Streptococcus viridans* isolated from CSF shunt infections has been of oral origin (<https://www.evidence.nhs.uk> – search

**Fig. 28.5** Hydrocephalic shunt.

on 'hydrocephalus shunts and antibiotic prophylaxis'; accessed 30 September 2013).

SPINA BIFIDA

General aspects

Spina bifida is failure of fusion of the vertebral arches; it is an important cause of spinal cord disease and severe physical handicap. Deficiency of folic acid in pregnancy may predispose but most cases are of unknown aetiology.

Clinical features

There is a range of impairments in spina bifida ([Table 28.6](#)) but patients with myelomeningocele are most severely handicapped and tend to suffer from an inability to walk, liability to develop pressure sores, urinary incontinence, faecal retention and other problems, such as hydrocephalus, epilepsy or learning impairment, and other vertebral or renal anomalies.

General management

Surgical closure of myelomeningocele and decompression of hydrocephalus are often carried out in early infancy. Patients require specialist attention to manage urinary tract, bowel and locomotion disabilities.

Dental aspects

Bowel and bladder are best emptied before dental treatment. Postural hypotension is likely, and thus the patient is best not treated supine. In any event, many are chair-bound (see above).

Care must be taken not to traumatize the patient who is unable to respond protectively. There is a very high prevalence of latex allergy in these people (Ch. 17) and some are on anticoagulants or other medication.

THALIDOMIDE SYNDROME

General aspects

In 1957, the hypnotic thalidomide was marketed for morning sickness and soon became the 'drug of choice to help pregnant women'.

Table 28.6 Types of spina bifida

Type	Features
Spina bifida occulta	Rarely any obvious clinical or neurological disorder but may be detected by a small naevus or tuft of hair over the lumbar spine in some patients, and radiographically in about 50% of apparently healthy children
Spina bifida cystica	Extensive vertebral defect through which the spinal cord or its coverings protrude
Meningocele	Protrusion of the meninges as a sac covered by skin, rarely causing neurological defect, but 20% have hydrocephalus
Myelomeningocele	Characterized by meninges and nerve tissue protruded and exposed, and liable to infection, particularly meningitis. Causes severe neurological defects, typically complete paralysis of, and loss of sensation and reflexes in, the lower limbs (paraplegia)

Fig. 28.6 Thalidomide phocomelia.

It was widely prescribed. The years that followed witnessed a dramatic increase in babies born with birth defects, which included deafness, blindness, cleft palate, malformed internal organs and phocomelia (seal-like limbs). Thalidomide did not affect normal intelligence. Since the withdrawal of thalidomide, those affected are now adults.

Thalidomide has activity against tumour necrosis factor (TNF) and is therefore now being used sometimes to treat leprosy, cancers, Behçet disease and major aphthae, on a named-patient basis.

Clinical features

The severe limb deformities (phocomelia) manifest as trunks lacking either arms or legs or both, or sometimes flippers extended from the shoulders, or toes extended directly from the hips (Fig. 28.6).

Dental aspects

Many thalidomide victims have a globular head with hypertelorism (widely spaced eyes), depressed nasal bridge and a central facial naevus extending from the forehead down to the nose. Oral effects include enamel hypoplasia, cleft palate and abnormalities in tongue morphology.

Table 28.7 Causes of learning impairment

Cause	Examples
Genetic conditions	
Chromosomal anomalies	Autosomal trisomies (Edward, Patau and Down syndromes). Deletions (chromosome 5, short arm – <i>cri du chat</i> syndrome; chromosome 4, short arm – Wolf syndrome) Sex chromosome anomalies (XO Turner syndrome; XXX superfemale; XXY Klinefelter syndrome; XYY syndromes). Fragile X syndrome
Inborn errors of metabolism	Hypothyroidism (cretinism), phenylketonuria, homocystinuria, Wilson disease, galactosaemia, mucopolysaccharidosis, Tay–Sachs disease, Gaucher disease, Lesch–Nyhan syndrome
Phakomatoses	Neurofibromatosis (von Recklinghausen disease), encephalofacial angiomatosis (Sturge–Weber syndrome), tuberous sclerosis (epiloia)
Microcephaly	Angelman syndrome
Pregnancy problems	
Drugs	Fetal alcohol syndrome, fetal anticonvulsant syndrome
Infections	Herpes simplex virus, cytomegalovirus, human immunodeficiency virus (HIV), rubella, syphilis, toxoplasmosis
Hypoxia	
Prematurity	
Birth problems	
Hypoxia	
Metabolic/toxins	Rhesus incompatibility, kernicterus, hypoglycaemia
Postnatal problems	
Infections	Pertussis, measles, meningitis, encephalitis, HIV
Metabolic/toxins	Hypoglycaemia, extreme malnutrition, lead or mercury
Trauma	Accidents or assaults with head trauma
Hypoxia	
Radiation	
Alzheimer disease	

LEARNING IMPAIRMENT

General aspects

Learning impairment or disability is a term used for limitations in mental functioning and in skills such as communicating, self-care and social skills. In the USA, this same term is usually used to denote specific learning impairments, such as dyslexia, rather than impaired cognition.

The average intelligence quotient (IQ) score in the general population is 100. An IQ of less than 70 is the arbitrary dividing line that defines learning disability. Learning impairment affects as many as 3 out of every 100 people and is frequently the result of brain damage, often of unknown reason; defined causes are shown in Table 28.7.

Clinical features

Most patients have an IQ between 50 and 75, and often live at home. However, patients with severe learning impairment (IQ below 50) are often totally dependent on others. Brain damage may cause not only mental but also physical impairment and epilepsy; visual defects, hearing, speech or behavioural disorders, facial deformities or cardiac defects are often associated. The limitations cause children to learn and develop more slowly than normal children. They typically take longer to learn to speak, walk and take care of their personal needs, such as dressing or

Fig. 28.7 Self-harm in a person with learning impairment.

eating, and often have trouble learning. They may sit up, crawl, walk or talk late, or have difficulty speaking. They may find it hard to remember things, and have trouble solving problems or thinking logically. They may also find it difficult to understand social rules and how to pay for things and can have trouble seeing the consequences of their actions.

Other problems may include psychiatric disorders (symptoms are often modified by poor language development and other defects), hyperkinesia and stereotyped movements (body-rocking and self-mutilation are common; Fig. 28.7). Feeding difficulties may be present. Pica (the ingestion of inedible substances) is also fairly common.

General management

Learning impairment is diagnosed by the ability to learn, think, solve problems and make sense of the world, and whether the person has the skills needed to live independently (adaptive behaviour or adaptive functioning). Adaptive behaviour skills include skills of daily living (getting dressed, going to the bathroom and feeding), communication skills (understanding what is said and being able to answer) and social skills (with peers, family members, adults and others).

Learning impairment is so varied in severity and character that generalizations about care cannot be made. Many people learn to live independently as adults in community housing. Others can be cared for adequately by committed parents or guardians.

Limited access to buildings and reluctance of staff to provide care are major barriers. Complications may result from prolonged medication (e.g. sedatives, tranquillizers or anticonvulsants); overindulgence (with consequent obesity and its sequelae); or infections (viral hepatitis, gastrointestinal infections or infestations, and tuberculosis – particularly a problem in institutionalized persons in the past).

Access and informed consent to treatment can be difficult issues for people with learning impairment. Some individuals may not be able to give informed consent themselves and, in many countries, relatives and staff have no legal right to give consent on the patient's behalf. If a person is not capable of giving or refusing consent, and has not validly refused such care in advance, treatment may often still be given lawfully if it is deemed to be in the patient's best interests. However, this should happen only after full consideration of its potential benefits and unwanted effects, and after consultation with the carer(s), relatives and other people close to the patient. See Chapter 2 and the Mental Capacity Act (<http://www.justice.gov.uk/protecting-the-vulnerable/mental-capacity-act>; accessed 30 September 2013).

Dental aspects

Diet make-up, maintenance of good oral hygiene, and prevention of caries and periodontal disease can be significant challenges. People with learning disability tend to have the same pattern of caries as the general population of similar age but with more teeth decayed and missing, and fewer filled teeth. Age-adjusted community periodontal index of treatment need (CPITN) scores differ significantly. Those people with severe physical and learning disability have the highest CPITN 3 category mean score. It is frequently impossible for these patients to improve their level of plaque control because of impaired cognition, mobility and manual dexterity. Powered toothbrushes may be easier and more effective for these people to use, or they may need help.

Many people with learning disability are amenable to treatment in the dental surgery, but more time may be required and they may require special facilities or an escort. Regular routine scaling usually improves the oral health considerably. Routine conservative dental treatment should be carried out wherever possible to preserve the teeth. Local anaesthesia (LA), if necessary with inhalational or intravenous sedation, is preferable and usually satisfactory. Up to one-third require sedation or general anaesthesia (GA) for dental treatment, sometimes because they are unable to understand and cooperate. GA may also be used to carry out more complex procedures and save time. GA must be performed in hospital with advanced life support facilities. Intraoperative complications are uncommon but may include non-fatal ventricular arrhythmias, slight falls in blood pressure or hypertension (more than 20% of the preoperative value), laryngospasm and minor airway problems resulting in a desaturation of oxygen to a level below 85%.

Restoring the dentition and preventing further dental disease avoids the situation of loss of teeth and the need to manage dentures. Clinical prosthetic work can be very difficult. Impression-taking is facilitated by using a viscous composition or a putty-type material. If the patient objects violently, it can be readily removed without leaving unset material in the oropharynx. If patients will not keep their mouths open, a mouth prop on alternate sides and sectional impressions may overcome the difficulty. In severely handicapped patients with severe cerebral palsy, stridor can be caused by a bite block. Those people who are more severely handicapped tend to have a deterioration of breathing function when using a bite block. Registration of occlusal records can be very difficult.

Prostheses may also be contraindicated in severe epileptics, who may inhale foreign bodies during a convulsion. Any prosthesis for an epileptic should be constructed of radio-opaque material and marked with the patient's name on a strip added to the fitting surface at flasking and covered with clear acrylic before processing. Those patients incapable of managing full dentures become dental cripples in addition to their other disabilities.

Self-mutilation may involve the oral or orofacial tissues, as in those with severe mental health problems or Lesch–Nyhan syndrome (Ch. 23), in which the lips or tongue may be chewed severely. Rarely, oral self-mutilation is accidental in patients with congenital indifference to pain, including Riley–Day syndrome (familial dysautonomia; Ch. 23).

AUTISM SPECTRUM DISORDERS

Autism spectrum disorders (ASDs) include:

- classic autism
- Asperger syndrome
- Rett syndrome
- childhood disintegrative disorder

Table 28.8 Differences in behaviour of young children with and without autism

Autism	Non-autism
Avoid eye contact	Study mother's face
May appear deaf	Are easily stimulated by sounds
Start developing language, then abruptly stop talking altogether	Keep adding to vocabulary and expanding grammatical usage
<u>Social relationships</u>	
Act as if unaware of others	Recognize familiar faces and smile
Physically attack and injure others without provocation	Cry when mother leaves room
Are inaccessible	Become anxious with strangers
	Become upset when hungry or frustrated
<u>Exploration of environment</u>	
Remain fixated on single item or activity	Move from one object or activity to another
Display habitual rocking or hand-flapping	Reach out to acquire objects
Sniff or lick toys	Explore and play with toys
Appear to have no sensitivity to burns or bruises	Seek pleasure
	Avoid pain
May engage in self-mutilation	

- pervasive developmental disorder not otherwise specified (usually referred to as PDD-NOS).

This is a distinct group of developmental neurological conditions characterized by a greater or lesser degree of impairment in language and communication skills, as well as repetitive or restrictive patterns of thought and behaviour.

Autism

General aspects

Autism is a spectrum of disorders with three cardinal clinical features: onset within the first 2–3 years of life, autism (profound aloneness) and an obsessional desire for maintaining an unchanging environment. Autism affects about 1 or 2 in every thousand and is 3–4 times more common in boys; it is seen mainly in first-born males and a genetic basis is possible. Genes on chromosomes 5 and 7, which affect synapses, are implicated. The genes involved appear to include: *NLG1*, *ASTN2*, *CDH9* and *CDH10* – which code for nerve cell surface proteins that facilitate adhesion between neurons; and *DOCK4* and *IMMP2L* – which affect dendrite development.

Clinical features

Autists seem to live in isolated worlds of their own (Table 28.8), apparently indifferent and remote, unable to form emotional bonds, and incapable of understanding other people's thoughts, feelings and needs. They appear to have severe difficulties in communicating and in forming relationships with other people, in developing language, and in having repetitive and limited patterns of behaviour and obsessive resistance to any changes in familiar surroundings.

Children with autism reject people, act strangely, and lose language and social skills already acquired. They seem to have difficulty learning to engage in the give-and-take of human interaction. They appear to fail to respond to any stimuli, even to being lifted by their parents. They show complete lack of interest in other humans but are often fascinated

by inanimate objects. They seem to prefer being alone, may resist attention and affection or passively accept hugs and cuddling, and seldom seek comfort or respond to anger or affection. They rarely become upset when the parent leaves or show pleasure when they return. There is ritualistic or compulsive behaviour. Autists typically demand consistency in their environment – eating the same foods, at the same time, sitting at precisely the same place. They may become annoyed with any minor change in their routine (e.g. if their toothbrush has been moved). Many engage in repetitive activities, such as rocking or banging their heads, or rigidly following familiar patterns in their routines. Most characteristic are finger-flicking near the eyes, hand-flapping, facial grimaces, jumping and toe-walking, and all such mannerisms are exaggerated if the person becomes anxious or excited. Some autists are especially sensitive to sound, touch, sight or smell, but some seem oblivious to cold or pain. Rages, tantrums and self-directed aggression are common.

The autistic child rarely employs the pronoun 'I' and frequently uses meaningless words or phrases in a generally immature speech. Language and intelligence often fail to develop fully, making communication and social relationships difficult; delayed or immediate echolalia (repetition of words heard) may develop. Some autistics are highly intelligent but 70% have an IQ of less than 70. Temporal lobe epilepsy develops in about 30%.

It is essential to rule out other disorders, including hearing loss, speech problems, learning disability, neurological problems and Rett syndrome (a progressive brain disease that affects only girls and causes repetitive hand movements, bruxism and loss of language and social skills).

General management

Medications used to treat certain symptoms of autism include clomipramine and selective serotonin reuptake inhibitors (SSRIs).

Dental aspects

It is essential to ensure that the child is not kept waiting and has a short, quiet visit with a routine that includes always seeing the same dental staff. Patients with autism may be disturbed by noise, such as a high-speed aspirator or air rotor, and it may be necessary to avoid their use. Autists may be unable to accept dental treatment under LA. GA may be needed but some patients may be on medication, such as antidepressants, which can complicate treatment.

Asperger syndrome

Asperger syndrome (AS) is an ASD. AS is considerably more common than classic autism; however, in AS features typically appear later in childhood. Indeed, the diagnosis is not usually suspected or made until school age, and patients often go on to have the capacity to live an independent adult life. The sex ratio of AS is about 8 boys to 1 girl and the prevalence among schoolboys is about 0.3%.

Unlike with autism, children with AS retain their early language skills. The most distinguishing symptom of AS is a child's obsessive interest in a single object or topic to the exclusion of any other. Children with AS want to know everything about their topic of interest and their conversations with others will be about little else. Their expertise, high level of vocabulary, and formal speech patterns make them seem like little professors. Other characteristics of AS include repetitive routines or rituals; peculiarities in speech and language; socially and emotionally inappropriate behaviour and the inability to interact successfully with peers; problems with non-verbal communication; and clumsy and uncoordinated motor movements.

Children with AS become isolated because of their poor social skills and narrow interests. They may approach other people but make normal conversation impossible by inappropriate or eccentric behaviour, or by wanting only to talk about their singular interest. Children with AS usually have a history of developmental delays in motor skills and are often awkward and poorly coordinated, with a walk that can appear either stilted or bouncy.

Positron emission tomography (PET) scan studies in AS have shown an absence of the normal task-related activity in the left medial prefrontal cortex region, although normal activity is observed in the areas immediately adjacent.

Treatment for AS may include social skills training, cognitive behavioural therapy and medication for coexisting conditions.

SPECIFIC TYPES OF LIMITED LEARNING DISABILITY

Dyslexia (reading disability)

Dyslexia is a commonly known learning disability: an impairment in the ability to translate written images into meaningful language. It is primarily used to describe difficulty with language processing and its impact on reading, writing and spelling. People with dyslexia have normal intelligence and normal speech, but often have difficulty interpreting spoken language and writing, and read at levels lower than expected. There is often a family history.

Clinical features

Common signs are delay in speaking; delay in learning the alphabet, numbers, days of the week, months, colours and shapes; reduced reading achievement; lack of awareness of phonemes (sounds that make up words); difficulty in spelling and difficulty with sequences of letters in words; and problems in understanding language subtleties (such as jokes). Inability to recognize words and letters on a printed page; reading ability level much below that expected; problems processing and understanding; difficulty with rapid instructions, more than one command at a time or remembering the sequence of things; and reversals of letters (e.g. b for d) and words (e.g. saw for was) are common. Untreated, dyslexia may lead to low self-esteem, behavioural problems, delinquency, aggression, and withdrawal or alienation from friends, parents and teachers.

General management

Treatment is by remedial education.

Dysgraphia

Dysgraphia involves difficulty with writing but there are also issues with spelling and the formulation of written composition. The common signs include problems involving the steps of putting together a written document, bad handwriting, awkward pen grip, avoidance of tasks that involve writing, difficulty fleshing out ideas on paper in contrast to the ability to discuss such ideas verbally, and inconsistency in the way letters and words look. People with dysgraphia can benefit from explicit instruction in the skills required to produce written work. Computers can help enormously.

Dyscalculia

Dyscalculia involves difficulty with mathematical skills (addition, subtraction, multiplication) and concepts (sequencing of numbers).

Memory of mathematical facts, concepts of time, money and musical concepts can be affected. Language and other skills, however, may be advanced, and visual memory for the printed word is good. There may be a poor sense of direction, as well as trouble reading maps, telling the time, grappling with mechanical processes, handling abstract concepts of time and direction, dealing with schedules, keeping track of time, and knowing the sequence of past and future events. Individuals with dyscalculia need help in organizing and processing information related to numbers and mathematical concepts. Again, computers can help.

Dyspraxia

Dyspraxia (apraxia) is difficulty with motor planning, affecting a person's ability to coordinate appropriate body movements. It results in various problems such as:

- *ideomotor dyspraxia* (inability to perform single motor tasks, such as combing hair or waving goodbye)
- *ideational dyspraxia* (difficulty with multilevel tasks, such as taking the proper sequence of steps for brushing teeth)
- *dressing dyspraxia* (difficulty with dressing and putting clothes on in order)
- *oromotor dyspraxia* (difficulty with speech)
- *constructional dyspraxia* (difficulty with spatial relations).

Features may include: coordination problems, including awkwardness in walking, clumsiness or trouble with hopping, skipping, throwing and catching a ball, or riding a bicycle; confusion about which hand to use for tasks; inability to hold a pen or pencil properly; sensitivity to touch; poor short-term memory; trouble with reading and writing; poor sense of direction; speech problems; phobias or obsessive behaviour; and impatience.

CHROMOSOMAL ANOMALIES

Chromosomal anomalies may sometimes be associated with physical and/or mental impairments. Most human cells contain 46 chromosomes (23 pairs), half of which are inherited from each parent. Only the reproductive cells (the sperm cells in males and the ova in females) have 23 *individual* chromosomes, not pairs. When the sperm and ovum combine at fertilization, the fertilized egg that results contains 23 chromosome pairs. A fertilized egg that will develop into a female contains chromosome pairs 1–22 and the XX pair. A fertilized egg that will develop into a male contains chromosome pairs 1–22 and the XY pair.

Chromosomal anomalies affect sex chromosomes and autosomes equally. Sex chromosome anomalies are usually compatible with life and are rarely associated with severe physical disability. Autosomal anomalies affecting the larger chromosomes commonly cause spontaneous abortions and natal and early neonatal deaths. However, anomalies of the smaller chromosomes may be compatible with life, though they can cause multiple impairments, as in Down syndrome.

The most common source of major chromosomal anomalies is an error in meiosis (non-disjunction). One chromosome too few, or one too many, enters a gamete and subsequently the zygote. Most of the chromosomal anomalies are rare and many affected individuals survive for only a few years. Chromosomal deletions may also cause learning disability.

The most common chromosomal anomalies of significance in dentistry are Down syndrome and fragile X syndrome. Medical problems and the main oral manifestations of other chromosomal anomalies are summarized in Appendix 28.1.

Table 28.9 Genes implicated in Down syndrome

Gene	Gene product	Possible sequelae
APP	Amyloid beta A4 precursor protein	Cognitive difficulties
COL6A1	Collagen type 1	Cardiac defects
CRYA1	Crystallin, alpha-A	Cataracts
DSCR1	Down syndrome critical region gene 1	Defect in signal transduction pathway involving both heart and brain
DYRK	Tyrosine phosphorylation-regulated kinase 1A	Poor mental development
ETS2	Avian erythroblastosis virus E26 oncogene homologue 2	Lymphocyte and thymus abnormalities
IFNAR	Interferon receptor	Impaired interferon expression; immune defect
SOD1	Superoxide dismutase	Dementia; immune defect

Fig. 28.8 Down syndrome facies.

Down syndrome (mongolism or trisomy 21)

General aspects

Down syndrome is the most frequent genetic cause of learning impairment, appearing in 1 in 800 live births. It is caused by an error in cell division that results in the presence of an additional third chromosome 21 (trisomy 21), derived from the mother in 88%. The resultant range of physical disabilities varies, depending on the proportion of cells carrying the additional chromosome 21.

In 92%, there is an extra chromosome 21 in all cells (*trisomy 21*). In 2–4% there is a *mosaic trisomy 21* – the extra chromosome 21 is present in some cells only. In approximately 3–4%, material from one chromosome 21 is translocated on to another chromosome (*translocation trisomy 21*); cells then have two normal chromosomes 21, but also have additional chromosome 21 material on the translocated chromosome, usually chromosome 14 or 15. There may be an increased likelihood of Down syndrome in future pregnancies when the mother has had a child with translocation trisomy 21. An older mother is more likely to have a baby with Down syndrome but, since older mothers have fewer babies, about 75% of babies with Down syndrome are born to younger women. A range of chromosome 21 genes is implicated in Down syndrome features (Table 28.9).

Clinical features

The characteristic features are short stature, learning disability, and a typical facies with brachycephaly, widely spaced eyes, Brushfield spots in the iris and epicanthic folds (Fig. 28.8). The hands show clinodactyly (short fifth finger) and simian (single) palmar creases. However, Down syndrome also affects many, if not most, organs, and some patients succumb in their first few years (Fig. 28.9). Approximately 50% have congenital cardiac disorders (atrial septal defect, mitral valve prolapse or, less often, atrioventricular and ventricular septal defect) and associated early onset of pulmonary hypertension (Fig. 28.10). Mitral valve prolapse can lead to arrhythmias, embolism or sudden death. If it causes a systolic murmur, it can predispose to infective endocarditis, particularly in older persons.

Seizure disorders affect between 5% and 13%, a tenfold greater incidence than in the general population. Dementia, or memory loss and impaired judgment similar to that in Alzheimer disease patients, may develop. There is susceptibility to transient myelodysplasia or defective development of the spinal cord. Atlantoaxial instability can cause spinal cord compression if the neck is not handled gently. The external

Fig. 28.9 Down syndrome.

Fig. 28.10 Down syndrome: cyanosis and prognathism.

ear and the bones of the middle and inner ear may develop differently and thus up to 90% have hearing loss of greater than 15–20 decibels in at least one ear. Cataracts appear in approximately 3%. Children with Down syndrome are 10–15 times more likely than other children to develop leukaemia.

Multiple immune defects mean that infections of the skin and gastrointestinal and respiratory tracts, and periodontal disease are common; superoxide dismutase has been shown to increase in Down syndrome and may be implicated in the immune defect. Chronic respiratory infections include tuberculosis and recurrent middle ear, tonsil, nasal and sinus infections. Institutionalized patients are also liable to be hepatitis B carriers. There is a 12-fold higher mortality rate from infectious diseases, particularly pneumonia.

The life expectancy for people with Down syndrome, though low, has increased substantially to age 50 and beyond, particularly because infections are now more readily controlled.

General management

Many specialists recommend that women who become pregnant at age 35 or older undergo prenatal testing for Down syndrome. After counselling, this includes the following:

- blood screening for maternal serum alpha-fetoprotein (MSAFP – low in Down syndrome), human chorionic gonadotropin (hCG – raised in Down syndrome) and unconjugated oestriol (uE3 – low in Down syndrome)
- amniocentesis – analysis of a small sample of fetal cells from the amniotic fluid (generally safe but cannot be done until the 14–18th weeks of pregnancy, and it usually takes more time to determine whether cells contain extra material from chromosome 21)
- chorionic villus sampling (CVS), conducted at 9–11 weeks of pregnancy; involves testing a small amount of chorionic villi, obtained through the abdomen or cervix, for extra material from chromosome 21
- percutaneous umbilical blood sampling (PUBS), the most accurate method and used to confirm the results of CVS or amniocentesis; cannot be performed until later in the pregnancy (during the 8th–22nd weeks) and carries the greatest risk of miscarriage.

With assistance from family and carers, many adults with Down syndrome develop the skills required to hold jobs and to live semi-independently.

Dental aspects

People with Down syndrome are usually amiable and cooperative, and generally more easily managed than many other types of patient with learning disability.

Most can be treated under LA with sedation if necessary. GA must be administered by a specialist anaesthetist in hospital or is best avoided where possible, in view of other management difficulties; the latter may include cardiac defects, anaemia, possible atlantoaxial subluxation (care needed when extending the neck) or respiratory disease. There may also be difficulty in intubation because of the hypoplastic midface, congenital respiratory anomalies and the increased susceptibility to chest infections.

The tongue may be absolutely or relatively large and is often scrotal, especially after the age of about 4 years (Table 28.10). The circumvallate papillae enlarge but filiform papillae may be absent. The lips tend to be thick, dry and fissured. Poor anterior oral seal and also a strong tongue thrust may be seen.

Table 28.10 *Orofacial abnormalities in Down syndrome*

Hard tissue	Soft tissue
Omega-shaped palate	Macroglossia
Midface hypoplasia	Tongue fissuring
Hypodontia	Lip fissuring
Microdontia	Cheilitis
Delayed eruption in both dentitions	Droling
Bruxism	

Anterior open bite, posterior cross-bite and other malocclusions are common. The maxillae and molars are small and the mandible is relatively protrusive. Class III malocclusion is common, but 46% of cases are class I. The orthodontic prognosis may be poor because of learning disability, parafunctional habits and severe periodontal disease. The palate often appears to be high, with horizontal palatal shelves (the omega palate), but a short palate is more characteristic. There is also a higher incidence of bifid uvula, cleft lip and cleft palate.

The first dentition may begin to appear only after 9 months and may take 5 years to complete, if ever. The deciduous molars may erupt before the deciduous incisors, and deciduous lateral incisors are absent in about 15%. The eruption of the permanent teeth is frequently also irregular. Missing teeth are common; the third molars and lateral incisors are most often absent. Up to 30% have morphological abnormalities in both dentitions, particularly teeth with short small crowns and roots. The occlusal surfaces of the deciduous molars may be hypoplastic and both dentitions may be hypocalcified. Caries activity is usually low in both dentitions.

Severe early-onset periodontal disease may be partly due to poor oral hygiene, but may be the result of impaired cell-mediated and humoral immunity and a deficient phagocytic system. Acute ulcerative gingivitis may also be seen. Short roots and poor manual dexterity and oral hygiene often complicate the situation.

A well-planned preventive dental health programme, started early, can lead to some success in the prevention of dental diseases.

Fragile X syndrome

General aspects

Fragile X syndrome affects 1 in 1500 of the population and is, after Down syndrome, the second most common chromosomal defect associated with learning impairment. Fragile X syndrome is so named because the tip of the X chromosome is susceptible to breakage. Fragile X syndrome is a sex-linked dominant trinucleotide repeat disorder (other trinucleotide repeat disorders include Huntington chorea, spinocerebellar ataxia, myotonic dystrophy and Friedreich ataxia).

Clinical features

Fragile X syndrome affects males and manifests with learning impairment, long face, prominent ears, large testes and seizures.

Dental aspects

Hyperactivity, a short attention span and behavioural disorders similar to those of autism often make dental management difficult. Cross-bite and open bite are abnormally frequent.

ATTENTION DEFICIT (HYPERACTIVITY) DISORDER

Attention deficit (hyperactivity) disorder (ADD/ADHD) may be associated with learning difficulties (Ch. 10).

OTHER HANDICAPPING SYNDROMES

See Appendices 28.1 and 23.1 for inborn errors of metabolism.

APPENDIX 28.1 CHROMOSOMAL ANOMALIES ADDITIONAL TO THOSE DISCUSSED IN THE TEXT

Syndrome	Anomaly	Features and possible management problems	Orofacial manifestations
Angelman syndrome	Chromosome 15 deletion	'Happy puppet' – laughs and claps, learning impairment, ataxia, seizures	Microcephaly
<i>Cri du chat</i> syndrome	Chromosome 5 short arm deletion	Learning impairment, cardiac defects, respiratory infections	Cranial abnormalities Malocclusions
DiGeorge syndrome	Chromosome 22 microdeletion	Hypoparathyroidism, thymic hypoplasia, T-cell defect, major cardiac anomalies, learning disability	Cleft palate Candidosis Dental hypoplasia
Edwards syndrome	Trisomy 18	Learning impairment, cardiac defects, renal disease	Cranial abnormalities Microstomia Hypoplastic parotids Gingival cysts
Klinefelter syndrome	47,XXY	Tall stature, personality defects, diabetes, asthma	Taurodontism
Patau syndrome	Trisomy 13	Rarely survive infancy, learning impairment, cardiac defects in 80%, deafness, epilepsy	Cranial abnormalities Cleft lip or palate in 75%
Superfemale	Trisomy X (47,XXX)	Tall females, learning impairment, early menopause	–
Turner syndrome	Monosomy X (45,X)	Females only, normal intelligence, infertility, short stature, webbed neck, renal anomalies, cardiac defects, diabetes, keloid formation, lymphoedema	Small mandible Malocclusions
Williams syndrome	Microdeletion of elastin gene on chromosome 7	Supravalvular aortic stenosis, hypercalcaemia, learning impairment	Elfin facies Dental anomalies
Wolf syndrome	Short arm of chromosome 4 deletion	Learning impairment	Hypodontia
XYY	47,XYY	Tall males, normal intelligence, behavioural abnormalities	–

Few of the dental materials or drugs commonly used cause significant interactions or adverse reactions (see Appendices). The main concern is allergies (e.g. especially to latex [Ch. 17] and some drugs). Other issues include adverse reactions to dental materials (especially amalgam/mercury, chlorhexidine, nickel, iodides and radiocontrast media, resins, titanium), fluorides and anaesthetics – and other drug adverse effects, oral adverse effects, drug interactions and the effects of foods on drugs.

DENTAL MATERIALS

Allergies are discussed in Chapter 17 and also below, alphabetically. Possible toxic effects of mercury on the nervous system are discussed here and in Chapter 17; fluoride is also discussed in this chapter.

ALLERGIES

Latex allergy

Latex allergy (see also Ch. 17) is one of the most important factors to be elicited from the medical history. People with severe latex allergy can react with anaphylaxis as they enter a health-care facility where latex is present in the environment!

Chlorhexidine allergy

Chlorhexidine is a cationic chlorophenyl-biguanide antiseptic and disinfectant, commonly used as the diacetate or digluconate salt, and has excellent antimicrobial properties. Chlorhexidine allergy must be rare but is important, since chlorhexidine is present in many antiseptic preparations, including some mouth rinses, disinfectants and cosmetics. Medical devices that incorporate chlorhexidine include: intravenous catheters, topical dressings and implanted surgical mesh.

Chlorhexidine used topically, intra-urethrally as catheter lubricant, as a mouthwash and with impregnated catheters has been associated with hypersensitivity reactions and some deaths. Chlorhexidine has been used in the UK since 1954 and reactions have been reported since 1962, ranging from contact dermatitis, to urticaria to anaphylactic shock with cardiac arrest. Fatal cases of anaphylaxis prompted the FDA in 1998 to issue an alert to the medical community. Patients with suspected allergies should be investigated for evidence of chlorhexidine-specific IgE by skin or blood tests.

Management is along the lines for latex allergy (Ch. 17), essentially avoiding exposure, and using povidone-iodine as an alternate skin preparation or hexetidine mouthwash as an alternate for oral use.

Patch testing using chlorhexidine has revealed positive reactions in more than 2% of patients tested. In eczema patients, the rate may be as high as 5%.

Reactions to other dental materials

Dental materials such as alloys, bonding, cements, plastics, primers, resins and other materials can cause allergies leading to dermatitis, rashes, blistering, itching or burning – though these features are usually seen only in people highly sensitive to epoxy resins. Illustrative of the

difference between skin and mucosa in response to sensitizing agents is the fact that a substance, to which the patient is sensitized when it is put in the mouth, can occasionally induce the typical skin rash. This has been reported, for example, in the case of nickel sensitivity when a nickel-containing denture caused a rash but no oral reaction.

Alloys

With few exceptions, metals used in dentistry are alloys – solid mixtures of two or more metals.

'Gold allergies'

Gold alloys may occasionally be used for dental restorations or prostheses. Pure gold, because of its softness, is not indicated for use in the mouth except as gold foil – rarely used now. The basic alloys used are casting gold, gold solder, wrought gold and gold plate, and these may contain silver, copper, platinum, palladium or zinc. Lichenoid oral reactions to gold alloys are rare.

'Mercury allergy'

Dental amalgam is a combination of mercury mainly with a silver–tin alloy. The American Dental Association (ADA) specifies that the alloy must include a minimum of 65% silver, and maximums of 29% tin, 6–13% copper and 2% zinc by weight. Alloys with high copper content usually have lower creep values than conventional silver–tin alloys. Some alloys are completely zinc-free and can therefore be used more successfully in a moisture-contaminated environment. Dental amalgam may cause mucosal reactions such as lichenoid lesions, but the evidence is controversial and mercury absorbed from amalgams into the mucosa frequently causes no histological reaction.

Mercury and its salts are potential sensitizing agents; exposure to them can occasionally lead to contact dermatitis, and the frequency of positive patch tests increases as dental students progress through their course. Also, a few patients have genuine contact sensitivity to mercury, though they can generally tolerate the placement of amalgam restorations, provided that none is spilt on to the skin. 'Baboon syndrome' is a special form of systemic contact-type dermatitis manifesting with bright red buttocks and flexural eczema that occurs after ingestion or systemic absorption of a contact allergen in individuals previously sensitized by topical exposure to the same allergen in the same areas; it has been reported as a reaction to mercury.

Another group of patients appear to have symptoms such as headache, lassitude or a general feeling of ill-health that they ascribe to mercury toxicity, although there is no reliable evidence that mercury underlies these problems. Such patients may also suffer more frequently from other unrelated complaints, such as chronic craniofacial pain, than do controls.

Nickel allergy

Nickel-containing alloys are widely used, especially in orthodontics. The highest nickel content is in nickel–titanium, especially in flexible wires, but even stainless steel contains almost 10% nickel; most of this is bound, however, and unlikely to cause allergy – so can safely be used in nickel-allergic people. Nickel allergy often arises from jewellery and the prevalence appears to have increased with the advent of body piercing. Safe alternatives to nickel wires include stainless steel,

composites, titanium and gold-plated wires. Wires of nickel–titanium that are ‘altered’ or coated with plastics or resin might be safe. Brackets of stainless steel, titanium, ceramics or polycarbonates are safe. Plastic-coated studs on headgear will avoid the issue with nickel studs.

‘Titanium allergy’

Degradation of metallic biomaterials may result in products leading to metal hypersensitivity reactions. Titanium has been considered an inert material but it has been suggested that it can rarely induce toxicity or allergic type I or IV reactions in susceptible patients. In a systematic review it has been shown that titanium allergy develops among patients at any age, the most common clinical manifestations being dermal inflammatory conditions and gingival swelling. A significantly higher risk of positive allergic reactions was found in patients showing allergic symptoms after implant placement or unexplained implant failures. The risk of an allergy to titanium is increased in patients who are allergic to other metals. Alternative materials (e.g. zirconium oxide) are available.

Cements

Dental cements include zinc phosphate, zinc oxide and eugenol, polycarboxylate (zinc oxide powder mixed with polyacrylic acid) and glass ionomer cements (GICs). Allergic reactions to most dental cements are rare but GICs contain a polyalkenoic acid such as polyacrylic acid plus a fluoride-containing silicate glass (fluoroaluminosilicate) powder, and do occasionally cause reactions. Resin-modified glass ionomer cements (RMGICs) usually contain HEMA (hydrophilic monomer) plus a fluoride-containing glass and polyacrylic acid. Tri-cure GICs also incorporate a chemical curing tertiary amine-peroxide reaction to polymerize the methacrylate, along with the photo-initiation and acid–base ionic reaction. These resins may cause reactions.

Plastics and resins

Some chemicals in resins may cause reactions. Polymethyl methacrylate (PMMA), polystyrene, polyvinylchloride (PVC) and so on contain potential allergens such as long hydrocarbon-based chains produced from small monomer units (e.g. methyl methacrylate [MMA], styrene, vinyl chloride, etc.). A few individuals may react to the potential allergens shown in Box 29.1 and some reactive materials may leach from set material at least for a few days, as may degradation products (e.g. formaldehyde).

PMMA (acrylic) is used for clothing, plastic items or dentures and is itself probably inert, but dental MMA contains a wide range of components that are potentially sensitizing (Table 29.1). There are rare cases, particularly in dental health-care professionals (HCPs), of allergic reactions to MMA monomer and associated chemicals. Affected persons should avoid exposure. Surgical rubber, latex or vinyl gloves offer little, if any, protection, as they are quickly penetrated by the chemicals, but commercial laminated disposable protective gloves are available.

Resins are also used in dentistry as bonding agents, composite resins, pit and fissure sealants, and resin-based cements. Often referred to as direct-filling resins, they are of several types; the older type was an unfilled polymethacrylate, while the more recent type is a composite resin based mainly on dimethacrylates plus silanated glass. Acid-modified composites (compomers) consist of methacrylate monomers such as urethane dimethacrylate (UDMA) and fluoride-containing glass. The monomers most commonly used are UDMA and 2,2,-bis(4(2-hydroxyl-3-methacryloxyloxypropoxy)-phenyl) propane – bisphenol A glycidyl methacrylate (BPA; BIS-GMA) – combined with lower-molecular-weight monomers such as triethylene glycol dimethacrylate

Box 29.1 Potential allergens in dental resins

- 1,4-Butanediol dimethacrylate (BUDMA)
- 1,7,7-Trimethylbicyclo-2,2,1-heptane
- 2-Hydroxyethyl methacrylate (2-HEMA)
- 2-Hydroxypropyl methacrylate (2-HPMA)
- 2,2-Dimethoxy-1,2-diphenyletanone (DMBZ)
- 4-Dimethylaminobenzoic acid ethyl ester (DMABEE)
- Acrylated epoxy oligomer
- DL-Camphorquinone
- Ethylene glycol dimethacrylate (EGDMA)
- Methyl methacrylate (MMA)
- Triethylene glycol dimethacrylate (TEGDMA)
- Urethane dimethacrylate (UDMA)

Table 29.1 Typical components of dental methyl methacrylate

Liquid	Powder
Dimethacrylate (cross-linker)	Organic peroxides (initiators)
Hydroquinone (inhibitor)	Pigments
Methyl methacrylate (monomer)	Polymethyl methacrylate
Organic amines (accelerator)	Titanium dioxide
Ultraviolet absorber	

(TEGDMA). Photo-initiators such as camphoroquinone facilitate polymerization via light curing.

The major sensitizers appear to be EGDMA, 2-HEMA, 2-hydroxypropyl methacrylate (2-HPMA), MMA and acrylated epoxy oligomer. 1,4-Butanediol dimethacrylate (BUDMA) and UDMA seem to be only weak sensitizers.

Allergic reactions in the mouth are typically lichenoid but occasionally urticarial or anaphylactoid, and dermatological reactions in HCPs are usually contact dermatitis or eczema – so direct skin contact is best avoided. Allergic reactions may be produced by the catalyst methylchlorobenzene sulphonate in dibenzyltoluol present in *Impregum* and by the catalyst methyl *p*-toluene sulphonate in dibenzyltoluol present in *Scutan*. Some people are sensitive to colophony resins, found in wound sticking plasters, periodontal dressings, impression materials, cements, fix adhesives and some fluoride varnishes (e.g. Duraphat). Eugenol in periodontal dressings can also be a contact allergen.

Apart from allergic reactions, there are few data to indicate significant toxicity from most resin components, though BPA may have some oestrogenic activity *in vitro*. BPA has also been implicated in heart disease and diabetes, though only minuscule amounts are found in dental resin restorations, and much more is present in other items such as plastic bottles and can linings. BPA leaches out from food and beverage containers, as well as from dental resins. Indeed, a recent survey by the Centers for Disease Control and Prevention (CDC) found bisphenol in the urine of 95% of people in USA. High levels of BPA have been correlated with obesity, diabetes, cardiovascular diseases, polycystic ovaries or low sperm count. In 2008, the ADA stated:

There is also evidence that some dental sealants, and to a lesser extent dental composites, may contribute to very low-level BPA exposure. The ADA fully supports continued research into the safety of BPA but, based on current evidence, the ADA does not believe there is a basis for health concerns relative to BPA exposure from any dental material.

CONCERNS ABOUT DENTURE FIXATIVES

Some denture fixatives contain zinc, which may be absorbed and cause copper deficiency, myelopathy and 'human swayback disease' with polyneuropathies.

CONCERNS ABOUT FLUORIDE

Some studies, now criticized for their analyses, suggested associations of bladder cancer with occupational fluoride exposure and of osteosarcoma with water fluoridation. A recent systematic review confirmed the benefit of fluoride in protection against dental caries, and found that water fluoride to a concentration of 1 ppm had no proven adverse effects on bone strength, bone mineral density, fracture incidence (protective or deleterious), cancer incidence or mortality, or on other conditions such as prevalence of Down syndrome, congenital abnormalities or stillbirths. For details, see <http://www.nhmrc.gov.au/guidelines/publications/eh41> (accessed 30 September 2013).

Another recent systematic review and meta-analysis, however, produced results that supported the possibility of an adverse effect of high fluoride exposure on child neurodevelopment.

CONCERNS ABOUT MERCURY

Mercury is a well-known neurotoxin and nephrotoxin. There also may be an association between mercury exposures over time and coronary artery disease, including myocardial infarction. There are three kinds of mercury involved in exposure (and poisoning): organomercury, inorganic mercury and elemental (metallic) mercury poisoning.

Organic mercury poisoning from methylmercury is the most common type; it is well recognized and, except in rare cases (e.g. exposure to laboratory reagents), is exclusively associated with fish ingestion. Mercury in the environment, especially that released into the air through industrial pollution, falls into and can accumulate in rivers and oceans, where it is turned into methylmercury. Fish absorb the methylmercury as they feed and so it accumulates in them. Shark, swordfish, king mackerel and tilefish contain high mercury levels, and white tuna can have fairly high levels. The most commonly eaten fish that are low in mercury are shrimp, canned light tuna, salmon, pollock and catfish. The US Food and Drug Administration (FDA) outlines pregnancy concerns and fish mercury levels at <http://www.fda.gov/Food/FoodborneIllnessContaminants/Metals/default.htm> (accessed 30 September 2013).

The most infamous example of methylmercury poisoning was at Minamata Bay and Nigata, Japan, in the 1950s. Many people suffered neurological damage, some died and there was a high incidence of cerebral palsy in neonates (Minamata disease) as a result of eating fish contaminated by mercury in industrial discharge found in the sea. Mercury poisoning of this type continues as a problem in parts of China, Brazil, Peru, Philippines, Suriname and Venezuela, and is associated mainly with occupations such as mining activities. Examples of gold mining-associated mercury pollution (often with cyanide and arsenic) are known in Africa, Canada, China, Philippines, Siberia, South America and USA. For further information, see <http://www.nrdc.org/health/effects/mercury/medical.asp> (accessed 30 September 2013).

Inorganic mercury salts poisoning, now rare, caused acrodynia (pink disease), a condition seen mainly at the end of the nineteenth century in children and others who used calomel (a mercury salt) in teething powders and gastrointestinal medications; it was also caused by inorganic mercurials used as disinfectants in detergents and baby powders. Inorganic mercury poisoning is still occasionally seen in people using mercuric chloride in skin creams available in the developing world, in

some traditional Chinese and herbal preparations, in some ritual spiritual or 'medical' practices, in suicide attempts and in forensic science, as well as in bizarre accidents. Poisoning can cause:

- acrodynia – skin peeling, salivation, hypotonia, swelling of extremities
- gastrointestinal ulceration and necrosis
- renal failure.

Metallic mercury poisoning is an issue with dental amalgam but is actually confined almost exclusively to the occupational setting. Dental amalgam is a mixture of 50% metallic mercury with other metals, and there is concern that mercury can be released as vapour, ions or fine particles, which can be inhaled or ingested. Studies of amalgam exposure, even during pregnancy, have not documented any toxicity, including birth defects, neurologic sequelae, spontaneous abortions or reduction in fertility. Poisoning was, however, well recognized in the past among people working with metallic mercury (e.g. thermometer makers and makers of felt hats – hence, 'mad as a hatter'). Poisoning has more recently been reported among people who use mercury for activities such as gold mining, where mercury is added to the pan to amalgamate the gold and is subsequently boiled off. Metallic mercury is also used in Santería – a Caribbean religious practice in which mercury may be sprinkled inside a home and can cause serious over-exposure. Accidents also continue to occur, metallic mercury still being found in some older equipment such as thermometers, fluorescent lights and computers. Mercury can be absorbed by inhalation of its vapour or through skin and mucous membranes (and mercury salts can be absorbed after their ingestion). There are even some who inject it intravenously in suicide attempts! Mercury is highly lipid-soluble, rapidly penetrates the blood–brain barrier and infiltrates neurons.

Acute poisoning by massive inhalation of mercury vapour is rare but can cause potentially fatal pneumonitis and neurological symptoms, particularly tremor and excitability. Chronic poisoning by mercury vapour inhalation primarily causes lassitude, gastrointestinal disturbances, anorexia and weight loss, and affects the central nervous system (CNS) with tremor, memory loss and excitability (erethism). Other effects include hypersalivation, accelerated periodontitis and a black gingival line due to deposition of mercury sulphides (like the lead line). Rarely, jaw necrosis follows.

Mercury hazards to dental health workers

Amalgam use may be associated with occupational exposure of dental health workers (DHWs) to metallic mercury if personnel fail to follow good work practices. On average, up to 1.5 kg of mercury are used by a dental practice annually; in the past, when less attention was paid to occupational hazards, mercury vapour in the surgery atmosphere and its levels in the blood, hair, nails and urine of DHWs were frequently above controls. Droplets of mercury could also accumulate in significant amounts in surgery carpeting or crevices in the floor. Mercury is also absorbed during the outmoded practice of hand trituration of amalgam or during other skin contact. In the past, after decades of practice, a few DHWs suffered chronic mercury toxicity with tremor, incoordination, polyneuropathies and accelerated senility. Autopsy studies have also shown mercury deposits, particularly in the pituitary glands and occipital lobes. Rarely, deaths have been reported after prolonged heavy exposure.

In a study of female DHWs, a history of reproductive failures, menstrual disorders and spina bifida in their children was suggested to be related to mercury levels in hair, but this has not been widely

confirmed – and other larger studies have shown no such correlation. Indeed, the perinatal death and birth defect rate for infants born to dentists is currently *lower* than average. Further, urinary mercury levels appeared to be falling in studies of dentists in the 1990s, and more recent studies of DHWs have not shown excessively high urinary mercury levels where good mercury hygiene was practised. Another study found no consistent association between either urinary mercury or chronic mercury exposure and any category of self-reported symptoms of depression, anxiety and memory loss. Exposure of DHWs to mercury is currently now very low – probably as a result of increased awareness of mercury toxicity and improved methods of preparing amalgam – especially the use of encapsulated mercury amalgam. Thus it seems unlikely that there is now a significant risk to DHWs who work in practices where adequate standards of mercury hygiene appertain. Indeed, mercury levels in DHWs are highest in those who eat fish, indicating that at least part of their mercury burden was from dietary – not dental – sources.

Risks from dental amalgam restorations

Dental amalgam restorative materials continually emit mercury vapour, which is increased by chewing, eating, brushing and drinking hot liquids. The World Health Organization's maximum recommended mercury intake is 2 micrograms/kg/day; release of mercury from dental amalgam is around 10 micrograms/day. Hydrogen peroxide can increase mercury release, so should be avoided. Removal of old amalgams from teeth with an air-rotor produces traces of mercury vapour – but not if adequate water-cooling and aspiration are used. The responses of official bodies to public concerns about mercury toxicity are shown in Appendix 29.1, and suggest a very low risk of toxicity. In one large study, children who received dental restorative treatment with amalgam did not, on average, have statistically significant differences in neurobehavioural assessments or in nerve conduction velocity, compared with children who received resin composite materials only. In the New England Children's Amalgam Trial, a randomized study involving children, the hypothesis that restorations using amalgam resulted in worse psychosocial outcomes than restorations using composite resin over a 5-year period following initial placement was not supported by the results. These findings, combined with the trend of higher treatment need later among those receiving composite restorations, suggested that amalgam should remain a viable dental restorative option for children.

Thus, according to present scientific evidence, the use of amalgam is not a proven health hazard and, to date, there is no dental material that can fully substitute for amalgam as a restorative material. More recent studies and reviews have also found little to no correlation between systemic or local diseases and amalgam restorations, although extensive amalgam restorations in pregnant or nursing women are not recommended. Nevertheless, the state governments of California, Connecticut, Maine and Vermont, and the federal governments of Denmark, Finland, Norway and Sweden have legislation requiring that dental patients receive informed consent information about the restorative material that will be used. Apart from Norway, Denmark and Sweden, dental amalgam has not been banned in any European Union country. A European Commission report by the BIO Intelligence Service (BIOIS), however, recommends the phasing-out of amalgam, and of mercury in button cell batteries (http://ec.europa.eu/environment/chemicals/mercury/pdf/review_mercury_strategy2010.pdf; accessed 30 September 2013).

Mercury disposal

The greatest hazard from inhalation of mercury vapour is as a result of any spillage. Dentists should use dental amalgam separators to trap

excess amalgam waste coming from surgeries and avoid release into the sewers; separators generally have a removal efficiency of approximately 95%. Captured amalgam solid waste should be appropriately recycled or retorted. Amalgam in waste waters proceeds to publicly owned treatment works (POTWs), most of which have more than 90% efficiency at removing amalgam waste. The rest is discharged from POTWs as a component of sewage sludge, which may then be disposed of:

- in landfills – where mercury may be released into the groundwater or air
- through incineration – when mercury may be emitted into the air
- through use on agricultural land as fertilizer – when mercury may be released into the groundwater or atmosphere.

Mercury waste from dental surgeries thus contributes significantly to the overall mercury contamination in wastewater, and may be the source of about 50% of all mercury entering POTWs – far exceeding pollution from all other commercial and residential sources. Other amalgam constituents (e.g. silver, tin, copper and zinc) have not been reported in dental clinics' wastewater.

Cremation and burial can also be responsible for mercury pollution. Cremation has recently gained in popularity due to the shedding of negative religious connotations but it releases quantities of atmospheric mercury from amalgams. Burial is important for many cultures, such as Catholics and Muslims; it also releases mercury and might reach drinking water sources. This issue is being addressed (<http://www.epa.gov/hg/dentalamalgam.html> and http://ec.europa.eu/environment/chemicals/mercury/pdf/review_mercury_strategy2010.pdf; both accessed 30 September 2013). The United Nations Environmental Programme (UNEP) has expressed concerns and also outlined the action required (<http://www.unep.org/hazardoussubstances/mercury/tabid/434/default.aspx>; accessed 30 September 2013).

CONCERNS ABOUT TOOTH-WHITENING PRODUCTS

Tooth-whitening products are widely available for sale over the counter (OTC) or ARE dispensed by dentists for patients' use at home. Most products release hydrogen peroxide (H_2O_2). Self-applied bleaching agents either contain or generate H_2O_2 , as gel in trays, paint-on films or whitening strips. A nightguard bleach typically uses 10% carbamide peroxide (which contains approximately 3% H_2O_2) and OTC whitening strips contain approximately 6% H_2O_2 , while in-surgery bleach uses 25–35% H_2O_2 . These can all potentially produce comparable whitening but strips are slightly more effective at whitening than is a gel in a tray. In the UK, Cosmetic Product (Safety) Regulations apply to products that contain or release more than 0.1% H_2O_2 .

Recently, attention has focused on dentist-prescribed home bleaching, in which the teeth and oral soft tissues can be in contact with peroxide-type agents for long periods; this creates a different situation from the use of in-surgery bleaching or home oral health-care products, such as peroxide-containing toothpastes and mouthwashes, from the standpoint of both dose and time. Hydrogen peroxide is a highly reactive substance that can damage oral soft and hard tissues when employed at high concentrations and with prolonged exposures. Direct exposure of mucosae, skin or eyes to 30% H_2O_2 may cause severe irritation, burns, blistering and ulceration. The much lower concentrations used in dental whitening products do not appear to produce such adverse effects, but tooth sensitivity and gingival irritation are common.

CONCERNS ABOUT ORAL HEALTH-CARE PRODUCTS

Contact dermatitis can occasionally be precipitated on the lip vermilion or, more frequently, the perioral skin by components of

toothpastes, lipsticks and some foods (notably mangoes and oranges) or by dental impression materials. Toothpastes or chewing gum components, especially cinnamon, can also cause plasma cell gingivitis or inflammation of other parts of the oral mucosa. Gingivitis, cheilitis, perioral dermatitis and other lesions have been described in patients using tartar-control toothpastes that contain cinnamonaldehyde or pyrophosphates. Some substances (e.g. zirconium) occasionally cause granulomatous oral reactions, and allergic reactions may underlie orofacial granulomatosis.

DRUGS

Relatively few drugs are used in general dentistry, and the rarity of hypersensitivity reactions and lack of evidence of significant interactions of local anaesthesia (LA) with drugs must be stressed. The many relative and absolute drug contraindications, as well as drug interactions, are discussed in Chapter 3 and its appendices. Drugs used in the practice of oral medicine and surgery may also produce adverse reactions or interactions.

However, children need lower doses of virtually all drugs. Older people tend to be more liable to adverse drug reactions, and the reactions tend to be more serious and last longer than in younger people. Older people are also more likely to be given drugs.

Sedative techniques are more likely and general anaesthesia (GA) is much more likely to produce adverse reactions.

DRUG REACTIONS AND ALLERGIES

Any suggestion of a previous drug adverse reaction or allergy, and particularly any adverse reaction during anaesthesia or imaging, must be taken seriously. Drug allergy or hypersensitivity results from interactions between a drug and the immune system, mediated by immunoglobulin E (IgE), but some reactions involve additional, poorly understood mechanisms. Identifiable risk factors for drug reactions include:

- advancing age
- female gender
- concurrent illnesses
- previous hypersensitivity to related drugs.

Furthermore, patients with allergy to one drug, and individuals with Sjögren syndrome or human immunodeficiency virus (HIV) disease may be particularly liable to drug allergies.

Drug hypersensitivity is usually a clinical diagnosis made on the basis of a rash or anaphylaxis. Laboratory testing may be useful, with skin testing providing the greatest specificity. Treatment includes discontinuation of the offending agent, symptomatic treatment and patient education.

Drug-induced hypersensitivity syndrome (DIHS) is a glandular fever-like syndrome (fever, rash, cervical lymphadenopathy, raised white cell count with atypical lymphocytes, and liver dysfunction) that follows the use of certain drugs – especially anticonvulsants such as carbamazepine and phenytoin, isoniazid and sulphonamides. Many cases also appear to be associated with the reactivation of human herpesvirus 6 (HHV-6) or other herpesviruses.

Many drug reactions could not be predicted and it is only by recording suspected adverse drug reactions to an appropriate authority (Figs 29.1 and 29.2) that serious adverse reactions of apparently safe drugs can be elicited (e.g. the cardiotoxicity of cyclo-oxygenase-2 inhibitors). Drug interactions are possible and it is also important to bear in mind that OTC and herbal preparations, foods and other substances can

sometimes interact by affecting drug absorption or efficacy, or by causing other interactions (Ch. 27 and Appendix 3.3).

DRUG ADVERSE EFFECTS

Many adverse drug reactions are probably not, at present, recognized. A full medical history should always be taken, asking specifically about adverse drug reactions. Certain conditions increase the risk of adverse reactions (Table 29.2) and can influence the choice of drugs. The excessive use of virtually any drug can cause harm. Patients should be warned if serious adverse reactions are likely, and provided with the appropriate warning card.

Anaesthetics and related agents

The use of excessive amounts of LA agents can be dangerous. Lidocaine with adrenaline (epinephrine), the most widely used drugs in dentistry, have proved to be remarkably safe in practice over very many years but gross overdose can be dangerous. One dentist has been found guilty of manslaughter, having given 16 cartridges of lidocaine with adrenaline to an elderly patient, who subsequently died.

Intravenous anaesthetic agents can cause anaphylactic-type reactions, either because of hypersensitivity or by directly inducing histamine release (the term ‘anaphylactoid’ may then be more appropriate). Tachycardia, vascular collapse and skin reactions (flushing, oedema or urticaria) are the most frequent signs, but reactions can range from minor symptoms to bronchospasm and a sharp fall in blood pressure. Treatment is as for anaphylaxis.

Anaphylactoid reactions have been reported particularly for thio-pental. Such reactions have sometimes been fatal, probably because of failure to recognize their nature, since the loss of consciousness that results must be distinguished from the onset of anaesthesia; many intravenous agents have been discontinued because of this.

Suxamethonium, the muscle relaxant, may also cause an anaphylactoid reaction but alcuronium, tubocurarine and other relaxants are sometimes implicated; as there does not need to be previous exposure to the agent, cross-reacting antigens are presumably implicated.

Halothane hypersensitivity may be a cause of ‘halothane hepatitis’ (Ch. 9). LA agents have been routinely used since the late nineteenth century but adverse reactions and allergy are not common (Ch. 3). True IgE-mediated LA allergy must be very low indeed; one recent paper reviewed 23 case series involving 2978 patients with reactions and found only 29 patients with true IgE-mediated allergy to LA (less than 1%).

Hypersensitivity to the ester-type LA agents, which used to be commonly employed, is low and esters such as amethocaine and benzocaine are now restricted mainly to use in surface anaesthetics. The risk with amide LAs, such as articaine, lidocaine, mepivacaine or prilocaine, is probably lower. Lidocaine rarely causes reactions. The most sensitizing component of LA solutions has been the preservative: initially, methylparabens was used (parabens are now rarely used). There may be allergies to sulphite antioxidants or to latex in the LA cartridge diaphragm or bung (Ch. 17).

Attempts to confirm putative allergy to LAs by skin testing (prick tests or intracutaneous tests) are time-consuming and usually uninformative; they can provoke anaphylaxis in the uncommon instances of true allergy and are therefore rarely justified. Challenge tests are also typically negative. Where there are multiple supposed allergies, it may be best to administer sterile saline subcutaneously first to demonstrate any non-allergic response, and then give rising concentrations of diluted LA at 30-minute intervals (resuscitation facilities must be at hand). Clearly, it is of great importance to avoid labelling patients

In Confidence

COMMITTEE ON SAFETY OF MEDICINES

SUSPECTED ADVERSE DRUG REACTIONS

If you are suspicious that an adverse reaction may be related to a drug or combination of drugs please complete this Yellow Card. For reporting advice please see over. Do not be put off reporting because some details are not known.

PATIENT DETAILS		Patient Initials: _____		Sex: M / F		Weight if known (kg): _____	
Age (at time of reaction): _____		Identification number (Your Practice / Hospital Ref.): _____					
SUSPECTED DRUG(S)							
Give brand name of drug and batch number if known							
Route	Dosage	Date started	Date stopped	Prescribed for			
_____	_____	_____	_____	_____			
SUSPECTED REACTION(S)							
Please describe the reaction(s) and any treatment given:							
Date reaction(s) started: _____ Date reaction(s) stopped: _____							Outcome
Do you consider the reaction to be serious? Yes / No							Recovered ☐
If yes, please indicate why the reaction is considered to be serious (please tick all that apply):							Recovering ☐
Patient died due to reaction ☐							Continuing ☐
Life threatening ☐							Other ☐
Congenital abnormality ☐							
Involved or prolonged inpatient hospitalisation ☐							
Involved persistent or significant disability or incapacity ☐							
Medically significant; please give details: _____							
OTHERS DRUGS (including self-medication & herbal remedies)							
Did the patient take any other drugs in the last 3 months prior to the reaction? Yes / No							
If yes, please give the following information if known:							
Drug (Brand, if known)	Route	Dosage	Date started	Date stopped	Prescribed for		
_____	_____	_____	_____	_____	_____		
_____	_____	_____	_____	_____	_____		
_____	_____	_____	_____	_____	_____		
_____	_____	_____	_____	_____	_____		
Additional relevant information e.g, medical history, test results, known allergies, rechallenge (if performed), suspected drug interactions. For congenital abnormalities please state all other drugs taken during pregnancy and the last menstrual period.							
REPORTER DETAILS				CLINICIAN (if not the reporter)			
Name and Professional Address: _____				Name and professional Address: _____			
_____				_____			
Post code: _____ Tel No: _____				Post code: _____			
Speciality: _____				Tel No: _____ Speciality: _____			
Signature: _____ Date: _____				If you would like information about other adverse reactions associated with the suspected drug, please tick this box ☐			

* This is to enable you to identify the patient in any future correspondence concerning this report

SECOND FOLD HERE

Remember if in Doubt - Report

SUSPECTED ADVERSE DRUG REACTIONS REPORTING ADVICE

New Black triangle (▼) Drugs - report ALL suspected adverse reactions
(New medicinal drugs can be identified by the presence of a black triangle(▼)
both on the product information for the drug and BNF and MIMS)

Other Drugs - only report SERIOUS suspected adverse reactions
For instance those which are:

- Fatal
- Life threatening
- Involves or prolongs inpatient hospitalisation
- Involves persistent or significant disability or incapacity
- Congenital abnormality
- Medically significant (please exercise your judgement)

Please remember the areas of particular concern— delayed drug effects, the elderly, congenital abnormalities, children (including offlabel use of medications) and any herbal remedies

For more information contact:

- The National Yellow Card Information Service on Freephone 0800-7316789
- The MHRA website <http://medicines.mhra.gov.uk>
- Reporters can send suspected adverse drug reaction reports by electronic Yellow Card, via the MHRA Website.
- More detailed guidelines are given in the BNF

DO NOT BE PUT OFF REPORTING BECAUSE SOME DETAILS ARE NOT KNOWN

FIRST FOLD HERE

Fig. 29.2 Form for reporting serious adverse drug reactions in UK. (See <http://yellowcard.mhra.gov.uk>; accessed 30 September 2013).

Table 29.2 Risk factors for adverse drug reactions^a

Factors	Non-immune reaction (majority)	Hypersensitivity (minority)
Female gender	+	+
Infections: herpes, human immunodeficiency virus (HIV)	+	+
Systemic lupus	+	+
Others	Alcoholism	Adult
	Chronic kidney disease	Asthma
	Liver disease	Beta-blocker use
	Polypharmacy	Previous hypersensitivity to chemically related drug
	Serious illness	

^aAdapted from Riedl MA, Casillas AM. Adverse drug reactions: types and treatment options. *Am Fam Physician* 2003; 68:1781.

inappropriately as allergic to LAs in the first place. If a patient claims to be allergic to an LA, then a non-cross-reacting agent should be used; alternatively, a GA may be required.

Analgesics

Non-steroidal anti-inflammatory drugs (NSAIDs) may, rarely, induce allergic reactions. Aspirin can provoke allergic reactions but, in relation to the scale of its use, these are almost negligible. Aspirin-induced asthma is a rare possibility, seen mainly in patients with nasal polyps ('triad asthma' – asthma, nasal polyps and aspirin sensitivity). Other NSAIDs may, even more rarely, induce allergic reactions. If there is a history of allergy to a drug, it should not be given.

NSAIDs should not be used in patients taking anticoagulants, alcohol or high-dose methotrexate. They should also be avoided in older or renally impaired patients on digoxin, and avoided over the long

term in those taking other NSAIDs. It is possible, but unconfirmed, that NSAIDs should not be given to patients taking lithium. NSAIDs are probably appropriate in the short term for patients taking anti-hypertensives, unless they have severe congestive heart disease or renal function is compromised.

Aspirin is a safe analgesic but readily causes platelet dysfunction, and excessive doses have led to post-extraction bleeding. It should also not be given to patients taking oral hypoglycaemics, valproic acid or carbonic anhydrase inhibitors.

Paracetamol (acetaminophen) is also safe but, when given in repeated doses, can cause severe liver damage. It may be used in the short term for any patient with a healthy liver, but should not be given to heavy drinkers or to persons who have recently stopped alcohol after chronic intake.

Opioids should not be given to heavy alcohol drinkers.

Antibiotics

Some antimicrobials (erythromycin, clarithromycin, metronidazole, ketoconazole and itraconazole) give rise to potentially life-threatening interactions with a host of other drugs, whose metabolism is impaired by them.

Antibiotics may also interfere with the effects of warfarin via suppression of gut bacteria that produce vitamin K. Commonly employed antibiotics may also impair the effectiveness of oral contraceptive agents, though the evidence for this is not strong (Fig. 29.3).

Anaphylaxis to antibiotics is a real possibility and has been estimated to have caused approximately 300 deaths annually in USA. Hypersensitivity reactions to beta-lactams (in penicillin and cephalosporins) are the most common reactions and are more likely to follow parenteral than oral administration. Patients allergic to penicillin usually react to any other penicillin except aztreonam. Individuals with penicillin allergy should avoid carbapenems and use caution with cephalosporins. About 10% of those sensitized to penicillin are said also to react to the cephalosporins. However, some allergic reactions can be selective for certain semi-synthetic penicillins, and some patients tolerant of benzylpenicillin can show delayed reactions to aminopenicillins. The causal antigen appears to be the penicilloyl group, which forms from metabolic cleavage of the beta-lactam ring and acts as a hapten, binding to body proteins to become antigenic. Specific IgE antibodies to penicillin are the cause of the anaphylactic reactions by

Fig. 29.3 Effects of antimicrobials on the contraceptive pill and vitamin K (hence on warfarin).

binding to mast cells and triggering mediator release. There appears to be *no* association between penicillin anaphylaxis and atopic disease, despite both being mediated by the same mechanism. The most common drug allergic reactions, apart from anaphylaxis, are urticarial and irritating rashes or sometimes a serum sickness type of reaction (joint pains and fever follow days or weeks after administration).

A history of previous reactions to penicillin suggests a greater risk of acute anaphylaxis – but there is no completely reliable method of prediction. Unfortunately, the first manifestation of sensitivity can occasionally be anaphylaxis and, rarely, a patient who has had penicillins on several occasions without ill effect can suddenly develop anaphylaxis. A negative history therefore reduces the chances but does not exclude the possibility of anaphylaxis when the patient claims to be allergic to penicillin. From the practical and medicolegal viewpoints, therefore, reliance has to be placed on the history and an alternative antimicrobial should be used – but never any penicillin derivatives (except aztreonam). Since a negative history of penicillin allergy does not totally exclude the possibility of anaphylaxis, it is arguable that penicillin should not be given immediately before a GA, since recognition under such circumstances can be difficult. If penicillin has to be given, 30 minutes should be allowed to elapse before induction of GA; after such a period, a severe reaction is unlikely. Depot penicillins, which are slowly excreted, can maintain the antigenic challenge so that treatment of an allergic reaction may have to be continued until all the antigen is used up. Occasionally, procaine penicillin can additionally cause vertigo, hallucinations and acute anxiety reactions if given intravenously (or if it accidentally enters a vein) – reactions that may be mistaken for anaphylaxis.

A patient should, of course, be lying down when any injections are given, as fainting after injections is common and may be confused with anaphylaxis.

Anticonvulsants

Anticonvulsants are used to treat epilepsy and trigeminal neuralgia. Anticonvulsant hypersensitivity syndrome (AHS) is a potentially fatal, drug-induced, multiorgan syndrome reported with carbamazepine, phenytoin, phenobarbital and lamotrigine. The exact mechanism of AHS is unclear but it may have three components: deficiency or abnormality of the epoxide hydroxylase enzyme that detoxifies metabolites of aromatic amine anticonvulsants; reactivation of herpesviruses; and ethnic predisposition, especially an association with human leukocyte antigen (HLA)-B*1502 (HLA BFNx011502 allele) in some Asian but not in Caucasian and Japanese patients.

Whilst up to 1 in 5 patients on phenytoin may develop skin eruptions, only a small proportion will progress to AHS – with urticaria, purpura, erythema multiforme and exfoliative dermatitis. Toxic epidermal necrolysis is uncommon, and usually occurs in patients who are re-exposed or who continue to receive anticonvulsants after hypersensitivity has developed. AHS is a clinical diagnosis; fever, rash and hepatitis are common features. Treatment is symptomatic. The offending drug should be immediately discontinued. Topical steroids and antihistamines are helpful in controlling symptoms. Systemic corticosteroids are often used.

Radiocontrast media (RCM) reactions

Intravascular iodinated RCM agents are based on a tri-iodinated benzene ring and can cause adverse reactions. These can be:

- anaphylactoid
- non-anaphylactoid

- chemotoxic – organ-specific:
cardiovascular toxicity
nephrotoxicity
neurotoxicity
- vasovagal.

RCM usually act by directly releasing histamine from mast cells rather than provoking an allergic response. High-osmolar contrast media (HOCM) are the oldest but have largely been superseded by less toxic non-ionic compounds – low-osmolar contrast media (LOCM). Additional modifications to reduce toxicity further include: adding calcium ions (reduces cardiotoxicity), having a neutral pH (low pH predisposes to vasodilatation), and altering number and distribution of OH ions (decreases neurotoxicity).

People at higher risk for reactions to RCM include those who:

- have had past reactions to RCM (up to 40% chance of repeat reaction)
- have asthma
- have a history of allergies
- have a history of heart disease
- have a history of kidney disease
- are taking beta-blockers
- are female
- are older.

Reactions to RCM are relatively quite common – 5–8% of people receiving an intravenous dye. Most reactions are mild: a feeling of warmth, nausea and vomiting, lasting only briefly and requiring no treatment. Moderate reactions, including severe vomiting, hives and

swelling, occur in 1% of people receiving RCM, and may need treatment. Severe, life-threatening reactions, including anaphylaxis, occur in 0.1% of people receiving RCM and occasionally are fatal. Delayed contrast reactions can occur anywhere from 3 hours to 7 days following the administration of contrast. Non-ionic low-osmolality contrast media LOCM are the preferred form, given their better safety record, although they are far more expensive than HOCM. Unfortunately, there is no test available to diagnose RCM allergy, and even ‘test doses’ can be fatal.

Iodine and iodides are also present in some antiseptics such as povidone–iodine, and can provoke dangerous reactions. Povidone–iodine is a commonly used antibacterial agent used in other products such as foods, drugs (e.g. antihistamines, diuretics and analgesics), hair products and toothpastes. Allergic contact reactions to povidone–iodine preparations are rare and do not necessarily indicate reactivity to RCM; anaphylaxis to povidone–iodine is thought to be caused by povidone, and cross-reactivity between these antiseptics and iodinated contrast media has not been demonstrated. Reactions to RCM can be limited by prophylaxis with a systemic steroid, diphenhydramine, and ephedrine or a histamine H₂-receptor antagonist.

Monoclonal antibodies

Monoclonal antibodies (see also Ch. 19) specifically bind to a substance and can serve to detect or purify that substance or act as a therapeutic medicine. When used as medications, the generic name ends in *-mab*. Monoclonal antibodies are available to treat cancer, cardiovascular disease, inflammatory diseases, transplant rejection, multiple sclerosis and viral infections (Table 29.3).

Table 29.3 Some therapeutic monoclonal antibodies (mAb)/fusion proteins^a

mAb/fusion protein	Brand names	Target	Applications
Abatacept	Orencia	Cluster of differentiation 80 (CD80) and CD86	Transplant rejection, rheumatoid arthritis
Abciximab	ReoPro	Glycoprotein II/IIIa	Coronary interventions
Adalimumab	Humira	Tumour necrosis factor alpha (TNF α)	Crohn disease, rheumatoid arthritis, psoriasis
Alefacept	Amevive	CD2	Psoriasis
Alemtuzumab	Campath	CD52	Chronic lymphoid leukaemia, rheumatoid arthritis
Anakinra	Kineret	Interleukin (IL)-1R	Rheumatoid arthritis
Basiliximab	Simulect	IL-2R	Transplant rejection
Belatacept	Nulojix	CD80 and CD86	Transplant rejection
Bevacizumab	Avastin	Vascular endothelial growth factor (VEGF)	Cancers (various)
Bortezomib	Velcade	Proteasome	Multiple myeloma
Canakinumab	Ilaris	IL-1beta	Juvenile arthritis
Catumaxomab	Removab	Epithelial cell adhesion molecule	Cancers
Certolizumab	Cimzia	TNF α	Crohn disease, rheumatoid arthritis, psoriasis
Cetuximab	Erbitux	Epidermal growth factor receptor (EGFR)	Head and neck cancer
Daclizumab	Zenapax	IL-2R	Transplant rejection
Denosumab	Prolia	Receptor activator of nuclear factor kappa-B ligand (RANKL)	Osteoporosis
Eculizumab	Soliris	C5	Paroxysmal nocturnal haemoglobinuria
Efalizumab	Raptiva	CD11a	Psoriasis
Etanercept	Enbrel	TNF α	Crohn disease, rheumatoid arthritis, psoriasis, sarcoid
Gemtuzumab	Mylotarg	CD33	Acute myeloid leukaemia
Golimumab	Simponi	TNF α	Crohn disease, rheumatoid arthritis, psoriasis
Ibiritumomab	Zevalin	CD20	Non-Hodgkin lymphoma (NHL)
Infliximab	Remicade	TNF α	Crohn disease, rheumatoid arthritis, psoriasis, sarcoid
Muromonab	Orthoclone OKT3	CD3	Transplant rejection
Natalizumab	Tysabri	Integrin receptor antagonist	Multiple sclerosis, Crohn disease
Omalizumab	Xolair	Immunoglobulin E (IgE)	Asthma
Palivizumab	Synagis	Respiratory syncytial virus	Respiratory syncytial virus

(Continued)

Table 29.3 (Continued)

mAb/fusion protein	Brand names	Target	Applications
Panitumumab	Vectibix	EGFR	Cancers
Ranibizumab	Lucentis	VEGF	Age-related macular degeneration
Raxibacumab	ACthrax	<i>Bacillus anthracis</i>	Anthrax
Rilonacept	Arcalyst	IL-1	Autoinflammatory disease
Rituximab	Rituxan or MabThera	CD20	NHL, rheumatoid arthritis
Sunitinib	Sutent	Tyrosine kinase	Cancers (renal)
Tocilizumab	Actemra	IL-6R	Rheumatoid arthritis
Tofacitinib	Xeljanz	Janus kinases	Rheumatoid arthritis
Tositumomab	Bexxar	CD20	NHL
Trastuzumab	Herceptin	ErbB2 (Her 2)	Breast cancer
Ustekinumab	Stelara	IL-12 and IL-23	Psoriasis

Immunomodulator agents

An immunomodulator (see also Ch. 19) is a substance (e.g. a drug) that has an effect on the immune response (Table 29.4), which may be stimulatory or suppressive. Immunostimulatory agents include, for example, vaccines and colony-stimulating factors. Immunosuppressive agents (see Chs 16, 18 and 35) can be classified into:

- glucocorticosteroids
- cytostatic agents
- antibodies
- drugs acting on immunophilins
- others (e.g. interferons, tumour necrosis factor [TNF]-binding agents, mycophenolate).

Hyperbaric oxygen therapy (HBO)

Hyperbaric oxygen therapy is the medical use of oxygen at a level higher than atmospheric pressure. Indications, contraindications and possible adverse effects are summarized in Table 29.5.

Other agents

Other medicines, such as sulphonamides, sulphones and allopurinol, have also caused a multiorgan hypersensitivity syndrome. Starch glove powder can cause direct skin irritation, interfere with wound healing and impair implant osseointegration and composite bonding.

DRUG INTERACTIONS

Almost any drug may cause interactions, so no drug should be given unless there are good indications (Table 29.6). Drug metabolism can be affected by other drugs. Polypharmacy should be avoided and dentists should only use drugs with which they are familiar. Possible drug interactions are more likely when GA is used (Ch. 3), in older people and in patients with learning disability.

Drug absorption can be impaired by other drugs; for example, iron, magnesium and aluminium in drugs can impair absorption of tetracyclines. Aluminium can impair absorption of azole antifungals. Metoclopramide enhances absorption of paracetamol (acetaminophen) and aspirin.

DRUG CONTRAINDICATIONS

Possible contraindications to the main drugs prescribable by the dental surgeon are tabulated in Chapter 3.

Table 29.4 Immunomodulators^a

Group	Mechanisms	Examples
Antimetabolites	Purine synthesis inhibitor	Azathioprine Mycophenolic acid
	Pyrimidine synthesis inhibitor	Leflunomide Teriflunomide
	Antifolate	Methotrexate
Interleukin-1 (IL-1) receptor antagonists	Block IL-1	Anakinra
IL-2 inhibitors	FK506 binding protein (FKBP)/cyclophilin/calcineurin	Abetimus Ciclosporin Gusperimus Pimecrolimus Tacrolimus
Inhibitors of (mammalian target of rapamycin mTOR)	Inhibit mTOR – a serine/threonine protein kinase that regulates cell growth, proliferation, motility, survival, protein synthesis and transcription	Ridaforolimus (deforolimus) Everolimus Sirolimus Temsirolimus Zotarolimus
Tumour necrosis factor alpha (TNF-α) inhibitors	Inhibit TNF	Lenalidomide Thalidomide

^aSee Chapter 19.

Table 29.5 Hyperbaric oxygen therapy

Possible indications	Contraindications	Possible adverse effects
Air embolism	Pneumothorax	Oxygen toxicity
Carbon monoxide poisoning	Upper respiratory infections	Barotrauma affecting sinuses, middle ear or teeth
Crush injuries or gas gangrene	Middle ear barotrauma	Possible ocular complications
Burns	Chest surgery	
Skin flaps that are compromised	Emphysema	
Intractable soft-tissue infections	Malignant disease	
Bone disorders such as osteomyelitis or osteoradionecrosis	Medication with disulfiram, doxorubicin, mafenide acetate or cisplatin	

ORAL ADVERSE EFFECTS OF DRUGS

Oral adverse effects caused by drugs are relatively uncommon but may be important. Drugs that may occasionally cause oral complications are listed in Appendices 29.2–29.23.

Table 29.6 Antimicrobial interactions

Drug	May interact with	Symptoms	Consequences
Ampicillin, amoxicillin	Beta-blockers	Hypertension	Lowered antihypertensive levels. Greater severity of anaphylactic reactions
Erythromycin	Benzodiazepines	Anxiety states	High benzodiazepine levels
	Carbamazepine	Epilepsy, trigeminal neuralgia	Carbamazepine toxicity
	Ciclosporin	Immunosuppression	Ciclosporin toxicity
	Digoxin	Cardiac failure	Digitalis toxicity
	Statins	Hyperlipidaemia	Muscle damage
	Terfenadine	Allergies	Arrhythmias
	Theophylline	Asthma	Theophylline toxicity
Metronidazole	Warfarin	Anticoagulation	Increased bleeding tendency
	Ethanol (alcohol)	Abuse	Disulfiram-type reaction
	Lithium	Manic depression	Lithium toxicity
Tetracyclines	Warfarin	Anticoagulation	Increased bleeding tendency
	Antacids	Gastric disease	Reduced tetracycline absorption
	Digoxin	Cardiac failure	Digitalis toxicity
Fluconazole	Statins	Hyperlipidaemia	Muscle damage
	Warfarin	Anticoagulation	Increased bleeding tendency
Miconazole	Statins	Hyperlipidaemia	Muscle damage
	Warfarin	Anticoagulation	Increased bleeding tendency

Some drugs almost invariably cause oral adverse effects; for example, the most common drug-induced oral disorders are dry mouth (caused by many drugs with an atropinic action), ulcers (from cytotoxic drugs and others), candidosis (usually caused by tetracyclines, ampicillin or corticosteroids), gingival swelling (usually caused by phenytoin, ciclosporin and calcium-channel blockers) and lichenoid reactions (from NSAIDs and many others). Some habits, such as the use of oral snuff (smokeless tobacco), can cause gingival recession and leukoplakia, and possibly predisposes to oral cancer; oral use of cocaine can cause gingival ulceration or desquamation.

Drug-related cheilitis

Cheilitis is commonly caused by contact reactions to cosmetics or foods, but drugs may be implicated.

Drug-related contact stomatitis (stomatitis venenata)

Fixed drug eruptions comprise repeated ulceration at the same site in response to a particular drug. However, intraoral contact stomatitis is a dubious entity. In any such reactions, the lips or perioral skin are far more likely to be affected.

Drug-related erythema multiforme

A wide range of drugs may give rise to erythema multiforme, and it may be impossible to distinguish drug-induced erythema multiforme clinically from disease with other causes.

Drug-related infections

Opportunistic infection secondary to cytotoxic chemotherapy can cause oral ulceration. In particular, herpes simplex virus 1, varicella zoster and cytomegalovirus give rise to oral ulceration. Less commonly, ulceration may be due to Gram-negative bacterial infections.

Candidosis arises secondary to treatment with broad-spectrum antibiotics, corticosteroids (both systemic and inhaled preparations) and other immunosuppressive regimens (e.g. ciclosporin) and cytotoxic drugs. More rarely, mucormycosis and aspergillosis may cause thrush-like areas in patients on long-term immunosuppressive treatment.

Human papillomavirus infection manifesting as wart-like growths may develop in patients on long-term immunosuppressive therapy. Oral hairy leukoplakia, usually affecting the dorsum and lateral borders of the tongue and floor of the mouth, may be a consequence of Epstein–Barr virus infection in patients on corticosteroids (topical and systemic), ciclosporin or other long-term immunosuppressive regimens.

Drug-related leukoplakia

Tobacco and alcohol use are important risk factors for leukoplakia and oral cancer. A greater frequency of lesions with epithelial dysplasia of the lips (but not oral mucosa) has also been observed in some iatrogenically immunosuppressed patients. Sanguinarine, the principal alkaloid of the bloodroot plant (*Sanguinaria canadensis*), which is used in some mouthwashes and dentifrices for its antiplaque activity, may be associated with the development of oral leukoplakia.

Drug-related lichenoid reactions

Since these were noticed as an adverse effect of antimalarial therapy, there has been an ever-growing list of drugs that may give rise to mucocutaneous lichen planus-like eruptions (lichenoid reactions). The drugs now most commonly implicated are the NSAIDs and the angiotensin-converting enzyme inhibitors (ACEIs).

Drug-related lupus-like disorders

Systemic lupus erythematosus (SLE) may be induced by a wide variety of different drugs.

Drug-related malodour (halitosis)

Oral malodour may be related to treatment with isosorbide dinitrate, dimethyl sulfoxide or disulfiram, although drugs causing xerostomia can indirectly lead to, or aggravate this problem.

Drug-related movement disorders

Several different drug-induced movements can affect the mouth and face, particularly tardive dyskinesia (secondary to antipsychotics) and dystonias (e.g. with metoclopramide). Although these disorders

principally affect the face, there can be abnormal movements of the tongue, e.g. dystonia secondary to carbamazepine therapy.

Drug-related neoplasms

Non-Hodgkin lymphoma, usually manifesting as ulceration of the gingivae, fauces or palate, and Kaposi sarcoma (see later) are rare complications of long-term immunosuppressive therapy.

Drug-related neuropathies

Facial or oral paraesthesia, hypoaesthesia or anaesthesia can be due to interferon-alpha, acetazolamide, labetalol, sultiamine, vincristine and occasionally some other agents, such as hepatitis B vaccination and some of the protease inhibitors.

Drug-related pain and dysaesthesia

Captopril and lisinopril may very rarely cause a scalded-type sensation of the mouth.

Drug-related pemphigoid and other bullous disorders

Drug-induced pemphigoid may be due to drugs acting as haptens or drug-induced immunological dysfunction.

Drug-related pemphigus

Pemphigus-like reactions may occasionally be associated with drugs with active thiol groups in the molecule, such as penicillamine and captopril, or by rifampicin or diclofenac.

Drug-related pigmentation

Superficial transient discoloration of the dorsum of the tongue, other soft tissues and teeth, which may be of various colours (typically yellowish or brown), may be caused by some foods and beverages (coffee and tea), habits (tobacco, betel and crack cocaine use) and some drugs (iron salts, bismuth, chlorhexidine or antibiotics), especially if these also induce hyposalivation.

Localized areas of pigmentation of the mucosa may be due to amalgam, while gingival pigmentation may be secondary to the gold or metal alloys of crowns. Heavy metal salts, used in the past, caused pigmentation, particularly of the gingival margin.

Blue, blue-grey or brown mucosal pigmentation can be an adverse effect of antimalarials, phenothiazines and phenytoin or amiodarone. Minocycline frequently causes widespread brown pigmentation of the gingivae and mucosae.

Discolouration of saliva may be caused by rifampicin, rifabutin and a few other drugs.

Drug-related salivary gland pain

Salivary gland pain can be an adverse effect of some drugs, such as bethanidine, bretylium, clonidine, methyldopa and some cytotoxics.

Drug-related sialorrhoea

Anticholinesterases are the main cause of sialorrhoea.

Others

Drug-related swelling

Gingival enlargement is a well-recognized oral adverse effect of treatment with phenytoin, ciclosporin and the calcium-channel blockers.

Drug-induced mucosal swelling predominantly affects the lips and floor of the mouth (although rare isolated swelling of the uvula is possible). It is typically due to type I hypersensitivity reactions.

Many drugs, particularly penicillins, ACEIs and aspirin, can cause angioedema.

Drug-related taste disturbance

Drugs commonly impair taste because they cause a loss of acuity (hypogeusia) or distortion of function (dysgeusia), either by interfering in the chemical composition or flow of saliva or, more specifically, affecting taste receptor function or signal transduction. Hyposalivation also disturbs taste.

Drug-related ulceration

Oral ulceration may follow burns from the local application of aspirin or toothache preparations, potassium tablets, pancreatic supplements and other agents, such as trichloroacetic acid or hydrogen peroxide.

Mucositis and ulceration are caused by many chemotherapy regimens, particularly those involving methotrexate, 5-fluorouracil, doxorubicin, melphalan, mercaptopurine or bleomycin.

Aphthous-like ulcers can be caused by NSAIDs and beta-blockers, and possibly by nicorandil, alendronate and everolimus.

Drug-related xerostomia

Common habits, such as tobacco smoking, alcohol use (including in mouthwashes) and use of beverages containing caffeine (coffee, some soft drinks), can cause some oral dryness.

Drugs are the most common cause of reduced salivation. Those most often implicated in dry mouth are the tricyclic antidepressants, antipsychotics, atropinics and antihistamines. The complaint of dry mouth is therefore particularly common in patients treated for hypertensive, psychiatric or urinary problems.

The cause for which the drug is being taken may also be important. Patients with anxiety or depression may complain of dry mouth even in the absence of drug therapy or evidence of diminished salivary flow.

APPENDIX 29.1 SUMMARY OF OFFICIAL BODY COMMENTS ON DENTAL AMALGAM SAFETY

In 2004, an expert panel reviewed the peer-reviewed, scientific literature published from 1996 to December 2003 on potential adverse human health effects caused by dental amalgam and published a report. The review, conducted by the Life Sciences Research Office (LSRO) and funded by the National Institutes of Dental and Craniofacial Research, National Institutes of Health and Centers for Devices and Radiological Health, US Food and Drug Administration (FDA) states that:

The current data are insufficient to support an association between mercury release from dental amalgam and the various complaints that have been attributed to this restoration material. These complaints are broad and nonspecific compared to the well-defined set of effects that have been documented for occupational and accidental elemental mercury exposures. Individuals with dental amalgam-attributed complaints had neither elevated urinary mercury nor increased prevalence of hypersensitivity to dental amalgam or mercury when compared with controls. (www.lsro.org)

In 2006, the *Journal of the American Medical Association* (JAMA) and *Environmental Health Perspectives* published the results of two independent clinical trials designed to examine the effects of mercury release from amalgam on the central and peripheral nervous systems and kidney function, concluding that:

there were no statistically significant differences in adverse neuropsychological or renal effects observed over the 5-year period in children whose caries are restored using dental amalgam or composite materials

and

children who received dental restorative treatment with amalgam did not, on average, have statistically significant differences in neurobehavioral assessments or in nerve conduction velocity when compared with children who received resin composite materials without amalgam. These findings, combined with the trend of higher treatment need later among those receiving composite, suggest that amalgam should remain a viable dental restorative option for children.

In May 2008, a Scientific Committee of the European Commission addressed safety concerns for patients and professionals, and the use of alternative restorative materials, concluding that dental amalgams are effective and safe for both patients and dental personnel, and also noted that alternative materials are not without clinical limitations and toxicological hazards.

The American Dental Association (ADA) Council on Scientific Affairs prepared a comprehensive literature review that summarized the state of the evidence for amalgam safety (from January 2004 to April 2009). Based on the results of this review, the Council reaffirmed at its July 2009 meeting that the scientific evidence supports the position that amalgam is a valuable, viable and safe choice for dental patients.

On 28 July 2009, the FDA issued its final rule on encapsulated dental amalgam, classifying amalgam and its component parts, elemental mercury and powder alloy, as a class II medical device. Previously there was no classification for encapsulated amalgam, and dental mercury (class I) and alloy (class II) were classified separately. This new regulation places encapsulated amalgam in the same class of devices as most other restorative materials, including composite and gold fillings. At the same time, the FDA also reaffirmed the agency's position that the material is a safe and effective restorative option for patients.

The situation has been summarized by one author as follows:

Amalgam fillings release mercury (mercury vapour or inorganic ions) at a low level (about 2–5 micrograms/day in an adult). Evidence on the health effect of dental amalgams comes from studies of the association between their presence and signs or symptoms of adverse effects or health changes after removal of dental amalgam fillings. More formal risk assessment studies focus on occupational exposure to mercury and health effects. Numerous methodological issues make their interpretation difficult but new research will continue to challenge policymakers. Policy will also reflect prudent and cautious approaches, encouraging minimization of exposure to mercury in potentially more sensitive population groups. Wider environmental concerns and decreasing tolerance of exposure to other mercury compounds (for example, methylmercury in seafoods) will ensure the use of mercury in dentistry remains an issue, necessitating dentists keep their patients informed of health risks and respect their choices. (Spencer AJ. Dental amalgam and mercury in dentistry. Aust Dent J 2000; 45:224)

APPENDIX 29.2 DRUGS IMPLICATED IN DRY MOUTH

• Alfuzosin	• Chlormezanone	• Diazepam	• Ephedrine
• Amiloride	• Chlorpromazine	• Dicycloverine (dicyclomine)	• Fenfluramine
• Amitriptyline	• Citalopram	• Didanosine (dideoxyinosine)	• Fluoxetine
• Amoxapine	• Clemastine	• Dihydrocodeine	• Furosemide
• Benzhexol	• Clomipramine	• Disopyramide	• Guanfacine
• Benztropine	• Clonidine	• Donepezil	• Hyoscine
• Biperiden	• Clozapine	• Dosulepin	• Imipramine
• Bupropion	• Cyclizine	• Doxepin	• Indoramin
• Buspirone	• Cyclobenzaprine	• Duloxetine	• Interferon-alpha
• Cannabis	• Desipramine	• Ecstasy	• Interleukin-2
• Cetirizine	• Dexamfetamine	• Elliptinium	• Ipratropium

(Continued)

• Iprindole	• Morphine	• Procyclidine	• Tiabendazole
• Isocarboxazid	• Moxonidine	• Propafenone	• Tiapride
• Isotretinoin	• Nabilone	• Propantheline	• Tiotropium
• Ketorolac	• Nefopam	• Propiverine	• Tizanidine
• Ketotifen	• Nortriptyline	• Pseudoephedrine	• Tolterodine
• Lansoprazole	• Olanzapine	• Quetiapine	• Tramadol
• L-Dopa	• Omeprazole	• Reboxetine	• Tranylcypromine
• Lithium	• Orphenadrine	• Rilmenidine	• Trazodone
• Lofepamine	• Oxitropium	• Risperidone	• Triamterene
• Lofexidine	• Oxybutynin	• Rizatriptan	• Trimipramine
• Loratadine	• Paroxetine	• Selegiline	• Tropicium chloride
• Maprotiline	• Phenelzine	• Sertraline	• Venlafaxine
• Mepenzolate	• Pipamperone	• Sibutramine	• Viloxazine
• Methyldopa	• Pipenzolate	• Sucralfate	• Zopiclone
• Mianserin	• Pirenzepine	• Tamsulosin	
• Mirtazapine	• Poldine	• Terazosin	

APPENDIX 29.3 DRUGS IMPLICATED IN SALIVARY GLAND PAIN OR SWELLING

• Bethanidine	• Famotidine	• Naproxen	• Phenytoin
• Bretylium	• Guanethidine	• Nicardipine	• Ranitidine
• Cimetidine	• Insulin	• Nifedipine	• Ritodrine
• Clonidine	• Interferon	• Nitrofurantoin	• Trimepramine
• Clozapine	• Isoprenaline	• Oxyphenbutazone	
• Deoxycycline	• Methyldopa	• Phenylbutazone	

APPENDIX 29.4 DRUGS IMPLICATED IN HYPERSALIVATION

• Alprazolam	• Guanethidine	• Mefenamic acid	• Tacrine
• Amiodarone	• Haloperidol	• Mercurials	• Tobramycin
• Buprenorphine	• Imipenem/cilastatin	• Nicardipine	• Triptorelin
• Buspirone	• Iodides	• Niridazole	• Venlafaxine
• Clonazepam	• Kanamycin	• Pentoxifylline	• Zaleplon
• Diazoxide	• Ketamine	• Remoxipride	
• Ethionamide	• Lamotrigine	• Risperidone	
• Gentamicin	• L-Dopa	• Rivastigmine	

APPENDIX 29.5 DRUGS IMPLICATED IN DISCOLOURATION OF SALIVA

• Clofazimine	• L-Dopa	• Rifabutin	• Rifampicin

APPENDIX 29.6 DRUGS IMPLICATED IN DISTURBED TASTE

• Acarbose	• Amrinone	• Baclofen	• Carboplatin
• Acetazolamide	• Anticholinergics	• Biguanides	• Celecoxib
• Albuterol	• Aspirin	• Bisphosphonates	• Cetirizine
• Alcohol	• Atorvastatin	• Bleomycin	• Chlorhexidine
• Allopurinol	• Auranofin	• Bretylium	• Chlormezanone
• Amiloride	• Aurothiomalate	• Calcitonin	• Choline magnesium trisalicylate
• Amitriptyline	• Azathioprine	• Captopril	• Cilazapril
• Amphetamines	• Azelastine	• Carbamazepine	• Cisplatin
• Amphotericin	• Aztreonam	• Carbimazole	• Clarithromycin

(Continued)

• Clidinium	• 5-Fluorouracil	• Lovastatin	• Propafenone
• Clofibrate	• Fluvoxamine	• Metformin	• Propantheline
• Clomipramine	• Glycopyrrolate	• Methimazole	• Propranolol
• Cocaine	• Gold	• Methotrexate	• Propylthiouracil
• Colestyramine	• Griseofulvin	• Methyl methacrylate	• Quinapril
• Diazoxide	• Hexetidine	• Methylthiouracil	• Ramipril
• Dicycloverine (dicyclomine)	• Hydrochlorothiazide	• Metronidazole	• Rifabutin
• Diltiazem	• Hydrocortisone	• Nifedipine	• Rivastigmine
• Dipyridamole	• Hyoscyamine	• Niridazole	• Selegiline
• Disodium etidronate	• Imipenem	• Nitroglycerin	• Sodium lauryl sulfate
• Dorzolamide	• Imipramine	• Ofloxacin	• Spironolactone
• Emelastine	• Indometacin	• Omeprazole	• Sulfasalazine
• Enalapril	• Interferon-gamma	• Palifermin	• Terbinafine
• Esomeprazole	• Iodine	• Penicillamine	• Tetracycline
• Eszopiclone	• Isotretinoin	• Pentamidine	• Tocainide
• Ethambutol	• L-Dopa	• Pergolide	• Topiramate
• Ethionamide	• Levamisole	• Perindopril	• Trandolapril
• Etoposide	• Lincomycin	• Phenformin	• Triazolam
• Famotidine	• Lisinopril	• Phenindione	• Venlafaxine
• Flunisolide	• Lithium	• Phenylbutazone	• Zopiclone
• Fluoxetine	• Lomefloxacin	• Phenytoin	
• Flurazepam	• Losartan	• Procaine penicillin	

APPENDIX 29.7 DRUGS IMPLICATED IN ORAL ULCERATION

• Adalimumab	• Everolimus	• Naproxen	• Potassium chloride
• Alendronate	• Flunisolide	• Nicorandil	• Proguanil
• Allopurinol	• Gold	• Non-steroidal anti-inflammatory drugs (NSAIDs)	• Sertraline
• Aurothiomalate	• Indometacin	• Olanzapine	• Sulindac
• Aztreonam	• Interferons	• Pancreatin	• Tacrolimus
• Captopril	• Interleukin-2	• Penicillamine	• Vancomycin
• Carbamazepine	• Isoprenaline	• Phenindione	• Zalcitabine (dideoxycytidine)
• Clarithromycin	• Ketorolac	• Phenylbutazone	
• Diclofenac	• Losartan	• Phenytoin	
• Emeprium	• Molgramostim		

APPENDIX 29.8 DRUGS IMPLICATED IN LICHENOID REACTIONS

• Allopurinol	• Dipyridamole	• Mercury (amalgam)	• Prazosin
• Amiphenazole	• Ethionamide	• Metformin	• Procainamide
• Bacille Calmette–Guérin (BCG) vaccine	• Flunarizine	• Methyl dopa	• Propranolol
• Barbiturate	• Gaunoclor	• Metronidazole	• Propylthiouracil
• Captopril	• Gold	• Niridazole	• Prothionamide
• Carbamazepine	• Griseofulvin	• Oral contraceptives	• Quinidine
• Carbimazole	• Hepatitis B vaccine	• Oxprenolol	• Quinine
• Chloral hydrate	• Hydroxychloroquine	• Para-aminosalicylate	• Rifampicin
• Chloroquine	• Interferon-alpha	• Penicillamine	• Rofecoxib
• Chlorpropamide	• Ketoconazole	• Penicillins	• Streptomycin
• Cholera vaccine	• Labetalol	• Phenindione	• Tetracycline
• Cinnarizine	• Levamisole	• Phenothiazines	• Tocainide
• Clofibrate	• Lincomycin	• Phenylbutazone	• Tolbutamide
• Colchicine	• Lithium	• Phenytoin	• Triprolidine
• Dapsone	• Lorazepam	• Piroxicam	
	• Mepacrine	• Practolol	

APPENDIX 29.9 DRUGS IMPLICATED IN ORAL CANDIDOSIS

- Broad-spectrum antimicrobials
- Corticosteroids
- Drugs causing xerostomia
- Immunosuppressives

APPENDIX 29.10 DRUGS IMPLICATED IN PEMPHIGOID-LIKE REACTIONS

- Amoxicillin
- Azapropazone
- Clonidine
- Furosemide
- Ibuprofen
- Isoniazid
- Mefenamic acid
- Nadolol
- Penicillamine
- Penicillin V
- Phenacetin
- Practolol
- Salicylic acid
- Sulfasalazine
- Sulphonamides

APPENDIX 29.11 DRUGS IMPLICATED IN PEMPHIGUS-LIKE REACTIONS

- Ampicillin
- Arsenic
- Benzylpenicillin
- Captopril
- Cefadroxil
- Cefalexin
- Diclofenac
- Gold
- Interferon-beta
- Interleukin-2
- Oxyphenbutazone
- Penicillamine
- Phenobarbital
- Phenylbutazone
- Piroxicam
- Probenecid
- Procaine penicillin
- Rifampicin

APPENDIX 29.12 DRUGS IMPLICATED IN ERYTHEMA MULTIFORME (AND STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS)^a

- Acetylsalicylic acid
- Allopurinol
- Amlodipine
- Arsenic
- Atropine
- Busulfan
- Carbamazepine
- Chloral hydrate
- Chloramphenicol
- Chlorpropamide
- Clindamycin
- Codeine
- Co-trimoxazole
- Diclofenac
- Diflunisal
- Digitalis
- Diltiazem
- Ethambutol
- Ethyl alcohol
- Fluconazole
- Fluorouracil
- Furosemide
- Gold
- Griseofulvin
- Hydantoin
- Hydrochlorothiazide
- Indapamide
- Measles/mumps/rubella (MMR) vaccine
- Meclofenamic acid
- Mercury
- Mesterolone
- Minoxidil
- Nifedipine
- Omeprazole
- Oxyphenbutazone
- Penicillin derivatives
- Phenolphthalein
- Phenylbutazone
- Phenytoin
- Piroxicam
- Progesterone
- Pyrazolone derivatives
- Quinine
- Retinol
- Rifampicin
- Streptomycin
- Sulfasalazine
- Sulindac
- Tenoxicam
- Tetracyclines
- Theophylline
- Tocainide
- Tolbutamide
- Trimethadione
- Vancomycin
- Verapamil
- Zidovudine

^aFor antiretrovirals see Chapter 20.

APPENDIX 29.13 DRUGS IMPLICATED IN LUPOID REACTIONS

- Ethosuximide
- Gold
- Griseofulvin
- Hydralazine
- Isoniazid
- Methyldopa
- Para-aminosalicylate
- Penicillin
- Phenothiazines
- Phenytoin
- Procainamide
- Streptomycin
- Sulphonamides
- Tetracyclines

APPENDIX 29.14 DRUGS IMPLICATED IN CHEILITIS

- Actinomycin
- Atorvastatin
- Busulfan
- Clofazimine
- Clomipramine
- Cyanocobalamin
- Ethyl alcohol
- Etretinate
- Gold
- Indinavir
- Isoniazid
- Isotretinoin
- Lithium
- Menthol
- Methyldopa
- Penicillamine
- Selegiline
- Streptomycin
- Sulfasalazine
- Tetracycline
- Vitamin A

APPENDIX 29.15 DRUGS APART FROM SMOKING IMPLICATED IN ORAL MUCOSAL HYPERPIGMENTATION

• Adrenocorticotrophic hormone (ACTH)	• Chlorhexidine	• Lead	• Quinidine
• Amodiaquine	• Chloroquine	• Manganese	• Silver
• Anticonvulsants	• Clofazimine	• Mepacrine	• Thallium
• Arsenic	• Copper	• Methyldopa	• Tin
• Betel	• Cyclophosphamide	• Minocycline	• Vanadium
• Bismuth	• Doxorubicin	• Oral contraceptives	• Zidovudine
• Bromine	• Gold	• Phenolphthalein	
• Busulfan	• Heroin	• Phenothiazines	
	• Iron	• Quinacrine	

APPENDIX 29.16 DRUGS IMPLICATED IN ORAL MUCOSAL COLOURATION: DIFFERENT COLOURS

Black	Blue	Brown (hypermelanosis)	Green	Grey	White
Amiodiaquine	Amiodarone	Aminophenazone	Copper	Amiodiaquine	Palifermin (keratinocyte growth factor)
Betel nut	Antimalarials	Betel nut		Chloroquine	Sanguinarine
Bismuth	Bismuth	Bismuth		Fluoxetine	
Methyldopa	Mepacrine	Busulfan		Hydroxychloroquine	
Minocycline	Minocycline	Clofazimine		Lead	
	Phenazopyridine	Contraceptives		Silver	
	Quinidine	Cyclophosphamide		Tin/zinc	
	Silver	Diethylstilbestrol			
	Sulfasalazine	Doxorubicin			
		Doxycycline			
		Fluorouracil			
		Heroin			
		Hormone replacement therapy			
		Ketoconazole			
		Menthol			
		Methaqualone			
		Minocycline			
		Phenolphthalein			
		Propranolol			
		Smoking			
		Zidovudine			

APPENDIX 29.17 DRUGS IMPLICATED IN GINGIVAL SWELLING

Drugs most commonly implicated	Drugs occasionally implicated
Amlodipine	Basiliximab
Ciclosporin	Co-trimoxazole
Diltiazem	Diphenoxylate
Felodipine	Erythromycin
Lacidipine	Ethosuximide
Nifedipine	Interferon-alpha
Oral contraceptives	Ketoconazole
Phenytoin	Lamotrigine
Verapamil	Lithium
	Mephenytoin
	Nitrendipine
	Norethisterone + mestranol
	Phenobarbital
	Primidone
	Sertraline
	Topiramate
	Valproate
	Vigabatrin

APPENDIX 29.18 DRUGS IMPLICATED IN ANGIOEDEMA

• Angiotensin-converting enzyme inhibitors (ACEIs)	• Disulfite sodium	• Mianserin	• Quinine
• Asparaginase	• Droperidol	• Miconazole	• Streptomycin
• Carbamazepine	• Enalapril	• Naproxen	• Sulphonamides
• Clindamycin	• Epoetin alfa	• Nitrofurantoin	• Thiouracil
• Clonidine	• Ibuprofen	• Penicillamine	
• Co-trimoxazole	• Indometacin	• Penicillin derivatives	
	• Ketoconazole	• Pyrazolone derivatives	

APPENDIX 29.19 DRUGS IMPLICATED IN TRIGEMINAL PARAESTHESIA OR HYPOAESTHESIA

• Acetazolamide	• Hydralazine	• Nicotinic acid	• Stilbamidine
• Amitryptiline	• Interferon-alpha	• Nitrofurantoin	• Streptomycin
• Articaine	• Isoniazid	• Pentamidine	• Sulphonylureas
• Chlorpropamide	• Labetalol	• Phenytoin	• Sultiame
• Colistin	• Mefloquine	• Prilocaine	• Tolbutamide
• Ergotamine	• Methysergide	• Propofol	• Tricyclics
• Gonadotropin-releasing hormone analogues	• Monoamine oxidase inhibitors	• Propranolol	• Trilostane
	• Nalidixic acid	• Prothionamide	• Vincristine

APPENDIX 29.20 DRUGS IMPLICATED IN INVOLUNTARY FACIAL MOVEMENTS

• Carbamazepine	• Methyldopa	• Metirosine	• Tetrabenazine
• L-Dopa	• Metoclopramide	• Phenytoin	• Trifluoroperazine
• Lithium			

APPENDIX 29.21 DRUGS IMPLICATED IN HALITOSIS

• Dimethyl sulfoxide (DMSO)	• Disulfiram	• Isosorbide dinitrate

APPENDIX 29.22 DRUGS IMPLICATED IN OROFACIAL PAIN

• Benztropine	• Lithium	• Stilbamidine	• Vinca alkaloids
• Biperiden	• Penicillins	• Ticarcillin	• Vitamin A
• Griseofulvin	• Phenothiazines		

APPENDIX 29.23 DRUGS IMPLICATED IN TOOTH DISCOLOURATION

• Antibiotics	• Fosinopril	• Pentamidine	• Terbinafine
• Clarithromycin	• Imipenem	• Perindopril	• Tetracyclines
• Enalapril	• Lisinopril	• Propafenone	• Trandolapril
• Essential oil	• Metronidazole	• Quinapril	• Zopiclone
• Etidronate	• Penicillin	• Ramipril	

This chapter focuses (alphabetically) mainly on medical issues related to ethnic and cultural groups, homeless people, immigrants, people in custodial institutions, refugees and asylees, Roma, sexual minorities and socioeconomically deprived people. The importance of 'protected characteristics' as defined by the Equalities and Human Rights Commission are noted in Chapter 2 (<http://www.equalityhumanrights.com/advice-and-guidance/new-equality-act-guidance/protected-characteristics-definitions/>).

ETHNIC AND CULTURAL GROUPS

This section tabulates some of the main aspects (Table 30.1). Population mobility increases inexorably, leading to enormous changes in the structure of many populations across the world. This is especially evident in the developed world and as a consequence of conflicts and climate change.

For example, by 2011 almost 1 in 8 people living in the UK were foreign-born. The proportion of the UK population born outside

Europe reached 10% overall, with large regional variations from, for example, 3% in the far south-west to 30% in East London. Ongoing expansion of the European Union is producing major changes, as are conflicts and economic issues worldwide. Some of these people fall into one or more of the groups below.

It is difficult to characterize all the different faiths and cultures, since differences exist according to social class, background, ethnicity and other factors, but Table 30.2 attempts to highlight some relevant aspects.

Communication is crucial between dental professionals and patients from different faiths, cultures and countries. Professional interpreters may therefore be required.

HOMELESS PEOPLE

Homeless people and those who live in poor accommodation tend to have more illness, mainly due to exposure, inadequate diet, inadequate hygiene, stress, violence, accidents and exposure to communicable

Table 30.1 Ethnic and cultural groups: languages, religions, habits and medical aspects^a

Ethnic group	Main language(s)	Main religion(s)	Common diet, habits and medical aspects
Albanians (Kosovars)	Albanian	Islam Christianity	Alcohol use and smoking endemic, and younger generation uses narcotics at an increasing rate
Afro-Caribbeans	English French Spanish	Christianity	Seventh Day Adventists consume no pork, tea, coffee or alcohol. Rastafarians often use marijuana but may be vegan or eat no pork. Crack and cocaine use is common in Jamaicans
Arabs	Arabic	Islam	See Table 30.2
Armenians	Armenian	Christianity	–
Bangladeshi	Bengali Urdu	Islam	Healthy diet. Dislike oral medication. Females prefer female health-care workers. Often smoke or use paan
Bosnian	Serbo-Croat	Islam	Healthy diet. Dislike oral medication. Females prefer female health-care workers
Cambodian	Khmer	Buddhist	Traditional medicine may be preferred
Chinese	Cantonese Mandarin	Taoism Confucianism Buddhism	Traditional Chinese medicine may be used. Doctor-shopping common. Often eat rice diet and smoke heavily. May not like venepuncture
Eritreans	Tigrinya Arabic	Christianity Islam	Coptic Christians do not consume meat or dairy products for more than half of each year
Ethiopians	Amharic	Christianity Islam	Coptic Christians do not consume meat or dairy products for more than half of each year
Ghanaian	Twi	Islam Christianity	Traditional medicine may be used
Greeks	Greek	Christianity	Healthy diet. High tobacco use
Gujaratis	Gujarati	Hinduism	Often eat no meat, eggs or fish
Indian	Hindi Punjabi English	Hinduism (mainly) Islam Christianity Sikhism Zoroastrianism	Traditional (Ayurvedic) medicine. Often vegetarian or vegan. High tobacco and betel use. Rarely, vitamin B ₁₂ -deficient from veganism
Iranian	Farsi	Islam	–
Iraqi	Arabic	Islam	–
Irish	English	Christianity	May have high alcohol intake

(Continued)

Table 30.1 (Continued)

Ethnic group	Main language(s)	Main religion(s)	Common diet, habits and medical aspects
Japanese	Japanese	Buddhism Shintoism	Diet often of rice, raw fish and eggs
Koreans	Korean (Han-gul)	Confucianism Shamanism Taoism Buddhism	Traditional medicine commonly used. Be aware of communication styles and patterns, such as no eye contact, smiling at inopportune times represents lack of respect and intelligence
Kurds (a diverse ethnic group from Kurdistan, encompassing parts of Turkey, Iran, Iraq, Syria)	Kurdish	Islam	–
Laotians	Laotian	Buddhism	–
Latin Americans	Spanish Portuguese	Christianity	–
Liberians	English		Traditional medicine may be used
Nigerians	Four peoples/languages: Hausa, Yoruba, Ibo and Fulani	Islam Christianity	Traditional medicine may be used
Pakistanis	Punjabi	Islam	See Table 30.2
Portuguese	Portuguese	Christianity	High tobacco use
Russian Federation	Russian	Christianity	–
Somalis	Somali Arabic	Islam	May have qat habit
South Africans (whites)	English Afrikaans	Christianity	–
Sudanese	Arabic English	Islam Christianity	Traditional medicine may be used
Tamils	Tamil	Hinduism	Vegetarian
Tibetans	Tibetan Chinese	Buddhism	Ayurvedic tradition
Turks	Turkish	Islam	See Table 30.2
Vietnamese	Vietnamese Cantonese	Buddhism Christianity	Vegetarian

^aAdapted with permission from Scully C, Wilson N (2006).

diseases and drug abuse (Fig. 30.2). Mental health problems, including psychotic illness, depression and anxiety, alcohol addiction or injecting drug use, are common. There are high rates of blood-borne and other infections, such as hepatitis B and C, and human immunodeficiency virus (HIV), all of which can be associated mainly with drug use and neglect of health. Tuberculosis is common (Ch. 15). Most report negative oral health impacts, having caries and inflammatory periodontal disease; over half have current orofacial pain. Additional oral health impacts include difficulty with eating, smiling, concentrating and talking. Dental anxiety status is related to dental disease experience, which impacts negatively on quality of life. Various studies have confirmed that few had dental care in the previous year.

The problems, summarized in Table 30.3, serve to perpetuate homelessness and impede access to health care. There is a need to provide more accessible and affordable health services to homeless people.

IMMIGRANTS

Immigrants and refugees can arrive from diverse social, economic, educational, cultural, religious and ethnic backgrounds for a variety of reasons: to seek work, education or economic advantage; flee war,

political upheaval or persecution; or join families from which they have been separated. Many arrive with inadequate resources and suffer social exclusion and inequality of health-care provision. The acute phase following immigration, particularly from the developing world, war zones and tropical regions, attracts most concern (Table 30.4), and is particularly at this time that health can be neglected.

Many come from health-care systems that differ from traditional Western medicine and may involve traditional remedies. Lifestyle factors predispose some to specific diseases (e.g. areca nut use and oral submucous fibrosis). Hereditary factors are sometimes important too, as in sickle cell disease, thalassaemia and glucose-6-phosphate dehydrogenase deficiency.

Other problems may include malnutrition, intestinal parasites (*Enterobius*, *Trichuris*, *Strongyloides* and *Ascaris*), filariasis, leishmaniasis, hepatitis A, B and C, tuberculosis, low immunization rate, typhoid fever, yellow fever, malaria, trachoma, syphilis, dengue fever, HIV infection, diarrhoeal illnesses, leprosy, hypertension, coronary disease, gastrointestinal problems, diabetes, depression, lactose intolerance, carcinomas of cervix, breast and mouth, vitamin D deficiency, alcoholism and substance abuse.

The second phase, transition, typically takes at least 5 years, with acculturation and modification of social norms, attitudes, values, behaviours and diet, bringing changes not least in the use of

Table 30.2 Main faiths/religions and their medical relevance^a

Faith/religion	Main festival or religious occasion(s)	Dietary aspects	Possible main medical problems	Other comments
Buddhism	Wesak	Often vegetarian	–	–
Jehovah's Witnesses	Christmas, Easter	–	Firmly believe that blood has sacred meaning and that it should not be removed from the body and stored; nor should donor blood be taken in during a transfusion. Often refuse blood transfusions and organ transplants, and human blood products like platelets (Ch. 8)	Jehovah's Witness Watchtower Society places a biblical ban on the storage/use of animal blood (see also Appendix 30.1 and Fig. 30.1)
Hinduism	Diwali, Maha Shivaratri, Ram Navami, Janmashtami	Often eat no meat (particularly beef) or meat products, eggs or fish Some drink no tea, coffee or alcohol, and eat no garlic or onions	Vitamin B ₁₂ -deficient from veganism	–
Islam (Muslim)	Ramadan, Mawlid, al-Nabi	Eat no pork, drink no alcohol. Eat only Halal meat. During Ramadan, between sunrise and sunset, eat and drink nothing (including water), and smoke nothing, unless ill, young, old or pregnant	May be non-compliant with oral medication during fasts such as Ramadan. Alcohol-free oral products should be used. Meningitis vaccination indicated at Haj and Umra	Often cover much of the body and head/face. Right hand is considered clean, and used for eating and shaking hands. Handshakes are appropriate only between men or between women. It is not acceptable for a man to shake the hand of a Shiite woman Women are not permitted to be alone with a man who is not her husband or relative. At public events, women are segregated from men
Judaism	Rosh Hashanah, Yom Kippur, Pesach	Eat no pork or shellfish, and only kosher meat Fast for 25h from eve of Yom Kippur	Orthodox Jews may refuse organ transplants. Liable to Tay-Sachs disease (inherited neurological defects), Canavan disease (inherited brain disorder), Fanconi anaemia, pemphigus	No work on Sabbath (Saturday)
Sikhism	Vaisakhi, Diwali, Hola	Eat no fish or eggs, and usually no beef or pork Often vegetarian	Vitamin B ₁₂ -deficient from veganism	Invariably cover head

^aIt is impossible to generalize; always consider the individual and their wishes and needs. See also Table 30.1.

Fig. 30.1 Jehovah's Witnesses' acceptance of various procedures/substances.

Fig. 30.2 Homelessness – a growing issue in many countries, even those that are resource-rich.

health-care services. Most younger people become well integrated into the community.

The third phase, 10 or more years after arrival, is typified by the resettled refugee suffering a variety of chronic conditions, seen at least partly as a consequence of resettlement, but many have acculturated and others continue to live and often work in their own communities, in a multicultural society.

PEOPLE IN CUSTODIAL CARE

Prisoners' general health is compromised by lifestyle behaviours, such as the use of tobacco, alcohol and drugs of abuse, high-sugar diets and homosexual practices. In particular, there are high levels of violence, mental illness and infectious disease, such as hepatitis virus infections and HIV. Prisoners' oral health status often includes high levels of caries and relatively high levels of both missing and filled teeth; oral health is poor, and remains poor in comparison with non-institutionalized individuals where appropriate comparisons have been made. The main barriers to health care are cost, anxiety and access.

Table 30.3 Medical problems prevalent in homeless people^a

Type	Detail
Assaults	Physical
	Psychological
	Sexual
Cardiovascular	Hypertension
	Peripheral vascular disease
Exposure	Hypothermia
Gastrointestinal	Vomiting and diarrhoea
Infections	Infestations (lice, fleas, scabies)
	Lower respiratory infections, e.g. influenza, pneumonia, tuberculosis
	Sexually shared infections
	Upper respiratory viral infections
	Viral hepatitis
Mental	Depression
	Schizophrenia
	Stress, anxiety, substance abuse
Nutritional	Malnutrition
Substance abuse	Alcohol
	Illegal drugs and volatile substance abuse
	Tobacco

^aOften multiple or complex problems, over and above the problems afflicting others, and poor access to health-care services.

REFUGEES AND ASYLEES

A *refugee* is someone who, 'owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country' (United Nations Refugee Convention 1951). *Asylees* (asylum-seekers) have submitted a claim for refugee status. Refugees and asylees comprise most displaced persons resettled to the developed world or from country to country within the developed or developing worlds. The current main countries of refugee origin are shown in Table 30.5.

ROMA

Roma (or Romanies) is the preferred term for people commonly but incorrectly known as gypsies. Most Roma refer to themselves as *rom* or *rrom*. Worldwide there is an estimated population of at least 15 million Roma but many are not registered for fear of discrimination. Most Roma are from Eastern Europe (Romania, Bosnia, Bulgaria, Czech Republic, Kosovo and Slovakia), southern Europe (Greece, Portugal, Spain) or America. 'New Age travellers' are *not* Roma.

Roma are generally a nomadic people with an alternative lifestyle and refusal to conform; they speak Romani – derived primarily from Sanskrit. There is no separate Romani religion; they traditionally adopt the dominant religion of the country in which they live, and are usually Hindu, Christian, Protestant or Muslim (Sufis).

Traditional Roma place a high value on the extended family. At the top of the family is the oldest man or grandfather, and men generally have much more authority than women. Virginity is essential in

Table 30.5 Countries of origin of refugees and asylees (2012–13, UK)

Refugees	Asylees
Afghanistan	Chad
Angola	China
Burundi	Iran
Democratic Republic of Congo	Pakistan
Iraq	Syria
Myanmar	Tanzania
Somalia	
Sudan	
Turkey	
Vietnam	

Table 30.4 The phases of acculturation^a

Phase	Possible medical and social problems	Barriers to care	Possible outcomes
Acute	Communicable illnesses (tuberculosis, hepatitis B virus, human immunodeficiency virus) and tropical diseases, malnutrition, trauma, conflict intergenerationally and with other cultures, domestic violence, gambling and substance abuse	Lack of language fluency and understanding of health-care system	Linguistic and cultural isolation; help-seeking behaviour becomes one of emergency care only
Transition	Hypertension, diabetes, psychological disorders and other post-traumatic stress	Lack of language fluency and understanding of health-care system by older generation	Younger generations integrate into host health-care system; continued isolation of older generations
Integration	Hypertension, coronary heart disease and diabetes are the most common disorders. Morbidity and mortality from cancers, particularly cervical, are high	Emotional difficulties as family structures break down	Intergenerational conflicts can arise and there can be heavy alcohol consumption

^aFrom Scully C, Wilson N (2006).

unmarried women, and both women and men tend to marry young; there may even be child marriage.

Roma often suffer from unemployment, socioeconomic deprivation and discrimination; they are frequently accused of petty crime and can be faced with barriers to education. Dietary habits include high fat and salt content in foods, and a large percentage of Roma smoke and are obese. These factors can put Roma at increased risk for hypertension, diabetes, occlusive vascular disease, strokes and myocardial infarction. Crowded living conditions can lead to an increase incidence of gastrointestinal infections and respiratory infections. Nutritional deficits, hepatitis B, tuberculosis and post-traumatic stress disorder may be increased in Roma populations. Social (or societal) isolation also leads to an increase in consanguineous marriages, and thus an increased risk for birth defects.

In the health-care setting, only the elder males of some groups are likely to communicate with health-care personnel. Women are not permitted to interrupt men or to be alone with a man who is not their husband or relative. Washing hands before touching the upper body is required after touching the lower body. Separate soap and towels are used on the upper and lower parts of the body and they must not be allowed to mix. When a clan member must enter a hospital, family members are expected to remain with that person day and night to watch over, protect and perform caring and curing rituals for them. Roma are especially fearful of any surgical procedure that requires general anaesthesia (GA) because of their belief that a person under GA undergoes a 'little death'. It is especially important for the family to gather around the person recovering from GA.

SEXUAL MINORITIES

Sexual minorities are those who identify as lesbian, gay, bisexual or transgender (LGBT), or who have sexual contact with persons of the same or both sexes. Many sexual minority youth successfully transition to adulthood but others struggle to cope because of increased risk for certain health issues. For example, health risks for which the prevalence is higher for gay, lesbian or bisexual students than for heterosexual students include binge drinking. Young gay and bisexual males have disproportionately high rates of HIV, syphilis and other sexually shared infections (SSIs), and lesbian and bisexual females are more likely to have been pregnant than their heterosexual peers.

Lesbians can suffer the same conditions as heterosexual women but additional issues of concern may include:

- breast cancer – lesbians are more likely to have risk factors for breast cancer yet less likely to undergo screening examinations
- depression/anxiety
- heart health – smoking and obesity are the biggest risk factors for heart disease among lesbians
- gynaecological cancer – lesbians have higher risks for certain types of gynaecological cancers compared to heterosexual women
- fitness – lesbians are more likely to be overweight or obese compared to heterosexual women
- tobacco – lesbians use tobacco more often than heterosexual women do
- alcohol – heavy drinking and binge drinking are more common among lesbians compared to other women
- substance use – lesbians may use drugs more often than heterosexual women
- intimate partner violence – some lesbians experience violence in their intimate relationships

- sexual health – lesbians can contract the same SSIs as heterosexual women.

Sexually active bisexuals and gays have a high rate of SSIs, including chlamydia, gonorrhoea, hepatitis viruses, herpesviruses, HIV, human papillomaviruses, pubic lice and syphilis. Men who have sex with men may be at an increased risk of SSIs but safe sex reduces the risk of receiving or transmitting infection. Women who have sex with women have lower rates of infections, but if they have sex with gay or bisexual men (who have increased rates), they may be at risk. Sex with multiple partners (of any gender) increases risk of infection.

Immunizations are available to prevent hepatitis A virus and hepatitis B virus infection. Safe sex is effective at reducing the risk and is currently the most reliable means of preventing HIV and hepatitis C virus infections.

Bisexuals may have problems with body image and are much more likely to experience an eating disorder. The use of substances such as anabolic steroids and certain supplements can be dangerous.

Bisexuals and gays appear to suffer depression and anxiety at a higher rate than the general population. They may also use substances at a higher rate than the general population, and these range from tobacco and amyl nitrate ('poppers'), to marijuana, Ecstasy and amphetamines.

Bisexuals and gays may be at risk for prostate, testicular, breast, cervical and colon cancer.

Sexual minorities may have behaviours that:

- contribute to violence
- relate to attempted suicide
- contribute to unintentional injuries
- result in adverse lifestyles (substance use, sexual risk) and adverse dietary habits, physical activity and weight management.

Sexual minorities may also face stigma, discrimination, family and social disapproval or rejection, and violence. These factors can:

- limit ability to access quality health care
- affect income, employment and the ability to get and keep health insurance
- contribute to poor mental health and suicide attempts
- affect ability to establish and maintain long-term sex relationships that reduce HIV and SSI risk
- make it difficult to be open about sex behaviours with others, which can increase stress, limit social support and negatively affect health
- increase risk of being bullied and/or of being rejected by their families and, as a result, increase risk of homelessness.

SOCIOECONOMICALLY DEPRIVED PEOPLE

Socioeconomic status is considered to be a major social basis for inequalities and an important predictor of health at all ages. Socioeconomic deprivation appears to predispose to a wide range of health issues, from disease to access to provision of and outcomes of health care. Examples are shown in [Box 30.1](#).

Socioeconomically disadvantaged men and women have higher overall mortality rates than persons with a higher socioeconomic status. Moreover, relationships between class and mortality are consistent for almost every cause of death, with only a few exceptions – notably certain cancers. In almost all countries, rates of death due to common causes (e.g. cardiovascular disease and cancer), causes related to smoking, causes related to alcohol use and causes amenable to medical

Box 30.1 *Some health issues that are more prevalent in lower socioeconomic groups*

- Arthritis
- Assaults
- Asthma
- Cancers
- Coronary heart disease, and death from first infarcts
- Obesity
- Oral health issues
- Malnutrition
- Mental health problems
- Physical health problems
- Psychiatric referral, admission rates and length of stay
- Substance abuse
- Surgical outcomes – unsatisfactory
- Uptake of blood pressure and medical checks

intervention (e.g. tuberculosis and hypertension), as well as poorer self-assessments of health, are substantially higher in groups of lower socioeconomic status.

Socioeconomic factors also influence oral health in terms of, for example, hygiene practices, diet, gingivitis and dental caries. Attending a state school, being female and having parents with low educational attainment were identified as risk factors both for having dental caries and for having a high level of caries. Lack of oral health care may lead to periapical abscesses and other odontogenic infections, which have caused morbidity and even mortality.

Such inequalities in health care might be reduced by improving educational opportunities, income distribution, health-related behaviour and access to health care. Policies related to preventive social, economic and behavioural interventions in areas such as poverty and income, education, unemployment, housing, transportation, the environment (including pollution) and nutrition may well have a much greater effect on reducing health disparities than would traditional medical interventions.

DENTAL ASPECTS IN MINORITIES

Dental issues related to ethnic and cultural groups, homeless people, immigrants, people in custodial institutions, refugees and asylees, Roma, sexual minorities and socioeconomically deprived people have much in common. Generally speaking, there is more oral disease in most groups, and often multiple barriers to care.

APPENDIX 30.1 ACCEPTABLE ALTERNATIVE PRODUCTS SUITABLE FOR JEHOVAH'S WITNESSES^a

Blood-oxygen monitoring devices

- Transcutaneous pulse oximeter
- Paediatric ultra-microsampling equipment
- Multiple tests per blood draw

Haemopoietic agents

- Intravenous iron
- Folic acid
- Vitamin B₁₂
- Vitamin C
- Granulocyte colony-stimulating factor
- Interleukin-11
- Recombinant stem-cell factor

Operative and anaesthetic techniques

- Hypotensive anaesthesia
- Induced hypothermia
- Mechanical occlusion of bleeding vessel

Haemostatic agents

- Avitene
- Gelfoam
- Oxygel
- Surgicel
- Desmopressin (DDAVP)
- Epsilon-aminocaproic acid (Amicar)
- Tranexamic acid (Cyklokapron)
- Vasopressin (Pitressin)
- Aprotinin (Trasylol)
- Vincristine (Oncovin)
- Conjugated oestrogens
- Vitamin K
- Recombinant factor VIIa
- Recombinant factor IX

Volume expanders: crystalloids

- Ringer's lactate
- Saline

Volume expanders: colloids

- Dextran
- Gelatin
- Hetastarch
- Pentastarch

Oxygen therapy

- Hyperbaric oxygen therapy
- Perfluorocarbon solutions

Surgical devices and techniques

- Electrocautery
- Ligation vessel

Personal decisions

Medical products and therapy

- Albumin
- Any drug buffered with albumin
- Immunoglobulins
- Natural clotting factors
- Cryoprecipitate
- Plasma protein fractions
- Tissue adhesives
- Natural interferons
- Haemoglobin-based blood substitutes
- Platelet-derived wound healing factors

Medical tests

- Red or white blood cell tagging

Surgical procedures

- Dialysis and heart–lung equipment
- Blood salvage without blood storage

^aAdapted with permission from <http://www.ajwrb.org> (accessed 30 September 2013).

This chapter discusses the health of dental health workers (DHWs; dental professionals). Many occupations, especially the construction industry and armed services, are far more dangerous. The chapter also covers hazards to patients from some physical or chemical agents.

HEALTH OF DHWS

The standardized mortality ratio (SMR) – the ratio of observed deaths in an occupation or from any disease to the national average death rate for the same age and sex – is lower in dentists than in the general population. The main causes of death among dentists in UK, USA and other industrialized countries are cardiovascular disease, cancer and suicides, as in non-dental groups of similar socioeconomic status.

The risks in male dentists from liver cirrhosis and suicide are somewhat higher than in the general population, and dentists are also a risk group for malignant melanoma – presumably a consequence of sun exposure on holiday. Dentists, however, have a lower SMR for cancers, ischaemic heart disease, cerebrovascular disease and chronic lung diseases (bronchitis, emphysema and asthma).

Infections and physical, chemical and radiation hazards are the main occupational problems for DHWs. Nearly half of DHWs report sharp instrument injury at some time while treating patients. There are also risks from other accidents, and damage to eyes, hearing, mental health, musculoskeletal system, the fetus in pregnancy, respiratory systems and the skin (Table 31.1). Significantly greater numbers of female DHWs seem to experience musculoskeletal disorders and allergy to latex than males. The most prevalent preventive measure reported by DHWs is changing gloves between patients and using a face mask. Also, most DHWs have undergone hepatitis B virus and other vaccinations.

In the UK, governmental concern and the defining of safe work practices have brought the question of occupational hazards into sharper focus, as have the measures for implementing safe practices enshrined in the Health and Safety at Work etc. Act (1974) and regulations such as the Ionizing Radiations Regulations (1988) and Control of Substances Hazardous to Health Regulations (1988). In the USA, the Department of Labor Occupational Safety and Health Administration (OSHA) has extensive legislation, which may be found at <http://www.osha.gov/SLTC/dentistry/standards.html> (accessed 30 September 2013).

INFECTIONS (SEE ALSO CH. 21)

Overall, the major infectious hazards are respiratory and hepatitis B (HBV) and C virus (HCV) infections, and, to a very much lesser extent, human immunodeficiency virus (HIV), prions and health-care-associated infections (HCAIs), such as meticillin-resistant *Staphylococcus aureus*, *Clostridium difficile*, tuberculosis and *Legionella*.

Blood, serum and saliva are the sources most likely to transmit serious infection, as well as dental instruments that are often contaminated after use, and also bites. The transmission of blood-borne viruses is determined by the dose and viral concentration of an

Table 31.1 Known occupational hazards in dentistry

Hazard	Examples
<u>Infections</u>	
Bacteria	Legionellosis Syphilis Tuberculosis
Viruses	Common cold and other respiratory viruses Hand, foot and mouth disease Hepatitis viruses Herpangina Herpesviruses HIV/AIDS and other retroviruses Human papillomavirus Parvoviruses
Prions	
<u>Physical and chemical</u>	
Accidents and assaults	
Burns (chemical heat/cold/radiation)	
Chemical sterilizers	
Disinfectants	
Electrical accidents	
Fires and explosions	
Flammable or explosive agents	
Formaldehyde	
Inhalational anaesthetic agents	
Mercury	
Minerals	
Non-anaesthetic agents	
Poisons	
'Sick building syndrome'	
Solvents	
Vibration injury	
X-ray processing chemicals	
<u>Radiation</u>	
Ionizing radiation	X-rays
Non-ionizing radiation	Electromagnetic radiation Light (ultraviolet, blue, white) Lasers
Video display units (VDUs or monitors)	
Pacemaker cardioverter and hearing aid interference	
<u>To specific body systems</u>	
Eyes	
Hearing	
Mental health	Reaction of staff to stress Adapting to stress
Musculoskeletal complaints	
Pregnancy	General anaesthetic agents Infectious agents Ionizing radiation Mercury

Fig. 31.1 Instrument decontamination.

exposure. Whereas HBV transmission can be prevented by immunization of DHWs, controlling HCV and HIV requires efforts to reduce the incidence and dosage of exposures to blood and body fluids. Such strategies include the design and use of safe devices, targeted interventions, the use of gloves and other barriers, and ongoing surveillance and analysis of exposures.

Since there is a potential for transmission of various infections, dental equipment should, where at all possible, be single-use and all reusable instruments must be sterilized or at least decontaminated (Fig. 31.1). DHWs should pay considerable attention to avoidance of needlestick (percutaneous inoculation; sharps) infections/injuries and bites.

Standard (universal) infection control must be implemented; infection control guidelines can be found at <http://www.bda.org/dentists/advice/ba/ic.aspx> (accessed 30 September 2013).

The main points to remember in order to minimize cross-infection are shown in Box 31.1.

NEEDLESTICK/OCCUPATIONAL EXPOSURE TO INFECTIONS

Exposure-prone procedures (EPPs) are defined by the UK Department of Health as those where there is a risk that injury to the worker may result in exposure of the patient's open tissues to the blood of the worker. These procedures include those where the worker's gloved

Box 31.1 Ten main points to minimize cross-infection in the dental surgery

1. Avoid needlestick or other sharps injuries
2. Use effective sterilization, decontamination and disinfection procedures
3. Have clinical staff immunized, particularly against hepatitis B
4. Ask patients to use 0.2% chlorhexidine mouth rinse preoperatively to decrease the number of oral microbes present
5. Use a rubber dam to isolate the tooth or treatment area; use high-speed evacuation
6. Avoid causing oral bleeding wherever possible
7. Wear protective gloves, masks, eyewear and/or face shields, and follow good hygiene procedures
8. Wear clean clinical attire; change clothes before leaving the clinic; disinfect hands with an alcohol-based disinfectant (containing 1–3% glycerol to avoid skin dehydration)
9. Minimize the working area; use a tray system, or cover surfaces and equipment with disposable plastic, paper or foil wraps. Uncovered surfaces and equipment should be wiped with absorbent towelling and then disinfected following work activities
10. Take especial care with patients in high-risk groups for blood-borne infections

hands may be in contact with sharp instruments, needle tips or sharp tissues (spicules of bone or teeth) inside a patient's open body cavity, wound or confined anatomical space where the hands or fingertips may not be completely visible at all times. Most procedures in dentistry are defined as EPPs, with the exception of:

- examination using a mouth mirror only
- extra-oral radiography
- visual and digital examination of the head and neck
- visual and digital examination of the edentulous mouth
- impressions of edentulous patients
- the construction and fitting of full dentures.

However, taking impressions from dentate or partially dentate patients would be considered exposure-prone, as would the fitting of partial dentures and fixed or removable orthodontic appliances, where clasps and other pieces of metal could result in injury to the dentist.

DHWs need not refrain from performing EPPs pending follow-up of occupational exposure to an HIV-infected source. The combined risks of contracting HIV infection from the source patient and then transmitting this to another patient during an EPP are so low as to be considered negligible.

Blood-borne microorganisms that can be transmitted via blood exposure include:

- viruses:
 - HBV
 - HCV
 - HIV
 - cytomegalovirus (CMV)
 - Epstein–Barr virus (EBV)
 - parvovirus
- bacteria:
 - Treponema pallidum* (syphilis)
 - Yersinia*
- parasites:
 - Plasmodium*.

Accidental exposure to blood caused by needle injuries or injuries following, cutting, biting or splashing incidents carries the risk of infection, particularly by blood-borne viruses though risks vary (Table 31.2).

Table 31.2 Blood-borne viruses

	Hepatitis C virus	Hepatitis B virus	Human immunodeficiency virus
Risk of transmission by needlestick injury	3% (3–10%)	30% (5–40%)	0.3% (0.2–0.5%)
Prevalence is higher than average in people who:	have had multiple blood transfusions; are dialysis patients or intravenous drug users	are intravenous drug users or men who have sex with men; are from developing countries	are men who have sex with men or intravenous drug users; are from areas where the condition is endemic

Preventing needlestick injury and avoiding infection

The single most important measure that will help to prevent needlestick injury is to avoid recapping and resheathing. Keep a rigid puncture-proof container close to hand for used needles to avoid the temptation of recapping. It is equally important to use proper protective clothing such as gloves, mouth mask and goggles.

Every DHW at risk from accidental exposure to blood should be trained in infection control and vaccinated against HBV (there are no preventive vaccines available for HCV or HIV).

Action after exposure to potentially contaminated material includes (Fig. 31.2) the following measures:

- If there is a wound, let it bleed for a moment and then cleanse thoroughly using an ample amount of soap and water followed by 70% alcohol.
- In case of contact with mucous membranes, it is important to rinse immediately and thoroughly, using water or a saline solution only, *not* alcohol.

Under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations (1995), it is not usually necessary to tell the Health and Safety Executive (HSE) about an occupational exposure to blood or saliva; however, if the occupational exposure involves a known carrier of a blood-borne disease, this is classified as a dangerous occurrence and reporting then becomes mandatory – as it is when acute ill health has resulted from exposure to, or transference of, a biological pathogen. Recording of occupational exposure to blood or saliva in an accident report book is strongly advised and the incident should be reported immediately to the department dealing with occupational accidents.

Post-exposure prophylaxis (PEP) against HIV has been estimated to reduce the risk of transmission by 75%; it should be carried out within 1 hour for maximum effect, so an initial assessment must be performed as soon as possible. Even if there is a delay, it is still worth considering PEP within 24 hours of the exposure. A blood sample should be taken from the exposed person as soon as possible after the injury to act as a baseline value in case infection does arise. Further blood samples to test for HBV, HCV and HIV are collected after 1, 3, 6 and 12 months. If the source of the blood is known, the patient must be asked for permission to take a sample of blood for an HCV and HIV test. If the patient refuses, then they must be assumed to be a carrier. If the origin of the blood is unknown, then any blood present on the needle can be used for a serological examination.

Management is based on determining the level of risk of contracting HBV, HCV or HIV, depending on whether or not the injured person is non-immune, partially immune or fully immune for HBV (from vaccination or otherwise). If there is only limited immunity to HBV, then 5 mL intramuscular hepatitis B immunoglobulin (HBIG) should be given within 48 hours of the injury. After a potential HCV infection, combination treatment of pegylated interferon and ribavirin is the treatment of choice. A liver specialist should be consulted.

No PEP is currently available for hepatitis C. However, early treatment of acute hepatitis C infection may prevent chronic hepatitis C

infection. Follow-up of exposed patients should be as that described in management for occupational exposure to hepatitis C.

A course of hepatitis B vaccination with or without immunoglobulin may be recommended as PEP following exposure to hepatitis B.

Post-exposure prophylaxis for HIV infection

After a potential HIV infection, the actual risk depends on the type of contact and on the amount of virus in the contaminated material. The risk of an HIV infection following exposure to blood is very small but factors associated with a higher risk are:

- deep wounds (e.g. needlesticks, scalpel wounds)
- visible blood on the instrument
- needlestick injury from using hollow-bore needles containing blood
- intravenous or intramuscular injection of contaminated blood
- blood from a patient with a high virus level (e.g. untreated or terminal AIDS patients).

Decision 1: What is the level of risk of HIV transmission?

Level of risk is classed as low or negligible, which does not require PEP, or as a significant injury with a higher risk of transmission, which may require PEP. In the latter case, the source should be informed that the injury is significant enough to carry a risk of transmission and their permission should be obtained for a review of their social and medical histories. In the case of a splash, the volume of exposure should be assessed, as both HIV and HCV are reported to have been transmitted through only 0.5 mL of blood to the conjunctiva. In the unlikely event of a splash to a mucous membrane, then the exposure would be classed as a significant injury.

Decision 2: Is your patient at risk of carrying HIV?

A social and medical history can help determine whether HIV transmission is likely to have occurred and the associated degree of risk of that happening. Questions will relate to the patient's sexuality and lifestyle; ideally, questioning should take place in a private room and the patient needs to be reassured that the discussion will remain confidential. The recipient of the injury should not ask the questions because he or she may be too anxious. When assessing the risk factors for acquiring HIV, the operator should concentrate on high-risk activities (Box 31.2) that increase the potential for transmission of the infection rather than concentrating on the main risk groups. The patient should be informed that guidelines are laid down by the UK health departments for the management of occupational exposures to blood or saliva, and that some questions need to be asked that relate to the risk of the patient having acquired HIV.

Low risk

If it is decided that the patient is in the low-risk category for HIV, then the procedure outlined under mild injury is followed.

Fig. 31.2 Algorithm for post-exposure prophylaxis (PEP). HBIG = hepatitis B immunoglobulin; HBV/HCV = hepatitis B/C virus; HIV = human immunodeficiency virus; PEG-IFN = pegylated interferon; RNA = ribonucleic acid. After Samaranayake and Scully 2013.

High risk

If the patient admits to having participated in a high-risk activity, in an area with a high prevalence of HIV, then the specialist may recommend an HIV test. The test must *not* be carried out until trained health-care advisors have counselled the patient about the consequences of such a test. This takes more than an hour to carry out and the specialist

may advise the recipient to attend a local hospital to be given initial doses of PEP drugs. Once the initial doses have been taken, a formal risk assessment for HIV may be carried out and a decision made as to whether to continue PEP until the HIV test result is known. If the injury occurs outside normal working hours, an alternative source of advice must be found and, if necessary, the first few doses of PEP

Box 31.2 Checklist for assessing the risk of contracting HIV

- Do you donate blood?
- Have you ever had sex with a partner from abroad?
- Have you ever had a partner who is bisexual or uses intravenous drugs?
- Have you ever had sex with anyone that you did not know well?
- Have you ever exchanged money or drugs for sex?
- Have you ever injected non-prescription drugs (recreational drugs like heroin, cocaine, speed, etc.) or used injectable steroids?
- Have you ever lived in or visited Africa?
- Have you ever had tattoos or body piercings?
- Have you attended a clinic for sexually shared diseases?
- Have you been tested for HIV?

Box 31.3 Checklist for assessing the need for post-exposure prophylaxis and the most suitable drug regimen

- Is the person generally well?
- Do they know their CD4 (T-helper cell) count and/or viral load, when it was taken and if the level has changed recently?
- Are they on any medication? If so, what?
- Has their medication changed recently and why?
- What is the name of their general medical practitioner, and the address and telephone number of the HIV clinic they are attending?

obtained. The designated specialist can give guidance on this and the local accident and emergency department would probably be the first contact for advice and PEP.

What happens if the patient refuses to be tested?

A patient cannot be forced to give consent for the taking and testing of blood. The designated specialist can evaluate the history taken and give advice on whether the patient is at risk of a blood-borne disease. The patient can be asked to give permission for the practitioner to consult with the patient's general medical practitioner for additional information. The incident should be recorded in detail in an accident report book.

What happens if the source patient is not known?

Exposure may occur while cleaning instruments from several patients. In this case, the patients should be identified and their medical histories reviewed. If the injury can be assessed as constituting a low risk for the transmission of HIV, the immediate administration of PEP against HIV is not necessary. The procedure outlined under mild injury should be followed, with the patients being contacted and asked to give blood for a hepatitis screen. If the injury is significant, then the designated specialist should be asked for advice as to whether PEP is necessary until the patients' medical histories can be reviewed.

Immediate action after high-risk exposure

If PEP is advisable (Box 31.3), then it is important to discuss:

- the advantages and disadvantages of PEP
- the necessary follow-up examinations (of liver and kidneys) after 2 weeks and at 1, 3 and 6 months
- follow-up examination for HIV infection (after 1, 3 and 6 months)

Box 31.4 Decontamination in general dental practice

Use a dedicated decontamination area, separated from the patient treatment area and preferably in another room or rooms, with:

- a separate hand-washing facility
- a setting-down area for dirty instruments
- a washing sink with detergent for cleaning instruments
- a setting-down area for washed instruments
- an ultrasonic cleaner (35–55 kHz), if appropriate
- a rinsing sink
- a setting-down area for rinsed instruments
- an automated washer–disinfector includes drying cycle; thermosinfectors fulfilling requirements in EN 15883 are the safest and most reliable)
- a setting-down area with task lighting and magnifier for inspection of all instruments (to check instruments for visible contamination and functionality or damage, and to ensure instruments are dry)
- an area for packing instruments (only if a benchtop vacuum sterilizer is to be used)
- a steam sterilizer (in accordance with EN 13060)
- an area for setting down and wrapping instruments sterilized in a benchtop non-vacuum (bowl and instrument) sterilizer
- clean, orderly, enclosed storage for instruments prior to use (not open shelving)
- a dedicated, clean, rigid, labelled box with a lid to transport instruments to the clinical area safely and securely

- the importance of avoiding transmission to sexual partner(s) (use of condoms).

Start PEP as soon as possible after this. PEP for cases constituting a high risk of HIV infection is a three-drug combination consisting of two reverse transcriptase inhibitors and at least one protease inhibitor. The current regimen is:

- one Truvada tablet (245 mg tenofovir and 200 mg emtricitabine [FTC]) once a day
- plus
- two Kaletra film-coated tablets (200 mg lopinavir and 50 mg ritonavir) twice a day.

The risk of acquiring HIV infection following occupational exposure is *low* – less than 3 per 1000 injuries.

Guidance on HIV PEP from the UK Chief Medical Officers' Expert Advisory Group on AIDS (EAGA; 2008) is given in Appendix 31.1.

Current CDC guidance is similar. Nelfinavir, which was once used, is no longer recommended, since some preparations contain ethyl methane mesylate (EMS), a known animal carcinogen, mutagen and teratogen. This might be relevant to the choice of drugs included in an HIV PEP regimen because many health-care personnel are female and many are of child-bearing age.

INFECTION CONTROL MEASURES

The four UK Health Departments' decontamination policies are generally driven by the European Union's Medical Devices Directive (MDD) 93/42/EEC and the Medical Device Regulations (MDR) 2005 (Box 31.4). 'HTM 01-05', published by the UK Department of Health in 2008 as 'Health Technical Memorandum 01-05: Decontamination in primary care dental practices' and superseded by a new edition published in April 2009 (http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_089245; accessed 30 September 2013), sets the standards for decontamination.

Infection control includes the safe disposal of sharps and disposable items, and the cleaning and sterilization of reusable dental instruments and devices. Care must be taken to ensure that all instruments are cleaned prior to sterilization, in a safe manner to avoid injury. Use of closed-system cassettes reduces the risk to the DHW during the execution of infection control. When using ultrasonic cleaners, washers and sterilizers, it is important always to follow the manufacturer's instructions. Assurance of sterility of instruments and devices can be obtained through the use of one of several tests; these tests must be performed regularly to ensure that the sterilizer is cleaning all instruments and devices and that these are safe for use on patients. Disinfection after cleaning reduces the number of viable microorganisms on instruments, making them safer to handle; it is not acceptable to use chemical disinfectants (unless this is specifically recommended by the manufacturer), however, and therefore thermal disinfection is necessary.

Thermal disinfection is best achieved by using an automated washer–disinfector (WD), which precedes the use of autoclaves (sterilizers). The high temperature of the water and chemical additives in these devices clean and disinfect the instruments.

Two types of sterilizer are found in primary care dentistry:

- The *vacuum benchtop sterilizer type B* is suitable for wrapped and unwrapped solid items, hollow items and porous loads, and as such is particularly valuable for sterilizing dental handpieces. It is the standard for use in dental practice, since wrapped items can be readily transported, remain sterile up to the point of use, and can be stored for use at a later date, minimizing the risk of cross-contamination.
- The *type N benchtop sterilizer* is an unwrapped instrument and utensil sterilizer suitable for solid devices that are not wrapped. Provided that the proper irrigation and cleaning of lumens and internals of handpieces has been achieved in combination with a WD, handpieces may also be processed in a type N sterilizer. Where remaining hollow items used in the practice are single-use, a type N sterilizer may be the appropriate solution, although this type of technology is being increasingly overtaken by the vacuum-type sterilizer (type B). Instruments processed in a type N sterilizer should ideally be used directly from the sterilizer, as transportation and storage of sterilized items may pose a risk of re-contamination, and should be risk-assessed and controlled to minimize the risk.

Some instruments cannot be steam sterilized and must then be decontaminated according to the manufacturer's instructions. If sending instruments for repair or disposal, decontaminate first.

HEALTH-CARE-ASSOCIATED INFECTIONS

Health-care facilities, particularly hospitals, are well-recognized reservoirs of infection and may be responsible for a wide range of nosocomial (hospital) infections (Ch. 21).

DENTAL UNIT WATER LINES

The main routes of spread for prions, viruses, bacteria, fungi and protozoa in dental environments are via blood, infected equipment, saliva and water droplets, and direct patient contact. The dental unit structure favours the formation of aquatic microbial biofilms in dental unit waterlines (DUWLs), the small-bore flexible plastic tubing that conveys water to handpieces.

Biofilms are well-organized microorganism communities, and active biofilms are a source of microbial contamination of delivered water.

Water delivered to a dental unit is by the so-called independent water system, the microbiological quality of which is extremely important for the water quality flowing from dental handpieces. In one study, over half of the water samples did not comply with the norms for potable water, though no *Enterococcus* or *Legionella* species were detected.

DHWs and patients can be exposed to direct contact with contaminated water both as splatter and as aerosol emitted by handpieces, including rotating and ultrasonic instruments. The most intensive aerosol and splatter emission occurs from an ultrasonic scaler tip or a high-speed handpiece.

Contamination of water in DUWLs is commonplace and the microbes isolated are various (Table 31.3). In one national survey (in Italy), for example, there was water microbial contamination in all dental surgeries examined, and 33% contained *Legionella* species.

Legionella are common in DUWL, as are *Legionella* antibodies in DHWs. One 82-year-old patient appears to have contracted and died from *Legionella* infection emanating from her dental practice, and another case of fatal legionellosis in a dental surgeon concluded that the DUWL was the likely source of the infection. Although there are reports of unusual microbes, such as fungi (*Exophiala mesophila*) or non-tuberculous mycobacteria (NTM; *Mycobacterium simiae* and *M. mucogenicum*), in DUWL, other serious sequelae appear to be reported rarely. DUWL water in one study was only weakly contaminated by *Legionella* species and NTM, leading the authors to conclude that their aerosolization during dental treatment was not significant. The proportion of water samples with microbial levels above those recommended decreases during working or following attempts at disinfection.

Similar microbial contamination is also found in the operatory air, particularly close to the patient and DHW. Nevertheless, the number of published cases of infection resulting from exposure to water from contaminated DUWL is limited.

There is, however, a medico-legal requirement to comply with potable water standards and to conform to public perceptions of water safety. Despite the lack of evidence of a significant level of infection risk, few patients (or DHWs) would choose to be treated in a dental unit where any infection might be present.

Reservoirs and DUWLs should be subject to an effective protocol to eliminate microbial contamination, and routine monitoring to guarantee uncontaminated water for use in dental treatment. Though most of the microorganisms isolated are of low pathogenicity, effective decontamination should be ensured, especially in view of the ever-increasing number of immunocompromised patients treated. It is not the mere presence of microorganisms that is important in DUWL contamination monitoring, but their number, the presence of potential pathogens, and patients' oral cavity microflora. There are challenges in biofilm removal and prevention of regrowth in DUWLs but strategies to reduce the level of contamination are shown in Box 31.5.

PHYSICAL AND CHEMICAL HAZARDS

BURNS

In dentistry, an obvious but avoidable cause of heat burns is instruments just removed from disinfectors/sterilizers; these burns are often caused by the difficulty in gauging the instruments' temperature through the rubber gloves worn by all staff. Autoclaves, WDs and laboratory and surgery compressors can also present explosive risks.

Provided the water-cooling is working efficiently, high-speed handpieces cannot cause burns; if not cooled, they can overheat and burn

Table 31.3 Microbes isolated in studies from dental unit water lines^a

<i>Staphylococcus saprophyticus</i>	
<i>Staphylococcus warneri</i>	
<i>Streptococcus</i> spp.	
<i>Streptomyces albus</i>	
<i>Xanthomonas maltophilia</i>	

^aMany are also identified in operatory air.

Box 31.5 Strategies to minimize water-line contamination

- Flushing water lines for several minutes at the beginning of the day and after periods of disuse
- Using an independent water reservoir system separate from the municipal water source (sterile water)
- Using an independent water reservoir system combined with periodic or continuous application of chemical germicides such as sodium hypochlorite
- Using water purification systems: carbon filtration, reverse osmosis and distillation

the patient’s mouth. Other possible causes of thermal burns include hot gutta percha, hot dental composition, hot wax, boiling water, steam, naked flames, flammable or explosive fluids, lasers or diathermy, and even operating lights. Fluids heated in a microwave oven may be hotter

than they appear, as the container remains cooler. Diathermy is a form of high-frequency electrical energy used either for local tissue warming or for cutting, which can cause burns. Accidents have resulted from metallic parts of the dental chair becoming involved in the electric current path. The localized increase in current density can then cause superficial burns of the skin. Some serious accidents of this nature have also resulted from the use of diathermy units in operating theatres, where higher powers are used and the current path is normally completed by a large area electrode to reduce the current density, which is placed under the patient. Diathermy can cause superficial burning, should the current be misdirected, but any part of the body can be involved if the current density is high enough.

Burns are more likely to occur in the laboratory. Bunsen burners are often causes of burns, and long hair and gloves or clothing can catch light in a Bunsen flame. Burns from the melting and casting of alloys can be more severe. Hot wax knives can cause burns.

CHEMICAL AND MATERIAL HAZARDS

Where work practices are poor, staff can be exposed to a wide range of noxious chemical substances in the dental environment, including gases, vapours, liquids, fumes, dusts and solids. The UK Control of Substances Hazardous to Health (COSHH) Regulations (1988 S1 No. 1657) place specific obligations on employers and the self-employed to control hazardous substances. Such a substance is ‘any natural or artificial substance whether it is in solid or liquid form or in the form of a gas or vapour (including micro-organisms) which can constitute a hazard’. In summary, employers are required to:

- assess health risks created by work involving substances hazardous to health
- prevent or control exposure to substances hazardous to health
- provide and use control measures, personal protective equipment, etc., and take all reasonable steps to ensure these are properly used or applied
- maintain control measures in an efficient state and in good working order and repair
- monitor exposure to substances hazardous to health
- provide suitable health surveillance, where appropriate, for the protection of all employees exposed to substances hazardous to health.

All employees and, so far as is reasonably possible, persons on the premises where the work is being carried out, who may be exposed to substances hazardous to health, must be properly informed, instructed and trained. Employees must take steps to protect themselves and others, make full use of control measures and report any defect immediately. COSHH is enforced in the same way as the Health and Safety at Work. Act or any other regulations made under it. Part IA1 of the Approved List for the Classification Packaging and Labelling of Dangerous Substances Regulations (1984; ISBN 011 8839012) lists very toxic, corrosive, harmful or irritant substances hazardous to health.

Most of the chemicals used in dentistry are currently listed on either the OSHA website at http://www.osha.gov/SLTC/laboratories/hazard_recognition.html (accessed 30 September 2013) or the European Union dangerous substances list – Annex 1 of the 67/548/EEC Directive, or are designated as sensitizers by the relevant agencies or institutions, such as the American Conference of Governmental Industrial Hygienists (ACGIH) or the German Senate Commission of the Deutsche Forschungsgemeinschaft (DFG).

Occupational exposure should be minimized wherever possible and it should be a fundamental principle to do this via safe work practices, particularly by storing material in correctly labelled, appropriate and preferably unbreakable containers; avoiding spills and splatter; avoiding contact with eyes and skin; and washing away spilt material with running tap water (see later).

It is better still to consider whether a potentially hazardous substance can be substituted with an innocuous one – as is the case with dental amalgams.

Amalgams and mercury

Mercury hazards are discussed in Chapter 29. Global production and consumption of mercury is decreasing, and the use of amalgam has fallen in many countries. In general, the mercury body burden of DHWs can be kept below the normally accepted toxicological limits and reproductive effects have not been proven, provided a proper mercury hygiene regimen is adopted. Also it is possible to reduce the environmental burden of mercury from dental clinics still further. Mercury levels in saliva do not correlate with the concentrations in blood and urine, but rather with the number of amalgam fillings or of the filling surfaces; mercury in saliva is therefore not recommended for biological monitoring.

Acids and chemicals

Generally, the primary issue for the DHW, as far as acids and chemicals are concerned, is the skin and the eyes (allergic and irritative dermatitis, ocular irritative diseases); acute effects, sensitive effects and inhalation may all be important. Volatile organic compounds (VOCs) in the dental environment include aldehydes (formaldehyde, acetaldehyde, glutaraldehyde propionaldehyde and benzaldehyde), benzene, chloroform, ethylbenzene, methyl methacrylate, toluene and xylenes. Inhalation of these should be avoided as far as possible. One study of chloroform reported no negative health effects on the dentist or assistant, with air vapour levels well below Health and Safety maximum levels.

Chemical burns are all too common. Acids used clinically, such as phosphoric, chromic and trichloroacetic, can cause burns. Many stronger acids and corrosives are used in the laboratory; hydrofluoric, sulphuric and nitric acids, as well as caustic soda, are especially dangerous. Such acids and pickling solutions must be stored safely in appropriate and clearly labelled containers and with proper safety precautions (see later).

Anaesthetic gases

Dental clinical personnel may be chronically exposed to anaesthetic gases and vapours, especially if the anaesthetic or relative analgesia equipment is faulty, poorly maintained or used without an effective scavenging system, or if the agents are abused. Nitrous oxide and halothane have known adverse effects but there are as yet few data on any possible adverse occupational effects of isoflurane, enflurane or other agents, apart from occasional asthma (Ch. 15). However, such pollutants are inhaled and absorbed, and appear in the blood and secretions such as breast milk. Headache is common, especially where halothane is used, and there are rare confirmed cases of occupationally acquired halothane hepatitis. However, occupational exposure does not appear to give rise to neuropsychiatric disorders. Mental and neurological performance is not significantly impaired by exposure to inhalational anaesthetic agents under normal working conditions; however, they are, not surprisingly, impaired after exposure to excessive amounts of

inhalational anaesthetics – to a greater degree by nitrous oxide than by halothane.

Abuse of nitrous oxide, however, is a well-recognized hazard and can produce neurological damage, a myeloneuropathy caused by nitrous oxide, interfering with vitamin B₁₂ metabolism and subsequent DNA production, similar to that of subacute combined degeneration of the spinal cord. Nitrous oxide impairs the enzyme methionine synthetase, which normally catalyses the conversion of homocysteine to methionine. There is early sensory impairment, L'Hermitte's sign (shooting pains when the neck is flexed), leg weakness, ataxia, impotence and loss of sphincter control. Fortunately, the myeloneuropathy improves after exposure to the gas is stopped, though some damage remains, especially in the central nervous system (CNS). Interference with vitamin B₁₂ metabolism probably also underlies the bone marrow damage, leading to megaloblastosis seen in bone marrow biopsies of dentists chronically overexposed to nitrous oxide but, surprisingly, macrocytic anaemia does not seem to result. Nitrous oxide appears to be the agent most frequently responsible for occupational exposure.

It has been suggested that DHWs exposed to inhalational general anaesthesia (GA) may be predisposed to disorders of health and reproduction, but the evidence is equivocal. Male dentists have been reported to have more liver, kidney and neurological disorders than controls, while their partners have been reported to have an increased rate of spontaneous abortions. Female dentists exposed to inhalational GA agents have been reported to have an increased risk of spontaneous abortion, congenital abnormalities in children and higher rates of cancer, renal and hepatic diseases. Dental nurses chronically exposed to GA agents may suffer from similar problems and (it has been suggested) may have an increased incidence of cancer of the cervix.

A recent critical review of the available evidence indicates that none of the criteria for the demonstration of toxicity by trace concentrations of GA agents has been adequately fulfilled, and that anxieties over occupational exposure may have been unjustifiably exaggerated. The consensus of data from animal experiments at sub-anaesthetic concentrations has not yielded convincing evidence of toxicity. Epidemiological studies have also provided no convincing evidence of any effect of chronic exposure to anaesthetic agents on mental performance, cancer or fetal disorders such as low birth weight, stillbirth or malformation. In contrast to anaesthetic personnel, exposure of DHWs to inhalational GA agents is usually for short periods, except where relative analgesia is frequently used.

Though there is little evidence of any significant hazard from gases in the surgery atmosphere, the following precautions should be taken where GA or relative analgesia (inhalational sedation) is used. To reduce contamination of the surgery atmosphere by gases, relative analgesia should not be overused, the machine should be carefully used, adequate surgery ventilation should be provided and, most importantly, a scavenger system should be used. Scavenging systems reduce air pollution by inhalational GA agents but, even when used, nitrous oxide levels in dental surgeries using relative analgesia can still exceed 150 ppm.

Occupational exposure to nitrous oxide can be minimized by the use of scavenging systems, local exhaust systems, careful sedation technique and equipment management. To provide a safer workplace, the following preventive measures should be implemented:

- Reduction of exposure levels to minimum
- Monitoring of levels in the surgery
- Use of effective scavenging equipment and monitoring devices
- Use of an effective delivery system, including a readily visible and accurate flow meter, and a vacuum pump with the capacity for up to 45 L of air per minute per workstation

- Regular inspection of administration equipment for leaks
- Regular maintenance and servicing of equipment
- Direction of waste gas away from windows, ventilators, air-conditioning inlets, or other areas that might allow gases back into the area
- Venting of exhaust gases to the exterior
- Maintenance of adequate ventilation (the general ventilation should provide good room air mixing)
- Use of an airsweep fan
- Minimization of conversation with patients and control of mouth breathing during the use of nitrous oxide
- Shutting off and securing the equipment after each day's use
- Fitting the nasal mask on the patient as well as possible.

Additional recommendations are as follows:

- Improvement of circulation in the surgery by opening a window or using a non-recycling air conditioning system
- Use of a variety of mask sizes to ensure a proper fit for individual patients.

Health-care personnel who should avoid exposure to nitrous oxide (Schumann 1990) include:

- women in the first trimester of pregnancy
- infertile individuals using *in vitro* fertilization procedures
- individuals with neurological complaints
- immunocompromised individuals who are at risk from bone marrow suppression.

Pregnant staff, or staff likely to become pregnant, should not work in a contaminated environment unless there is an effective scavenging system.

Antiseptics

DHWs and patients may also be exposed to chemical agents that are used as topical antiseptics in the dental practice. For example, carbol camphor, eugenol, guaiacol and thymol are endodontic medicaments used as pulp sedatives; zinc oxide as a pulp-capping agent and a root canal antiseptic; hydrogen peroxide and hypochlorite as root canal irrigants; m-cresol, formaldehyde and glutaraldehyde as root canal antiseptics; and chloroform and iodoform may be used during root canal filling. Benzalkonium chloride, benzethonium chloride, chlorhexidine and iodine are antiseptics directly administered to the oral mucosa.

Disinfectants

DHWs may be exposed to disinfectants (such as hydrogen peroxide, sodium hypochlorite, chlorhexidine, formalin, etc.), organic solvents and active (antibacterial) ingredients of disinfectants when they clean surfaces or instruments (with solvent-based disinfectants or water-based agents). Other workers commonly exposed include radiographers, X-ray technicians and cleaners. Reducing workplace exposure to its lowest possible level represents the most important hazard reduction strategy, achieved by keeping containers tightly sealed when not in use, maintaining adequate ventilation levels and adhering rigidly to the use of appropriate personal protective equipment.

Examples of active ingredients in the disinfectants used in the dental environment are *o*-phenylphenol, benzoyl-*p*-chlorophenol and *n*-alkyl-*n*-benzyl-*n,n*-dimethylammonium chloride, as well as many others (Box 31.6). Alcohols (ethyl and isopropyl alcohol) are rapidly bactericidal, tuberculocidal, fungicidal and virucidal, but not sporicidal.

Box 31.6 Disinfectants

Inorganic

- Acids: boric acid, hydrochloric acid, sulphochromic acid, tartaric acid
- Alkalis: calcium hydrate, potassium hydroxide, sodium carbonate, sodium hydroxide
- Oxidants: peroxide, potassium permanganate
- Inorganic halogens: calcium chloride, chlorine derivatives (chloramines, chlorate, hypochlorites), iodine
- Heavy metal salts: mercuric bichloride, mercuric ossicyanide

Organic

- Alcohols: ethyl alcohol, isopropyl alcohol
- Aldehydes/phenols: chlorine cresol, chlorine xyleneol, cresol; dichlorine, formaldehyde, glutaraldehyde, hexachlorophene, phenol, polyphenols; xyleneol
- Mercury organic compounds: mercurochrome, mercuric phenyl nitrate
- Chlorine/iodine organic compounds: chloramine, dichloramine iodine, povidone/betadine
- Quaternary ammonium derivatives: benzalkonium, benzoxonium, benzetonium chloride, cetrimide

Sodium hypochlorite has broad-spectrum antimicrobial activity but is inactivated in the presence of organic matter, and hypochlorite solutions may bleach and damage the texture of fabrics and corrode or damage materials such as stainless steel instruments. Hypochlorite solutions are unstable; they need to be prepared fresh for use and to be used within 24 hours. Antiseptics or disinfectants that have raised most concern have included formaldehyde and glutaraldehyde.

Formaldehyde is bactericidal, tuberculocidal, fungicidal, virucidal and sporicidal. However, its irritant and carcinogenic properties limit its use. Glutaraldehyde is an effective disinfectant but is irritant to eyes, skin and lungs, so gloves of material impermeable to glutaraldehyde, full facial shield and waterproof gowns or aprons are necessary for personal protection wherever glutaraldehyde preparations are used. It has been withdrawn or banned in many countries.

Methyl methacrylate

Acrylic monomer is the most common organic solution used in dentistry; the main component is methyl methacrylate, but it may also contain other monomers such as *N*-butylmethacrylate, isobutylmethacrylate, laurylmethacrylate, 1,4-butanediol dimethacrylate or ethylene glycol dimethacrylate. Polymerization inhibitors such as hydroquinone, *p*-methoxyphenol or butylated cresols; plasticizers such as dibutyl phthalate; ultraviolet light absorbers such as benzophenone; and activators such as dimethyl-*p*-toluidine may also be found.

Methyl methacrylate and cyanoacrylate may be used for solvent abuse but, in the absence of abuse, there is little evidence of a serious hazard if reasonable care is taken. Chemical hepatitis due to overexposure to methyl methacrylate monomer has been rarely reported, as have methyl methacrylate and cyanoacrylate-induced occupational asthma or dermatitis. Methyl methacrylate monomer may cause transient nausea if inhaled in large quantities, possibly by central depression of gastric motor function; *rarely*, monomer has caused dyspnoea and hypertension. It may also soften soft contact lenses.

In technicians using methyl methacrylate, the monomer is absorbed through skin, even to some extent where 'protective' creams are used. Unfortunately, many gloves are permeable to monomer, and barrier creams may impede the setting of acrylic. Urine analysis shows low methacrylate levels in the morning but clear evidence of percutaneous

absorption throughout the working day. Handling of methyl methacrylate may occasionally cause transient finger and palmar paraesthesia, pain and whitening of the fingers in the cold, local neurotoxicity and an eczema-like reaction. Contact dermatitis as a result of handling methyl methacrylate monomer is also a possibility but is surprisingly rare.

Methyl methacrylate is embryotoxic and fetotoxic to rats (as is toluene). Though there is no evidence of such a danger to humans from methyl methacrylate, this should be borne in mind as a hazard, but probably no more than a theoretical one, in the case of female dental technicians.

There is no evidence of any permanent toxic effects from methyl methacrylate monomer under conditions of normal use.

Volatile, highly flammable chemicals

Methyl methacrylate monomer and gases such as oxygen are commonly used in dentistry. These must be stored properly in a correctly labelled strong container and not used near flames, or a fire or explosion could result. Many alcohols, acetone, and solvents and thinners are toxic and may be flammable (Box 31.7). Some can also cause dermatitis and damage the eyes and respiratory tract; chronic exposure may cause renal or liver damage; and some, such as toluene, are teratogenic.

X-ray developers

Developers for radiographs contain hydroquinone; fixatives contain acetic acid and sodium thiosulphate. These solutions may cause

^aPossible carcinogens.

dermatitis, conjunctivitis or bronchitis, and so should be handled carefully and with rubber gloves, avoiding contact with the eyes (it is best to wear protective eyewear) and avoiding excessive inhalation.

'Sick building syndrome'

The term 'sick building syndrome' refers to vague symptoms that develop in some office workers during the working week but abate at weekends and during holidays. The cause is unclear.

'Darkroom disease'

There have been reports of an unexplained medical syndrome, 'darkroom disease', among radiographers or medical radiation technologists. Several of the symptom clusters reported are similar to those of other medically unexplained syndromes with overlapping features, such as sick building syndrome. These workers have potential exposure to processing chemicals involved in developing and fixing films, including sensitizers and irritants, such as glutaraldehyde, formaldehyde, sulphur dioxide (SO₂) and acetic acid.

RADIATION HAZARDS

Radiation hazards in dental practice are mainly from ionizing radiation, as in X-rays, but there may also be hazards from the light sources used for curing composite materials and occasionally from other sources, such as lasers.

IONIZING RADIATION

Ionizing radiation has a wavelength shorter than 10nm, and can be artificial (such as X-rays) or come from natural sources. Exposure can induce mutations in the germinal tissues (teratogenic effect) or malignant tumours in other tissues (oncogenic effect). Exposure to ionizing radiation must therefore be kept to the absolute minimum. It is a hazard especially to the fetus or young child, or where cells are proliferating rapidly, as in the gonads and bone marrow.

Acute high-level overexposure may cause radiation sickness and gastrointestinal and haematological damage, but most occupational exposure is at a lower level and is prolonged; radiosensitive, rapidly dividing cells (such as in the fetus, skin or bone marrow) are then at risk. Additional and possibly more important radiation hazards are those from accidents (e.g. Fukushima, Chernobyl), nuclear explosions, and domestic radon exposure in buildings situated over uranium-bearing strata, in such areas as parts of Cornwall, Devon, Somerset and Aberdeen, and also in some areas of Cumbria, Staffordshire, the West Midlands and Mid-Glamorgan. More than 75% of the annual exposure of the UK population to ionizing radiation is from such natural sources from radon (an alpha-emitting gas) – a hazard that might equal in magnitude that posed by cigarette smoking and toxic waste.

Therapeutic radiation may also predispose later to malignant tumours but there has really been concern only about diagnostic radiation in this respect. The use of dental diagnostic radiographs has been implicated as a risk for meningioma. Patients receiving bitewing or panorex dental X-ray examinations annually or more frequently were more than twice as likely to develop meningioma (in children the risk was greater). There may also be an increased risk of thyroid cancer.

Long-term follow-up studies of patients who have had radiation treatment have also shown significant risk for tumours to develop in

the radiation field. For example, radiotherapy for Hodgkin disease may lead to breast cancer later; patients irradiated for breast carcinoma, particularly smokers, may develop lung cancer.

There is an increased risk of salivary tumours in patients who have received radiation to the tonsils and nasopharynx. More worryingly, radiotherapy in the past for benign diseases of the skin (acne, tinea capitis, haemangiomas) and for tonsillitis led to substantially increased risks of thyroid cancer and parotid, parathyroid and CNS tumours. Radiation treatment for benign conditions has increased with the advent of stereotactic delivery and, in particular, single high-dose gamma-knife therapy. This is used for benign CNS tumours (e.g. vestibular schwannoma, meningioma, pituitary adenoma and haemangioblastoma). There are concerns regarding the use of radiotherapy in childhood and in tumour-predisposing syndromes. Intensity-modulated radiation therapy (IMRT) may reduce the adverse effects of radiation on normal tissues but this is controversial. Proton therapy may offer further improvement in dose localization over photons (X-rays) and reduce the risk of second malignancies.

NON-IONIZING RADIATION

Non-ionizing radiation has many forms.

Electromagnetic (radiofrequency) radiation is emitted by a variety of sources ranging from transmitter towers to electric power lines, computer terminals, electric clocks, microwave ovens and electric blankets. The public has become concerned about possible adverse effects from electromagnetic fields emanating from power transmission lines but the evidence indicates that there is little, if any, reliable evidence for a health risk; in any event, there is more exposure to electromagnetic radiation from household appliances and wiring than from power lines. Moreover, *natural* electromagnetic radiation is at least 100 times as intense as that induced by power lines. There is no evidence that exposure to electromagnetic radiation at these radiofrequencies and power levels poses any other health hazard to normal persons but some individuals fitted with cardiac pacemakers could be at risk (Ch. 5).

Ultraviolet (UV) light is emitted especially by the sun and the universally recognized consequence of overexposure is sunburn, but there are also hazards to the eyes mainly (cataracts) and skin (predisposition to melanoma and squamous or basal cell carcinoma). UV and other lights may be used in dentistry (Table 31.4). The eyes are at risk from acute and cumulative effects, mainly due to back-reflection of the blue light. Furthermore, phototoxic and photoallergic reactions originating from absorbed radiation in endogenous or exogenous substances accumulated in the DHW's eyes and skin, as well as the patients' oral mucosa, must also be taken into consideration. Prevent problems by reading the manufacturers' instructions and using radiation-filtering protection goggles.

UVB (wavelengths between 286 and 320 nm) is responsible for most sunburn and also snow blindness (actinic retinitis). UVA (wavelengths

between 320 and 400 nm) is the most dangerous and causes chronic damage to the eye, cataracts and damage to the retina. UVA light sources in dentistry include UV sources for curing of restorative resins and fissure sealants and UV plaque lights (320–365 nm), but these have largely been replaced by blue light sources. Protective eyewear should be worn to absorb the wavelengths of any light sources used.

Blue light (400–500 nm) sources were developed to overcome the dangers of UV radiation and activate diketones in dental composite materials. However, blue light is not entirely safe, since it contains high-energy photons with the potential to form reactive free radicals in the eye, and these produce peroxides that denature photoreceptors in the retina. Blue light may be up to 30 times more damaging than UV light to the retina and may possibly also predispose to cataract.

White (visible) light (400–700 nm) is much safer but also emits minute amounts of both UV and blue light, and green light (490–600 nm), so protective eyewear that absorbs these wavelengths should still be worn.

Laser is the acronym for *light amplification by stimulated emission of radiation*. In general, lasers rapidly heat and acoustically shock tissues; all are potentially hazardous, particularly because of eye damage, burns and the risks of fire or electric shock. There is also concern that microorganisms might be transmissible in laser smoke. *All* lasers should therefore always be used with great care and *never* shone into the eyes, in unintended directions or on to brightly plated instruments that reflect the laser. Protective eyewear and facemasks should be worn.

The effect of a laser on target tissue depends on the wavelength, beam power, degree of focus, duration of exposure and distance to target, as well as the absorption by the tissue. The wavelength of the photons (radiation) is controlled by the type of laser and the lasing medium. There are hundreds of different lasers in use but the main ones used in health care are the carbon dioxide (CO₂), Nd:YAG (neodymium, yttrium, aluminium, garnet) and argon-ion lasers (Table 31.5).

The CO₂ laser emits infrared light (wavelength 10.6 micrometres), which is invisible but absorbed by water-containing tissues. It damages tissue by heat and can be used to cut soft and hard tissues. Because the CO₂ laser is invisible, it is used co-axially with a helium–neon laser to produce a visible red beam. CO₂ lasers are expensive and potentially very dangerous.

Table 31.4 Light hazards

Radiation	Based on	Applications
Conventional blue or white light	Light-emitting diode (LED) or tungsten quartz halogen	Bonding, composite resin sealants and restorative materials, luting agents
Plasma arc lamps	430–490 nm	Rapid-cure resins
Intense pulsed light (IPL)	Xenon lamp	Aesthetic surgery

Table 31.5 Lasers

Laser	Based on	Applications
Argon	488 nm	Tooth whitening Increase of resin adhesion, polymerization and reduction of microleakage
Carbon dioxide	514.5 nm	Soft-tissue surgery
Diode	10600 nm	Soft-tissue surgery
	800–830 nm	Soft-tissue surgery
	980 nm gallium aluminium arsenide (GaAlAs)	Bleaching
Erbium	2940 nm and 2780 nm	Hard- and soft-tissue procedures
Nd:YAG (neodymium, yttrium, aluminium, garnet)	1064 nm	Soft-tissue surgery
Potassium titanyl phosphate (KTP)	532 nm	Aesthetic surgery

The *Nd:YAG laser* (wavelength 1.06 micrometres) and krypton lasers are also used clinically and have the great advantage that they can be transmitted down a fibreoptic path. The Nd:YAG (near-infrared) laser is invisible and therefore used with a helium–neon laser. It is employed in dentistry for cutting dentine and soft tissues, and also for photocoagulation.

The *argon laser* produces a blue–green light of 0.5-micrometre wavelength and can be transmitted by fibreoptics. It is used in dentistry mainly for polymerizing some composite materials. It is also used for photocoagulation.

Soft lasers include the helium–neon (He–Ne) laser, which produces light of 0.63-micrometre wavelength, and the diode laser (0.90-micrometre wavelength), which emits light in the near-infrared or visible part of the spectrum and, if restricted to only milliwatt powers, produces little if any heating or a direct photochemical effect on tissues. The beam of a soft laser penetrates directly only to a depth of about 0.8 mm and is less damaging than others, but still must be used with care as there is some hazard to the retina.

Video display units (VDUs or monitors) operate in the same way as television receivers, emitting light that forms the image on the screen, but excitation of the phosphors by the electron beam also causes emission of minute amounts of UV and infrared rays, and low-energy X-rays. Very low-frequency (VLF) and extremely low-frequency (ELF) electromagnetic radiation is also emitted but the levels are exceedingly low – often lower than those from domestic appliances.

The evidence indicates that VDUs are not responsible for cataracts, reproductive disorders, fetal congenital abnormalities or facial dermatitis. Musculoskeletal disorders and stress may be induced by VDUs. There is some evidence that these can be genuine problems, and that pains and stiffness in the neck, shoulders, back and wrists, along with carpal tunnel syndrome – repetitive strain injury (RSI), are not uncommon; however, this is related more to poor posture and the elimination of tasks that once required office workers to get up and move around once in a while, rather than concentrating on the VDU itself. Prolonged work at VDUs is fatiguing, particularly for those with minor visual defects, as correction for middle-distance viewing is rarely carried out adequately, and it is possible that the resulting eyestrain may lead to blurred vision, tension and headaches. This, in turn, can lead to depression and some of the other symptoms sometimes ascribed to working with VDUs. A further concern has been that the flickering of the VDU display might provoke epileptic attacks but there is no good evidence.

HAZARDS TO SPECIFIC BODY SYSTEMS

EYES

Care should be taken to avoid eye infections and damage from projected particles when using the air rotor, grinding metals or cutting wire. Penetrating wounds can cause deep injuries and even loss of sight. Chemicals such as chromic acid, hydrofluoric acid, phosphoric acid, sodium hypochlorite and trichloroacetic acid can also cause serious eye damage. Radiation is an eye hazard.

Blue and UV light sources with wavelengths shorter than 400–500 nm (this is mainly a UV danger) cause cumulative eye damage; the shortest wavelengths are most damaging. Protective glasses should be worn to filter out all light under about 500 nm; glasses with red-, orange- or yellow-coloured lenses of sufficient optical density are therefore indicated when using blue or UV light. Ordinary dark glasses do *not* filter

out these offending wavelengths; indeed, by absorbing visible light, they can cause pupil dilatation and therefore aggravate the problem.

HEARING

Loud noise (85 dB or more) can irreversibly damage the inner ear hair receptor cells of the organ of Corti in the cochlea. Ultrasonic scalers may produce slight tinnitus after prolonged use but this rarely appears to be clinically significant either to patients or to staff. Otherwise, the overall evidence suggests that hearing is not impaired in clinical DHWs compared with age-matched controls, provided modern well-maintained equipment (such as air rotors) is used.

MENTAL HEALTH

Despite the low risks in dentistry, DHWs clearly perceive that occupationally related diseases, especially stress, are common. Dentistry, even for students, appears to be somewhat stressful but perhaps less so than medicine and some other professions. Dentists and dental hygienists complain particularly of musculoskeletal discomfort and of stress; dental nurses complain mainly about allergies and respiratory infections.

Drug abuse in dentistry and medicine is increasing, and the incidence of alcohol and other drug abuse (including nitrous oxide or other inhalational anaesthetics) by doctors and dentists is higher than for comparable groups.

MUSCULOSKELETAL COMPLAINTS

Probably as a result of poor working positions and possibly stress, DHWs tend to develop musculoskeletal complaints. Although there appear to be few reliable objective studies of postural and skeletal problems in DHWs, one radiograph survey in Finland showed cervical spondylosis in about 50% of dentists, compared with about 20% of farmers of the same age. Dentists also had somewhat more radiographic changes in the shoulder joint but less lumbar spondylosis than farmers.

Activities involving repetitive wrist and hand movements, especially in women, may result in oedema beneath the transverse carpal ligament at the wrist. This can lead to compression of the median nerve and subsequent pain (especially at night), paraesthesia, hypoaesthesia and weakness in the wrist and hand (carpal tunnel syndrome). Though this is a common consequence of a variety of activities and is predisposed to by, for example, pregnancy or hypothyroidism, carpal tunnel syndrome has been reported in hygienists and endodontists in particular. Symptoms and signs consistent with partial carpal tunnel syndrome have been noted in one-quarter or more of hygienists in some surveys, but the diagnosis is far less frequent. Typists may also suffer the same symptoms.

Rest and analgesics usually provide adequate relief but, occasionally, splinting or corticosteroid injections are required. Surgical decompression may be indicated for recalcitrant cases.

PREGNANCY

Hazards from exposure to anaesthetic gases, mercury, ionizing radiation and infections have caused concern among female dental staff, but most evidence suggests that there is little if any specific occupational risk to the outcome of pregnancy. Pregnant female staff may,

understandably, be concerned about possible risks to their fetus from ionizing radiation but, provided the rules of radiation protection are carefully followed, even female radiography or radiology staff appear to be at no significant risk. However, non-immune or immunocompromised female staff and their fetus may be at risk from various infections, notably rubella, cytomegalovirus and varicella zoster virus. Pre-conception immunization and universal cross-infection control procedures should obviate this risk.

One study of 558 female dental surgeons and 450 high-school teachers who had given birth to at least 1 living child examined the effects of practising dentistry and of workplace exposure on fertility. Most of the female dental surgeons were using amalgam for fillings during the period they tried to conceive; 33% placed more than 50 fillings a week; 75% of the dental surgeons reported handling chloroform-based root-canal sealers; and 40% were exposed to disinfectants (containing ethanol and benzene) on a daily basis. No difference in fertility was found between the dental surgeons and the high-school teachers. Exposure to mercury, chloroform and benzene was not associated with decreased fertility.

RESPIRATORY SYSTEM

DHWs should position patients properly and use barriers (e.g. face shields, surgical masks, gowns), rubber dams and high-volume evacuators to prevent contact with splashes and splatter; these tend not to pass to the lungs but may settle on the conjunctiva or nasal mucosa, or on the nearby surfaces or equipment. Aerosols are suspensions of fine particles less than 50 micrometres in size; most of them are smaller than 5 micrometres. They remain airborne for extended periods of time – 24 hours or more, are dispersed widely by air currents and may be inhaled. Aerosols and splatter can contain microorganisms arising from the dental unit water or the patient, and readily contaminate the operating area. Infections of most concern, owing to their high morbidity or mortality, are hepatitis viruses and HIV, though the evidence discounts a risk (<http://www.cdc.gov/oralhealth/infectioncontrol/faq/aerosols.htm>; accessed 30 September 2013). However, respiratory viruses such as those causing avian flu, and bacteria such as those causing tuberculosis and legionellosis (Ch. 15), have been transmitted to dental staff, as have adenoviruses and a variety of agents, including *Chlamydia trachomatis* – but these incidents are rare.

Dusts can also damage the respiratory system. They can be created during various dental procedures and can constitute a hazard where work practices are poor, especially in the dental laboratory (Table 31.6).

There is little evidence of occupational lung disease among clinical dental staff but the drilling of teeth and old amalgams creates dust (and mercury vapour) if there is inadequate water-cooling. There has also been concern about the increased microbial counts and silica particles of the aerosols and dusts produced during procedures such as orthodontic debonding. Mixing alginate impression materials can also create dust from alginate salts and calcium sulphate, silica compounds and diatomaceous earth, fluoride salts, zinc oxide or barium sulphate and various filler particles. These materials may produce a hazard because of either the lead content or the siliceous fibres, though objective evidence for injury from these is weak.

In the laboratory, there are a number of possible sources of dust, ranging from pumice to various metals. The possible consequences of inhalation of these dusts are unclear but there are reports of mild dyspnoea, respiratory infections, pneumoconioses and possibly lung cancer in dental laboratory technicians. To date, most reports of pneumoconiosis in dental technicians relate to silica dust inhalation from

Table 31.6 Possibly hazardous mineral dusts in dentistry

Mineral	Found in some
Albite	Porcelain veneers
Andalusite	Silicate cement powders
Calcium sulphate	Gypsum products
Chrysolite	Asbestos ring liners
Cristobalite	Casting investments
Diatomite	Alginates
Labradorite	Porcelain veneers
Metals (various)	See text
Microcline	Porcelain veneers
Orthoclase	Porcelain veneers
Quartz	Casting investments
Sillimanite	Silicate cement powders
Spinelles	Cement powders

polishing and sandblasting using outdated equipment. Cancer may be due to tobacco use rather than dust inhalation.

Chemicals can also damage the respiratory system, directly or via allergic reactions. Clinical staff have occasionally developed asthma after exposure to enflurane. Dental laboratory technicians may be exposed to a number of toxic materials, including metal alloys such as Vitallium, Wisil, Duralium and Vironite, which are used in the production of crowns, bridges and dental prostheses; the most common constituents are chromium, cobalt, molybdenum, nickel, silica, tantalum and other metals. Occupational asthma has been precipitated in nurses and dental technicians by methyl cyanoacrylates and methacrylate. Beryllium, chlorhexidine, chromium, cobalt, formaldehyde, glutaraldehyde and nickel are other potential causes.

Electrostatic or high-efficiency particulate air (HEPA) filters significantly reduce aerosols containing microorganisms or dusts. Face masks rarely filter particles smaller than 5 micrometres in diameter and their filtering efficiency varies from 14% to 99%. Nevertheless, face masks do filter a great deal of debris. They should preferably be changed every hour. In the laboratory, local lathe ventilation is mandatory; a plexiglass shield will reduce splatter and dust extraction is vital.

SKIN

The main skin problems in dentistry are maceration (water-logging) and dermatitis from repeated hand-washing, candidosis secondary to maceration, and infections such as herpetic whitlow and contact dermatitis. It has been suggested that as many as one-third of dental staff suffer from contact allergies.

Dermatitis can result from direct chemical irritation of the skin or, in a susceptible individual, from an allergic response (contact allergy), which is a type 4 (delayed hypersensitivity) reaction (Table 31.7). Hand dermatitis is seen particularly frequently in dental technicians, of whom up to one-third may suffer; the most common causes are direct irritation and a reaction to acrylic monomer.

DHWs may be at increased risk of developing occupational allergic diseases, especially to methacrylates in acrylic resins, or dental bonding products that can permeate many disposable gloves. DHWs may develop dermatitis from chemicals or latex gloves, or mainly from repeated hand-washing.

Using adequate personal protective equipment, like nitrile rubber or neoprene gloves, is the most important preventive measure.

Table 31.7 Some skin irritants and allergens used in dentistry

Irritants	Recognized allergens	Rarely allergic
Abrasives (pumice, silica, calcium carbonate)	<i>p</i> -Chloro- <i>m</i> -xyleneol	Acrylic monomer
Adhesives (epoxy and cyanoacrylates)	Epoxy resin	Balsam of Peru
Amalgam	Ethylenediamine dihydrochloride	Beeswax
Detergents	Formaldehyde	Benzalkonium chloride
Essential oils (eugenol)	Lanolin	Benzocaine
Etching compounds (phosphoric acid, 38%)	Latex	Benzophenone
Germicidal solutions	Mercaptobenzothiazole (rubber gloves, rubber bands and dams, Band-Aids)	Benzoyl peroxide
Resins and catalysts	Neomycin	Bronopol
Soaps	Nickel	Camphor (plasticizer in acrylics)
Solvents	Parabens (medications, toothpaste)	Chlorhexidine
	Potassium dichromate	Chlorocresol
	Rosin (colophony)	Chlorothymol
	Thiomersal (disinfectants)	Cinnamon oil
		Cobalt
		Eugenol
		Glutaraldehyde
		Gold
		Hexachlorophane
		Hexylresorcinol
		Hydroquinone (inhibitor for acrylic resin systems)
		<i>N</i> -Isopropyl- <i>N</i> -phenyl- <i>p</i> -phenylenediamine (IPPD; rubber)
		Menthol
		Methyl dichlorobenzene sulphonate
		Methyl ethyl ketone (MEK) peroxide (catalyst for acrylic resin systems)
		Methyl- <i>p</i> -toluene sulphonate
		Methyl salicylate (toothpastes)
		Nickel
		Penicillin
		Povidone-iodine
		Procaine
		Resorcinol monobenzoate (ultraviolet inhibitor in clear plastics)
		Tetracaine (amethocaine)
		Triethylenetetramine (catalyst for epoxy resins)
		Zirconium (e.g. polishing paste)

APPENDIX 31.1 GUIDANCE ON HIV PEP FROM THE UK CHIEF MEDICAL OFFICERS' EXPERT ADVISORY GROUP ON AIDS (EAGA; 2008)

All health-care workers (HCWs) should be informed and educated about possible risks from occupational exposure, and should be aware of the importance of seeking urgent advice following occupational exposure.

Any significant exposure to blood and some other body fluids or tissues has the potential to transmit blood-borne infections. Many exposures result from failure to follow recommended safe handling and disposal of needles and syringes, or wearing personal protective eyewear.

An integrated approach to post-exposure management with respect to HIV, HBV and HCV is recommended. Employers should have a policy on the management of exposures, which should specify the local arrangements for risk assessment, advice and the provision of PEP. The policy must ensure that adequate 24-hour cover is available and should designate one or more doctors to whom exposed persons may be referred urgently for advice.

HIV AND SIGNIFICANT OCCUPATIONAL EXPOSURE

The risk of acquiring HIV infection following occupational exposure is *low* – less than 3 per 1000 injuries. There is no risk of HIV transmission where intact skin is exposed to HIV-infected blood.

Administration of zidovudine prophylaxis to HCWs occupationally exposed to HIV has been associated with an 81% reduction in risk for HIV infection.

Four factors are associated with increased risk of occupationally acquired HIV infection:

- Deep injury
- Visible blood on the device that caused the injury
- Injury with a needle that has been placed in a source patient's artery or vein
- Terminal HIV-related illness in the source patient.

IMMEDIATE ACTION

Immediately following *any* exposure – whether or not the source is known to pose a risk of infection – the site of exposure, e.g. wound

or non-intact skin, should be washed liberally with soap and water without scrubbing. Antiseptics and skin washes should not be used – there is no evidence of their efficacy, and their effect on local defences is unknown. Free bleeding of puncture wounds should be encouraged gently but wounds should not be sucked. Exposed mucous membranes, including mouth or conjunctivae, should be irrigated copiously with water.

Prompt reporting of injuries is a necessary first step to enabling appropriate and rapid prescribing of PEP.

A risk assessment needs to be carried out urgently by an appropriately trained doctor to determine the appropriateness of starting PEP; this should be done by a person who is *not* the exposed HCW.

CIRCUMSTANCES OF EXPOSURE

PEP should be considered after an exposure with the potential to transmit HIV, based on the type of body fluid or substance involved, and on the route and severity of the exposure. Exposures associated with significant risk include:

- percutaneous injury (from needles, instruments, bone fragments, significant bites that break the skin, etc.)
- exposure of broken skin (abrasions, cuts, eczema, etc.)
- exposure of mucous membranes, including the eye.

Some HCWs may have had occupational exposures that, after careful assessment, are not considered to have the potential for HIV transmission. Such workers should be advised that the potential side-effects and toxicity of taking PEP outweigh the negligible risk of transmission posed by this type of exposure because it is considered insignificant, whether or not the source patient is known or considered likely to be HIV-infected.

ASSESSMENT AND TESTING OF THE SOURCE PATIENT

If initial assessment indicates that an exposure has been *significant*, consideration should then be given to the HIV status of the source patient. Since HIV PEP is most likely to be efficacious if started within the hour, an urgent preliminary risk assessment should assess whether it is appropriate to recommend taking the first dose of PEP. A more

thorough risk assessment should then be undertaken to inform a decision about whether to continue the PEP regimen.

The designated doctor should ensure that appropriate arrangements are made to approach a source patient whose HIV status is not known and to ask for their informed agreement to HIV testing. *This approach should not be undertaken by the exposed worker.* A universal approach to asking source patients to agree to have an HIV test avoids the need to make difficult judgments, simplifies and normalizes the process, and avoids potential discrimination.

It is good practice for all hospitals to have the capacity to obtain an HIV test result within 8 hours ideally, and not more than 24 hours, after source blood is taken.

Starting PEP, where appropriate, should not be delayed while the result of source patient testing is being awaited.

EXPOSURE TO DISCARDED NEEDLE/UNKNOWN SOURCE

Where it is not possible to identify the source patient (e.g. needlestick injury caused by a discarded needle), a risk assessment should be conducted to determine whether the exposure was significant. PEP is unlikely to be justified in most exposures of this type.

WHEN TO PRESCRIBE PEP

PEP should be recommended to HCWs if they have had a significant occupational exposure to blood or another high-risk body fluid from a patient or other source either known to be HIV-infected or considered to be at high risk of HIV infection, but where the result of an HIV test has not or cannot be obtained.

PEP should not be offered:

- after exposure through any route with low-risk materials (e.g. urine, vomit, saliva, faeces) unless they are visibly blood-stained (e.g. saliva in association with dentistry)
- where testing has shown that the source is HIV-negative
- where risk assessment has concluded that HIV infection of the source is highly unlikely.

When offering PEP, it is important to take into account any views of the exposed HCW. Depending on the outcome of the preliminary risk assessment, if the exposure was significant, the exposed HCW may wish to consider starting PEP until further information is available about the source patient. In this way, the option of possible benefit from prompt PEP will have been kept open. Changes can be made to the PEP regimen, including cessation, if further information becomes available.

If the HIV status of the source cannot be established, the exposed HCW should have the opportunity to consider whether or not to continue PEP. The decision should be informed by all that is known about the source patient in terms of past exposure to risk of HIV infection and also the nature and severity of the exposure. These aspects should be considered, together with the potential for unpleasant short-term adverse effects and unknown long-term effects of taking PEP drugs.

The relative risk of HIV transmission may be increased considerably if the source patient has a high plasma viral load (e.g. at the time of seroconversion or in the later stages of HIV disease).

FURTHER MANAGEMENT ISSUES

All exposed HCWs should be encouraged to provide a baseline blood sample for storage and a follow-up sample for testing.

PEP is not a licensed indication for any antiretroviral drugs, which are therefore prescribed on an 'off-label' basis.

PEP is most likely to be effective when it is initiated as soon as possible after exposure (within hours, and certainly within 48–72 hours), and continued for at least 28 days. All HCWs occupationally exposed to HIV should have follow-up counselling, post-exposure testing and medical evaluation, *whether or not* they have received PEP.

EAGA now recommends, as a minimum, that follow-up should be for at least 12 weeks after the exposure or, if PEP was taken, for at least 12 weeks from when PEP was stopped, for the following reasons:

- A negative test at 12 weeks provides a very high level of confidence of freedom from infection.
- It minimizes the period of anxiety suffered by exposed HCWs waiting for the 'all clear'.
- In the majority of cases where seroconversion has occurred following occupational exposure, despite the use of triple PEP, seroconversion has been detected within 12 weeks of exposure.

Employers and medical, dental and nursing schools should consider making 7-day starter packs of PEP drugs available to workers/students travelling to countries where antiretroviral therapy is not commonly available.

BODY FLUIDS AND MATERIALS THAT MAY POSE A RISK OF HIV TRANSMISSION IF SIGNIFICANT OCCUPATIONAL EXPOSURE OCCURS

- Amniotic fluid
- Blood
- Cerebrospinal fluid
- Exudative or other tissue fluid from burns or skin lesions
- Human breast milk
- Pericardial fluid
- Peritoneal fluid
- Pleural fluid
- Saliva in association with dentistry (likely to be contaminated with blood, even when it is not obviously so)
- Semen
- Synovial fluid
- Unfixed human tissues and organs
- Vaginal secretions
- Any other body fluid if visibly blood-stained.

PEP DRUGS

Antiretroviral agents from three classes of drug are currently licensed for first-line treatment of HIV infection, namely:

- nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs)
- non-nucleoside reverse transcriptase inhibitors (NNRTIs)
- protease inhibitors (PIs).

Zidovudine (an NRTI) is the only drug to date that has been studied and for which there is evidence of a reduction in risk of HIV transmission following occupational exposure.

In HIV-infected patients, triple therapy has proved more effective than monotherapy or dual therapy in suppressing HIV replication and avoiding the emergence of viral resistance. US guidelines recommend two-drug PEP regimens following lower-risk incidents and three-drug regimens only for higher risks. This two-tier approach adds to the

complexity of the risk assessment process, at the expense of greater potency and protection for the exposed worker, and is not recommended. A potent three-drug PEP regimen is preferred because resistance to antiretroviral drugs is found at significant levels in both treated and untreated infected individuals in the UK.

PEP STARTER PACKS

Zidovudine is no longer recommended for PEP starter packs, preference being given to newer drugs with better tolerability.

Starter packs should provide a generic regimen of two NRTIs plus boosted PI – recommended for PEP following non-occupational exposure. For occupational exposure, the regimen is:

- one Truvada tablet (245mg tenofovir and 200mg emtricitabine [FTC]) once a day
- plus
- two Kaletra film-coated tablets (200mg lopinavir and 50mg ritonavir) twice a day.

Truvada plus Kaletra is the preferred regimen, but Combivir plus Kaletra may be considered as an option if there are difficulties sourcing starter packs containing Truvada. Due to concerns about long-term stability outside the original container, some prepacking units may be unable to supply starter packs containing Truvada.

ADVERSE EFFECTS

Side-effects of the NRTIs (e.g. tenofovir and emtricitabine) include gastrointestinal effects (e.g. nausea, diarrhoea), as well as dizziness and headache. In clinical trials of Kaletra, the most commonly reported side-effect was diarrhoea, followed by other gastrointestinal disturbances, asthenia, headache and rash. Inclusion of an NNRTI (nevirapine and efavirenz) in PEP regimens is not recommended; nevirapine has the potential to cause severe rashes (which may be confused with the rash associated with HIV seroconversion) and sometimes Stevens–Johnson syndrome, while efavirenz is associated with neurological side-effects and is also contraindicated in pregnancy. Serious adverse events (including life-threatening hepatotoxicity) have been reported in HCWs taking nevirapine as part of PEP.

Pregnancy is discussed in Chapter 25. This chapter deals with contraception and sexually shared infections, though others, especially those that are also bloodborne, such as hepatitis viruses are discussed in Chapter 9 and HIV in Chapter 20, and others in Chapter 21.

CONTRACEPTION

Different methods of contraception vary in effectiveness (Table 32.1). The most widely used and effective forms are the oral contraceptive pill (OCP; 'the Pill') and the male condom. The latter also confers protection against transmission of infections and, in the face of the increase in many sexually shared (transmitted) infections (SSIs), is therefore recommended. Contraception is best guaranteed by planned regular use of OCPs plus barrier precautions such as a condom.

EFFECTIVE CONTRACEPTION

Hormonal contraception is not completely effective in preventing pregnancy and provides no protection against SSIs.

Oral contraceptive pill

General aspects

OCPs act by inhibiting ovulation via their action on the hypothalamic–pituitary axis; by altering uterine cervical mucus composition; and by impeding ovum implantation. Emergency contraception may prevent pregnancy when taken within 72 hours of intercourse but is not reliable. OCPs are usually combinations of synthetic oestrogens and progestogens; the mini-pill contains only a progestogen and is less effective than the combination pill. Two types of synthetic oestrogen are used in OCPs – ethinylestradiol and mestranol. The synthetic progesterone is progestogen. Norethindrone and levonorgestrel are other examples.

OCP adverse effects are thought to be caused by the oestrogen component, which is now only 50mg or less. The major risk is the higher incidence of thromboembolic disease (thrombosis of deep veins and coronary or cerebral thrombosis), but the incidence of cardiovascular or cerebrovascular disease is normally so low in young women that, even with a four- or fivefold increase in incidence, these complications are still uncommon. Hypertension, diabetes, jaundice and liver tumours, usually benign, are also increased in those taking OCPs (Table 32.2; see also Ch. 29). Long-term OCP use may increase the risk of cervical cancer and possibly of breast cancer, but OCPs appear to lower the risk of ovarian cancer by 40% and may also reduce the risk of endometrial cancer. *However, any risks from adverse effects of OCPs are low compared with the health risks associated with pregnancy.*

OCPs are absorbed from the intestine, but their effect may be impaired by: excessive intestinal motility, as in diarrhoea; antimicrobials, such as amoxicillin, ampicillin or tetracycline, which suppress the gut flora that deconjugate bile salts, thereby interrupting the entero-hepatic recycling of the oestrogen; or drugs such as carbamazepine that enhance the liver enzymes that metabolize the OCPs. As a result, these drugs may, at least theoretically, increase the pregnancy risk; the risk

Table 32.1 *Methods of contraception*

Contraceptive methods	Efficacy (%)
Majority use	
Oral contraceptive pill (OCP), including the mini-pill	99
Male condom	98
Minority use

Breast pain		Gallstones
Fluid retention		Liver benign tumours
Weight gain		Cancer of cervix and breast

^aMore frequent in smokers and older women.

Table 32.3 *Some drugs interacting with oral contraceptive pills (OCPs) to reduce their effect and predispose to pregnancy*

Significantly interfering with OCPs	Slightly interfering with OCPs
Antibiotics:	Oral antibiotics:
Rifampicin (rifabutin)	Amoxicillin
Anticonvulsants:	Ampicillin
Barbiturates	Metronidazole
Carbamazepine	Tetracyclines
Dichloralphenazone	
Phenytoin	
Primidone	

is minimal for most antimicrobials, though rifampicin (rifabutin) is an exception (Table 32.3; see also Ch. 29). Rifampicin can interfere with:

- combined OCP
- progestogen-only OCP
- implant
- patch
- vaginal ring.

If antibiotics, or the illness the antibiotics are required for, cause diarrhoea or vomiting, the OCP may be affected.

Women on OCPs and prescribed antimicrobials are best advised to use additional contraceptive measures whilst taking the antimicrobial and for at least 7 days afterwards (4 weeks in the case of rifampicin). This is not an issue with other forms of contraception.

Carbamazepine and some anti-human immunodeficiency virus (HIV) agents may interfere with the OCP.

Contraceptive injections, implants and patches

Progestogen injections are available as two types: Depo-Provera (medroxyprogesterone), which protects from pregnancy for 12 weeks, and Noristerat (norethisterone), which protects for 8 weeks. They act by inhibiting ovulation, thickening cervical mucus, inhibiting the progress of sperm and thinning the endometrium.

A progestogen implant is a small flexible rod placed under the skin in the upper left arm. It works for up to 3 years. It contains etonorgestrel (Implanon). Some medicines render an implant less effective; these include drugs to treat HIV, epilepsy and tuberculosis, and St John's wort.

Contraceptive patches (Evra) provide progestogens and oestrogens, and work for about 1 week, so new patches are used each week for 3 weeks, followed by a week's break – just like the OCP.

Dental aspects of contraception

OCPs can interact with anticoagulants to disturb anticoagulant control and can impair the effect of tricyclic antidepressants. The significance of drug interactions for dental antibiotics with the OCP is probably low.

The predisposition to thromboembolic disease and hypertension theoretically necessitates precautions for operations under general anaesthesia (GA). However, if the patient is otherwise well, GA – in hospital of course – is not contraindicated. Despite the risk of thromboembolism, the disadvantages of discontinuing OCPs before GA outweigh any advantages.

OCPs may worsen gingivitis and possibly periodontitis and may increase the risk of dry sockets; jaw radio-opacities or altered trabecular patterns may appear.

Condoms

Male and female latex rubber condoms are available; they are inexpensive, have a high success rate approaching 100%, have virtually no side-effects and also protect against SSIs.

Other contraception that is more than 90% effective

- Intrauterine contraceptive device (IUCD): originally termed the coil or loop because early devices took those shapes, IUCDs are now often T-shaped. They contain some copper (to increase efficacy). The IUCD acts by inhibiting sperm movement through the uterus, altering the mucus and affecting the endometrium.
- Intrauterine system (Mirena): this intrauterine system contains a reservoir of progestogen steadily released for up to 5 years.
- Cap or diaphragm: this mechanically impedes sperm entry into the uterus.

UNRELIABLE FORMS OF CONTRACEPTION

- Withdrawal method: coitus interruptus (Latin for 'interrupted intercourse')

Table 32.4 The most important sexually transmitted diseases and their causal agents

Class of agent	Microorganism	Diseases
Bacteria	<i>Treponema pallidum</i>	Syphilis
	<i>Mycoplasma genitalium</i>	Non-specific urethritis
	<i>Ureaplasma urealyticum</i>	Non-specific urethritis
	<i>Neisseria gonorrhoeae</i>	Gonorrhoea
	<i>Chlamydia trachomatis</i>	Chlamydia
		Lymphogranuloma venereum
	<i>Haemophilus ducreyi</i>	Chancroid
	<i>Calymmatobacterium granulomatis</i>	Granuloma inguinale
	<i>Staphylococcus aureus</i>	Meticillin-resistant <i>Staph. aureus</i> (MRSA) in men who have sex with men
Viruses	Herpes simplex viruses (human [alpha] herpesvirus)	Genital herpes
	Human papillomaviruses	Genital warts (condyloma acuminatum)
	Hepatitis B and C viruses	Hepatitis
	Human immunodeficiency virus	HIV/AIDS
Fungi	<i>Candida</i>	Thrush
Parasites	<i>Phthirus pubis</i> (crab lice)	Pubic lice
	<i>Sarcoptes scabiei</i>	Scabies
	<i>Trichomonas vaginalis</i>	Trichomoniasis

- Natural family planning (the rhythm method): avoidance of intercourse when ovulation is probable, as assessed by the calendar method, temperature method or mucus test.

SEXUALLY SHARED INFECTIONS SEEN WORLDWIDE

Sexually shared infections (SSIs), or sexually transmitted diseases (STDs) or infections (STIs), include bacterial, viral and fungal infections, and infestations (Table 32.4); they were formerly termed venereal diseases (VDs). Non-specific urethritis (NSU) and *Chlamydia* are probably the most common. There can be infection with more than one SSI, and SSIs generally increase the liability to transmission of viruses such as HIV, especially if there is mucosal or cutaneous ulceration. The group of the most common serious SSIs has been given the acronym SHAG (syphilis, herpes, anogenital warts and gonorrhoea).

Young people (age 16–24 years) now account for half of all SSI cases, and the incidence of virtually all of these infections is increasing. In the UK in 2008, nearly half a million people attended clinics for SSIs. Sexually promiscuous people can be the source of transmission to literally hundreds of others (Fig. 32.1). The risk of infection is highest in sex workers.

Prevention

SSIs are passed from person to person by direct contact, mainly via the external genitals, vagina, anus or rectum, or on the lips and in the mouth. Transmission of the microorganism occurs during vaginal, anal or oral sex. Pregnant women can sometimes pass infection to the fetus.

**When you have sex with someone, you are having sex
With everyone they have had sex with, and with
Everyone they have had sex with, and with
Everyone they have had sex with, and with
Everyone they have had sex with, and with
Everyone they have had sex with, and with
Everyone they have had sex with, and with**

Fig. 32.1 Chart demonstrating the spread of sexually shared infections to other partners. (From www.positive-choice.org; accessed 30 September 2013).

Oral, anal, vaginal or penile ulcers or other lesions make it easier to transmit and acquire SSIs. However, because SSI lesions can be hidden in the vagina or anus, under the foreskin or in the mouth, it may not be obvious that a sex partner is infected. Unless a person knows that their sex partners have been tested and treated, they may be at risk of reinfection from an untreated sex partner.

Since SSIs are passed from person to person through unsafe sexual practices, the risk of infection can be reduced by avoiding casual and unprotected sexual intercourse via:

- abstinence
- being monogamous
- condom use always.

The surest way to avoid transmission of SSIs is to abstain from sexual intercourse, or to be in a long-term mutually monogamous relationship with an uninfected partner who remains so. A man should always use a condom during sexual intercourse, each time, from start to finish, and a woman should make sure that her partner uses one. A woman can also protect herself from SSIs by using a female condom. Dental dams have been advocated for protection against transmission of SSIs during cunnilingus or oroanal contacts.

Box 32.1 High-risk groups for sexually shared infections

- Promiscuous heterosexuals
- Gay or bisexual people
- Prostitutes
- Drug addicts
- Alcoholics
- Armed forces personnel
- Merchant seamen
- Aircrew
- People in custodial institutions
- Frequent business travellers
- People with learning impairment
- Sexual partners of the above groups

Fig. 32.2 The outfall from street prostitution: heroin syringe and condoms

Although any person can be at risk of contracting SSIs, members of certain groups can be at especially high risk; some sell sex to underpin their drug habits (Box 32.1 and Fig. 32.2). Close contact is essential to SSI transmission; they cannot be spread through social contact or via toilet seats, doorknobs, swimming pools, hot tubs, bathtubs, shared clothing or eating utensils.

It is important to refer all sexual partners of infected people to be checked to prevent spread of SSIs and to prevent the patient from becoming re-infected. Providers should routinely test persons who:

- are men who have sex with men (MSM)
- have HIV infection
- have partner(s) who have tested positive
- are pregnant.

Persons should abstain from sexual contact with new partners until the situation is clarified and treatment effective. Persons must notify their sex partners so that they also can be tested and treated.

Multiple infections are not uncommon and substance abuse may be seen. Vaccination against hepatitis B is to be considered. Preventive vaccines against oncogenic human papillomaviruses are available in some countries. When accidental exposure occurs, post-exposure prophylaxis (PEP) may be available for hepatitis B and HIV. Pre-exposure prophylaxis for HIV (PREP) is also available.

UK law on intentional or reckless transmission of sexual infection can be found under the alphabetical list at: <http://www.cps.gov.uk/legal/> (accessed 30 September 2013).

ALPHABETICAL LIST OF SEXUALLY SHARED INFECTIONS

This section discusses SSIs that are not discussed elsewhere; for viruses (herpesviruses, papillomaviruses, HIV), fungi (candidosis) and parasites (crab lice and scabies), see Chapters 20 and 21.

Chlamydia

General aspects

Chlamydia trachomatis, the most frequently reported bacterial SSI in the USA and UK in women, initially infects the cervix and urethra, or rectum. In men, infection is urethral or rectal. *Chlamydia* can be found in the pharynx of women and men who have oral sex with an infected sex partner.

Clinical features

About three-quarters of *Chlamydia*-infected women and half of infected men have no symptoms. If symptoms do occur, they usually appear within 1–3 weeks after exposure. Women may develop vaginal discharge or dysuria (a burning sensation when urinating). Some have lower abdominal pain, low back pain, nausea, fever, dyspareunia (pain during intercourse) or intermenstrual bleeding (between periods). *Chlamydia* can cause pelvic inflammatory disease (PID), which can permanently damage the fallopian tubes, uterus and surrounding tissues, or cause ectopic pregnancies. Rectal *Chlamydia* may cause pain, discharge or bleeding. Men may have a urethral discharge or dysuria. Complications among men are rare but include epididymitis with pain, fever and, rarely, sterility. Chlamydial infections in pregnancy can lead to premature delivery, and babies born to infected mothers can suffer chlamydial pneumonia and conjunctivitis (pink eye).

Rarely, genital chlamydial infection in adults can cause arthritis accompanied by skin lesions and inflammation of the eye and urethra (Reiter syndrome). *Chlamydia* may also cause lymphogranuloma venereum (LGV; see below).

General management

Culture, direct immunofluorescence, enzyme immunoassay (EIA), nucleic acid amplification tests (NAATs) and nucleic acid hybridization tests are available for *C. trachomatis* detection. The Centers for Disease Control and Prevention (CDC) recommends annual screening of all sexually active women aged 25 years or below, and those older women with risk factors (e.g. those with a new sex partner or multiple partners). Treatment is with azithromycin (single dose), doxycycline (twice daily for a week), erythromycin, ofloxacin or levofloxacin.

Gonorrhoea

General aspects

Gonorrhoea (meaning ‘flow of seed’) is caused by the bacterium *Neisseria gonorrhoeae*. Infection predominantly involves the urethra, endocervix, rectum, pharynx and conjunctivae. Transmission is by genital–genital, genital–anorectal, oro–genital or oro–anal contact, or by mother-to-child transmission at birth. Gonorrhoea is less common than most other SSIs but is about 15 times more common than syphilis. The highest incidence of gonorrhoea is in young adults with a disproportionate prevalence in ethnic minority groups and MSM.

Clinical features

Gonorrhoea in all sites is often asymptomatic, a fact that increases the chances of transmission. Rectal and pharyngeal infections in either gender are mostly asymptomatic. Some 50% genital tract infections in women (up to 10% in men) are asymptomatic. In males, acute urethritis is the main symptomatic presentation, with urethral discharge and dysuria; in females, endocervical and urethral infection causes increased or altered vaginal discharge, intermenstrual bleeding, dysuria and menorrhagia. In neonates of infected women, gonorrhoea can cause blindness.

An important complication of genital gonorrhoea is urethral stenosis. Infection can ascend the genital tract to cause PID and epididymo-orchitis or disseminate in bacteraemia.

General management

The diagnosis of gonorrhoea is established by identification of *N. gonorrhoeae* in secretions. Microscopy using Gram or methylene blue staining has high sensitivity and specificity where there is discharge but poor sensitivity in asymptomatic men and in the identification of endocervical or rectal infection. Culture allows confirmatory identification and antimicrobial susceptibility testing. NAATs are generally more sensitive than culture and can be used on urine, vaginal swabs, and swabs from the endocervix and urethra, and are significantly more sensitive than are cultures from pharyngeal and rectal swabs. Serological tests are uninformative. Demonstration of *N. gonorrhoeae* in a clinical specimen by detection of antigen or detection of nucleic acid via nucleic acid amplification (e.g., PCR) or hybridization with a nucleic acid probe, is most specific.

The level of tetracycline resistance in *N. gonorrhoeae* is high, so tetracyclines and penicillin are usually ineffective. Current treatment now uses single doses of:

- ceftriaxone 250 mg i.m.
- or
- cefixime 400 mg oral
- or
- spectinomycin 2 g i.m.

The fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin) cannot be used in pregnancy. Since co-infection with *Chlamydia trachomatis* is common in young heterosexuals with gonorrhoea, this should also be treated – with ceftriaxone plus doxycycline or azithromycin.

Dental aspects

Oropharyngeal infection appears uncommon, except in MSM. Fellatio is probably the main cause but normally saliva strongly inhibits *N. gonorrhoeae*. Gonococcal stomatitis may be suspected when there is severe but ill-defined inflammation or painful ulceration, red swollen tonsils with a greyish slough and regional lymphadenitis in a young adult, especially when there is a history of recent oro–genital or oro–anal contact. However, the infection can be asymptomatic and the throat may appear normal. There is no evidence that oral gonococcal infections can be transmitted to the dentist by coughing and droplet infection, or by saliva. Furthermore, dental procedures on an infected patient will not produce haematogenous spread or deep infection.

Hepatitis virus infection

See Chapter 9.

Herpesvirus infections

See Chapter 11.

HIV infection

See Chapter 20.

Human papillomavirus (HPV) infections

See Chapter 21.

Non-specific urethritis

Non-specific urethritis (NSU) is urethritis not caused by *Chlamydia* or gonorrhoea; it manifests with dysuria and stains on underwear. *Mycoplasma genitalium* or *Ureaplasma urealyticum* may be implicated. Diagnosis is from a smear showing numerous polymorphonuclear leukocytes. Treatment is doxycycline or azithromycin. Frequently, no cause for cervicitis is found and it is then referred to as 'non-specific'. Fewer than half are infected with *Chlamydia*; others have gonorrhoea, and a few have other bacterial or herpes simplex virus infections.

Pelvic inflammatory disease

Pelvic inflammatory disease (PID) refers to infection of the uterus, fallopian tubes and other reproductive organs. It is a serious complication of some SSIs, especially chlamydia and gonorrhoea. Sexually active women in their childbearing years are most at risk. The more sex partners a woman or her partners have, the greater her risk of developing PID. A prior episode of PID increases the risk of another episode. Women who have an IUD may be at slightly increased risk.

Clinical features

Features of PID vary from mild to severe and include fever, vaginal discharge, painful intercourse, painful urination, irregular menstrual bleeding and pain in the right upper abdomen. PID can lead to infertility (in 10%), ectopic pregnancy, abscess formation and chronic pelvic pain.

General management

Pelvic ultrasound is helpful to see whether the fallopian tubes are enlarged or an abscess is present. In some cases, a laparoscopy may be necessary to confirm the diagnosis.

PID is usually treated with at least two broad-spectrum antibiotics, and sex partner(s) should also be treated to decrease the risk of re-infection, even if the partner(s) is symptomless.

Syphilis

Syphilis is an SSI caused by *Treponema pallidum*, a bacterium that may damage cardiovascular and nervous systems, and can also be fatal. The incidence of syphilis, though low, is currently rising and over 80% of cases are in MSM. More than 60% of reported primary and secondary syphilis cases are among MSM, and 20–70% have HIV. In HIV, syphilis can be atypical and severe (lues maligna).

Syphilis is transmitted from person to person by direct contact with syphilis lesions via vaginal, anal or oral sexual contact. Infected pregnant women can pass it to their fetus. The average time between infection with syphilis and appearance of the first symptom is 21 days, but this can range from 10 to 90 days.

Other treponemal infections (*non-venereal* [endemic] treponematoses) can be acquired where poverty, overcrowding and unhygienic practices facilitate infection transmission (Appendix 32.1).

Primary syphilis

Over 80% of syphilis cases are in MSM. The incubation is about 3 weeks (range 10–90 days).

Clinical features

T. pallidum causes a chancre (primary or Hunterian chancre), which begins as a small, firm, pink and typically single macule (usually on the glans penis or vulva). This changes to a papule and then ulcerates to form a painless round ulcer with a raised margin and indurated base. Primary chancres occasionally involve the lips or tongue. Untreated chancres heal in 3–8 weeks, but are highly infectious and are associated with enlarged painless regional lymph nodes.

If the infected person does not receive adequate treatment, the infection progresses to the secondary stage.

Management of primary syphilis

Diagnosis is by microscopy of lesional exudate and serology. In oral lesions, the diagnosis can be confused by oral commensal treponemes, so specific fluoresceinated antibodies should be used or lesions should be thoroughly swabbed with sterile gauze or cotton wool to remove as many contaminating bacteria as possible, then gently but thoroughly scraped with an instrument such as a sterile plastic spatula. The scraping is then transferred to a slide and examined as quickly as possible by dark-ground microscopy. If the lesion is a chancre, many large but slender, regular, helical forms with a leisurely rotational movement across the field are seen. A negative test does not rule out syphilis. Biopsy may be suggestive, and diagnostic if specific antibodies are used. Demonstration of *T. pallidum* in clinical specimens by polymerase chain reaction (PCR) or equivalent direct molecular methods is specific.

Serology is required but often negative at this stage. *Non-specific (reaginic) serological tests*, useful for screening such, include the Venereal Disease Research Laboratory (VDRL) test, rapid plasma reagin (RPR) card test, automated reagin test (ART) and toluidine red-treated serum test (TRUST). Treponemal EIAs are an appropriate alternative but another treponemal assay, such as the *T. pallidum* haemagglutination test (TPHA), should be used for confirmation. The VDRL test appears positive towards the end of primary syphilis and usually becomes negative 1–2 years after treatment; but it remains positive in untreated secondary or tertiary syphilis. False-positive VDRL results may be seen after immunizations, in autoimmune disease and in some other infections (treponematoses, HIV, viral pneumonia, tuberculosis, malaria or leptospirosis). *Specific serological tests*, such as the fluorescent treponemal antibody absorbed (FTA-Abs) test, TPHA and the treponemal immobilization (TPI) test, overcome the problem of false-positive VDRL results but cannot differentiate syphilis from other treponematoses. The FTA-Abs is probably best reserved for specimens giving discrepant results. Specific tests become positive during primary disease and remain positive through untreated secondary or tertiary syphilis but, in contrast to VDRL, remain positive even in treated syphilis.

Primary syphilis is treated with procaine penicillin, doxycycline or erythromycin. Patients must be followed up clinically and serologically for 2 years and contacts traced.

Fig. 32.3 Rash of secondary syphilis. This SSI has increased enormously in many countries.

Secondary syphilis

Secondary syphilis follows the primary stage after 6–8 weeks.

Clinical features

Syphilis is the great mimic. Skin rashes (Fig. 32.3) and/or sores in the mouth, vagina or anus mark this stage. Features may often be non-specific, with malaise, weight loss, fever, headache, rash (symmetrically distributed, coppery maculopapules on the palms and soles, characteristically), patchy hair loss and generalized painless lymph node enlargement with unusual enlargement of epitrochlear nodes. Large, raised, grey or white lesions (condylomas) may develop in warm, moist areas such as the mouth, axilla or groin. Oral lesions are seen in only about one-third of patients and include painless ulcers (mucous patches and snailtrack ulcers), split papules and condyloma lata. The mucosal lesions are highly infectious.

The features of secondary syphilis resolve with or without treatment. Without treatment, syphilis will progress to the latent and possibly late stages.

Management of secondary syphilis

Mucosal lesions should be examined for *T. pallidum* as above and blood should be taken for serological examination. Treatment is as for primary syphilis (see below for the Jarisch–Herxheimer reaction).

Late and latent stages

The latent (hidden) stage of syphilis begins when primary and secondary symptoms disappear and can last years; although the person remains infected, they exhibit no signs or symptoms.

Tertiary syphilis

About 15% of people not treated develop late-stage syphilis, up to 10–30 years after infection.

Clinical features

Features include difficulty coordinating muscle movements, paralysis, numbness, gradual blindness and dementia. Syphilis damages the brain, nerves, eyes, heart, blood vessels, liver, bones and joints, and can result in death. The main feature is a localized non-infectious granuloma (termed a gumma), varying in size from a pinhead to several centimetres, which breaks down to form a deep punched-out ulcer. Skin gummas heal with depressed shiny scars (tissue-paper scars). Bone gummas may affect the long bones (especially the tibia – ‘sabre tibia’) or

skull, producing lytic lesions and periostitis with new bone formation. Mucosal gummas may destroy bone, particularly the palate, or involve the tongue. The other main oral manifestation is leukoplakia, particularly of the tongue dorsum, with a high potential for malignant change.

Cardiovascular syphilis (aortitis, coronary arterial stenosis or aortic aneurysms) affects about 10% of patients as a late complication.

Neurosyphilis, sometimes with sensorineural deafness, also affects about 10%. *Meningovascular neurosyphilis* has highly variable early symptoms but late effects may be hydrocephalus or lesions of the second, third and eighth cranial nerves, and the pupils are also unequal and unresponsive to light (Argyll Robertson pupils). *Paretic neurosyphilis* begins insidiously with subtle mental disturbance, going on to severe personality changes, complete dementia and widespread paralyses (general paresis of the insane; GPI). *Tabes dorsalis (locomotor ataxia)* is characterized by atrophy of lumbar posterior nerve roots and sometimes the optic nerves, and characterized by sudden attacks of lightning-like pain and paraesthesiae of leg or trunk, with loss of normal pain sensation and of deep proprioceptive reflexes. These latter cause a tabetic gait in which the feet are slapped on the ground as a result of loss of sense of their position, and the neuropathic joints then become disorganized (Charcot joints). Neurosyphilis is a rare cause of atypical trigeminal neuralgia.

Management of tertiary syphilis

The patients are serologically reactive and diagnosis is confirmed by serology. Treatment is procaine penicillin, 600 000 units daily for 3 weeks, and lifelong follow-up. Systemic corticosteroids are given at the start of antibiotic therapy to reduce the possibility of a Jarisch–Herxheimer reaction (febrile reaction often with exacerbation of the local syphilitic lesions).

Syphilis associated with HIV infection may take an atypical accelerated course with rapid progress to the tertiary stage; gummas may develop while the secondary stage is still active (lues maligna). The antibody response is atypical and unpredictable. Relapse is common, despite treatment, or the response to penicillin may be poor.

Congenital syphilis

A pregnant woman with syphilis can, after the fifth month, pass the infection to her fetus, with resultant low birth weight, premature delivery or stillbirth. An infected baby may be born without features of disease but, if not treated immediately, may develop serious problems within a few weeks (such as cataracts, deafness or seizures) and can die. Syphilis in the fetus may cause learning disability, deafness and blindness, and typically results in frontal bossing, a saddle nose and Hutchinson’s teeth – screwdriver-shaped incisors. A classic mucocutaneous sign is depressed linear scars radiating from the orifice of the mouth; these are termed rhagades (parrot lines). Affected children are highly infectious until about 2 years of age. To protect their babies, pregnant women at risk should be tested for syphilis regularly during the pregnancy and at delivery; if positive, they should receive immediate treatment, usually with penicillin.

Trichomoniasis

General aspects

The parasite *Trichomonas vaginalis* causes trichomoniasis (TV) – a common SSI. Women can acquire the disease from infected sex partners, but men usually contract it only from infected women. The vagina is the most common site of infection in women, and the urethra is the most common site of infection in men. Transmission is via

penis-to-vagina intercourse or vulva-to-vulva contact. Rarely, it is caught by sharing towels or washcloths with an infected person.

Clinical features

Symptoms are more common in women. TV usually causes an odiferous vaginal discharge, with vulval pruritus and erythema. In males, TV is usually symptomless but may cause dysuria.

General management

Metronidazole and tinidazole are usually effective.

SSIs SEEN MAINLY IN PEOPLE FROM THE DEVELOPING WORLD

Chancroid

Chancroid, caused by the Gram-negative bacterial rod, *Haemophilus ducreyi*, is a frequent cause of genital ulcers in developing countries but is uncommon in industrialized nations.

Clinical features

After an incubation of 2–10 days, a papule or pustule erupts and erodes to form a painful deep ulcer with ragged margins. More than one-half of patients have multiple ulcers. Painful regional lymphadenopathy is common.

General management

Azithromycin, ceftriaxone, erythromycin or ciprofloxacin is used.

Granuloma inguinale (donovanosis)

Calymmatobacterium granulomatis, a Gram-negative bacillus seen in people from the Americas, Far East and Africa, causes this chronic, ulcerative, granulomatous disease.

Clinical features

After an incubation of 1–4 weeks, a papule or nodule appears, usually in the inguinal or anogenital region, and progresses to a locally destructive granulomatous lesion. Three main types of donovanosis have been described: ulcerative, exuberant and cicatricial.

General management

Direct examination of a piece of granulation tissue compressed between two slides and stained by Giemsa for the presence of Donovan bodies (clusters of bacilli lying within leukocytes) is the best diagnostic method.

Tetracycline, ampicillin or trimethoprim–sulfamethoxazole is the first-line therapy.

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV) or lymphogranuloma inguinale, caused by *Chlamydia trachomatis*, is seen worldwide but is particularly common in Latin America, India, Indonesia and Africa.

Table 32.5 Possible complications from body art

Procedure	Complications
Dental grillz	Can impair oral hygiene, cause tooth movement or surface loss
Piercings	Pain, oedema, haemorrhage, infection <i>Staphylococcus aureus</i> infections, osteomyelitis, toxic shock syndrome and endocarditis, <i>Pseudomonas aeruginosa</i> infection and HIV transmission, Ludwig angina, bleeding into the pharynx and airways, and acute hypotension Oral piercings can impair speech and mastication, cause mucosal or gingival trauma, chipped or fractured teeth, hypersalivation, calculus accumulation, and foreign body granulomas or allergies
Tattooing	Pain, oedema, haemorrhage, infection <i>Staphylococcus aureus</i> infections, and transmission of hepatitis B and C viruses, and HIV Foreign body granulomas or allergies, or scarring
Tongue-splitting	Pain, oedema, haemorrhage, infection

Clinical features

LGV primarily affects the external genitalia, inguinal lymph nodes and lymphatics. About 10 days after exposure, a small vesicle appears, which ruptures and heals without scarring. About 1 week to 2 months later, there may be swelling and tenderness of the regional lymph nodes and suppuration. Healing involves scarring, which blocks lymphatic channels and causes oedema (elephantiasis).

General management

Diagnosis is by isolation of *C. trachomatis* and serological tests. A non-specific skin test (Frei test) is available. LGV is treated with sulphonamides, tetracycline, erythromycin or rifampicin.

BODY ART

Tattooing and more invasive procedures, with distortion or mutilation of body parts, have been commonplace in many cultures for centuries and often have sexual connotations. For example, facial scarification and female circumcision are common in some African cultures. In some East African groups, the uvula is removed in children in the belief that health will be improved. In some Amazonian tribes and in the Surma tribe of Ethiopia, large plates are worn in the lower lip.

In the developed world, the expression of individualism through body art such as tattooing and body piercing, and the wearing of jewellery in ‘unconventional’ sites is popular. Oral piercings, tongue splitting and ‘dental grillz’ (also termed bling, tooth jewellery, grillz or fronts) are increasingly seen. Grillz are generally removable and made from metal (silver, gold or platinum), some being encrusted with expensive precious stones and jewels.

Complications possible from body art are shown in Table 32.5.

APPENDIX 32.1 NON-VENEREAL TREPONEMATOSES (ENDEMIC TREPONEMATOSES)

Aetiology/epidemiology	Clinical features	Management
<i>Bejel (endemic syphilis)</i> Caused by <i>Treponema pallidum</i>; prevalent among nomads in the Arabian peninsula and sub-Saharan Africa	No obvious primary stage. Secondary and tertiary stages are encountered, mainly manifesting on skin and mucosae; mucous patches, angular stomatitis, rashes, pigmentary changes and tenderness of long bones may be seen. About one-third of patients develop lesions of the late or tertiary stage of the disease, which are mainly gummatous. Skin lesions are usually extensive, chronic and destructive, healing with scarring and depigmentation. Gummatous destruction of the nasal septum, lips, soft palate and nasopharynx may lead to facial deformity (rhinopharyngitis mutilans)	Dark-ground microscopy and serology are needed to confirm the diagnosis. Penicillin is the drug of choice; tetracycline and erythromycin are alternatives
<i>Pinta</i> Caused by <i>T. carateum</i>; almost exclusively confined to Central and South America; transmitted by either direct or indirect contact	Incubation period is usually 2–3 weeks. The primary lesion is a slowly developing subcutaneous granulomatous lesion on the trunk, leg or face, usually in young adults of 15–30 years of age. Secondary lesions (pintides) are papules that develop into plaques with scaly and centrally pigmented areas, tending eventually to become depigmented and atrophic. Hyperkeratosis of the palms and soles may be seen and facial skin is extensively affected	Dark-ground microscopy and serology are needed for the diagnosis. Penicillin is the treatment of choice
<i>Yaws (framboesia; pian; boubas)</i> Caused by <i>T. pertenue</i>; seen throughout Equatorial Africa, Asia, Central and South America, the South Pacific Islands and Australia; transmitted either by contact with the early infectious lesions or via contaminated utensils or possibly insects	Incubation period is between 9 and 90 days. The primary papular stage may be of very short duration. One to three months later, painless papillomas or framboesial granulomas appear in the axilla or groin, or around the body orifices. Skin lesions may spontaneously heal in about 3–6 months. Most patients then have a stage of latency, which may last a lifetime but in some, about 5 years after the primary infection, gummatous nodular ulcerative lesions may develop. Bone and cartilage lesions are frequently found, including osteitis, periostitis and dactylitis. In infected growing children, 'sabre tibia' may develop. Bone involvement may result in thickening of the face on either side of the nose, giving rise to a characteristic facial appearance called 'goundou'. The other type of lesion is a destructive lesion of the palate, eventually destroying parts of the nose (gangosa) and causing a 'saddle-nose' defect	Dark-field microscopy, biopsy and serology are useful. Treatment is with penicillin, erythromycin or tetracycline

SPORTS

Exercise has clear benefits to both health and quality of life (Ch. 36). However, there are occasional sudden deaths (Table 33.1) and there may be risks from trauma, such as in sports, sometimes from other issues such as travel, and occasionally from associated disordered eating, menstrual disturbances and supplement use.

TRAUMA

See also Chapter 24 and <http://www.aans.org/> (Sports-related head injury is under the Patient information/Conditions and Treatments tabs; accessed 30 September 2013).

Head, orofacial, ocular and other injuries are a risk in many sports; therefore the wearing of helmets and eye, face, jaw and mouth protection is often indicated, along with other protection.

Motion sports

Head injuries and maxillofacial and dental trauma are all too common in any sport involving fast movement, including those involving vehicles, roller-blading, skateboarding, snowboarding and skiing. Indeed, trauma is possible in all motion sports and as new types of sports become popular, the injuries associated with them also increase. Helmets are mandatory and, in some instances, protection for eyes, jaws, hands, knees, elbows and wrists is indicated.

Contact sports

Contact sports include football (soccer and rugby), boxing, martial arts (e.g. wrestling, karate and judo), gymnastics and hockey; to a degree, there is contact in some other sports such as baseball and basketball. Injuries to the teeth and orofacial soft tissues are common, particularly in football, boxing, martial arts and hockey.

Most sports injuries affect the maxillary incisors and involve young males. In soccer and rugby, players have about a 10% chance of injury per season. This may include head injury, cerebral concussion and neck injuries, which can be fatal or lead to paraplegia. Maxillofacial and dental injuries account for about 13% of the costs of all soccer injuries.

Prevention and adequate preparation are the key elements in minimizing injuries from such sports. Teaching skills such as tackling, use of appropriate equipment, safe playing areas and the wearing and utilization of properly fitted protective equipment like helmets and mouthguards are essential. A properly fitted mouthguard may also reduce the chances of sustaining a concussion from a blow to the jaw. Mouthguards are usually made of vinyl or acrylic, and three main types are available (Box 33.1).

Non-contact sports

Non-contact sports, such as tennis and volleyball, can also be dangerous. Custom-made protectors could offer the best protection against dental damage.

Box 33.1 Mouthguards

- Custom-made protectors – offer the best protection (vacuum custom-made and pressure laminated custom-made, ethylene vinyl acetate [EVA])
- Mouth-formed protectors – moulded on to the teeth ('boil and bite'); give variable protection but are useful where orthodontic appliances are worn
- Stock protectors – cheap and easily adjusted but less comfortable, protective or retentive

Water sports

Athletes who swim more than 6 hours per week in pools chemically treated to maintain safe water quality standards may develop tooth stains misnamed 'swimmer's calculus' and/or tooth erosion. The stains can usually be removed with professional cleaning.

Scuba divers depend on air in the form of compressed air from a tank, transmitted to the mouth by way of a regulator held in the mouth by the teeth, so that there is an airtight seal between the teeth and lips. Inability to hold the mouthpiece because of missing teeth poses a contraindication to scuba diving. Dental concerns in divers include temporomandibular joint (TMJ) and muscle pain from holding the regulator ('diver's mouth syndrome'), barotrauma and barodontalgia (from the effects of pressure changes), and the management of prostheses. Many divers experience TMJ and/or facial muscle pain or headache from the continuous jaw clenching. Mouthpieces are usually made of neoprene or silicone rubber and are held in place by bite tabs that fit into the dentition at the canine and premolar area. The average dive lasts 30–60 minutes and requires constant jaw muscle effort. Extending the bite tabs to cover the molar teeth balances the weight of the regulator and can relieve stress on the TMJ.

Barodontalgia (pain in the tooth caused by pressure changes) can arise in divers (or people in aircraft or at high altitude) if there are pulp lesions, abscesses or sinusitis. Antral pain may have a similar cause. Teeth that have been opened for endodontic treatment and temporarily sealed have been known to explode from air trapping and expansion on surfacing – mainly in deep divers using a helium–oxygen mixture. Full porcelain crowns can also shatter from relatively shallow dives of 65 feet. Raised pressure in the middle ear can occasionally cause facial palsy (baroparesis) but this typically resolves spontaneously over a few hours.

Divers cannot wear full or partial dental prostheses while diving, as they may be dislodged and aspirated. To eliminate the possibility of dislodgment completely, a custom mouthpiece to obviate the chance of aspiration of the prosthesis can be made. Full arch impressions are taken with the patient holding silicone putty in the roof of the mouth until it is set; they are then mounted in a hinge articulator and sent to the laboratory with the silicone putty impression.

DRUG USE IN SPORTS

Further information is available at: <http://sportsanddrugs.procon.org/> (accessed 30 September 2013).

Table 33.1 Endogenous causes of sudden death in athletes

Cardiac causes	Other causes
Anomalous origin of coronary artery	Alcohol
Aortic rupture (Marfan syndrome)	Amphetamine
Aortic stenosis	Cocaine
Coronary artery disease	Erythropoietin (EPO)
Electrical conduction system abnormalities	Head trauma
Hypertrophic cardiomyopathy	Vascular event
Long QT syndrome	
Myocarditis	
Obstructive cardiomyopathy	
Right ventricular dysplasia	

Table 33.2 Substances and methods not permitted for use by athletes^a

Prohibited at all times	Prohibited in competition	Prohibited in certain sports
S1 Anabolic agents	S6 Stimulants	Alcohol
S2 Peptide hormones, growth factors and related substances	S7 Narcotics	Beta-blockers
S3 Beta agonists	S8 Cannabinoids	
S4 Hormone and metabolic modulators	S9 Glucocorticosteroids	
S5 Diuretics and other masking agents		
M1 Manipulation of blood and blood components		
M2 Chemical and physical manipulations		
M3 Gene doping		

^aThe World Anti-Doping Agency (WADA) is responsible for maintaining and updating this list. See <http://www.wada-ama.org/en/World-Anti-Doping-Program/> (under 'International Standards/Prohibited List'; accessed 30 September 2013).

Sports people may wish to take drugs as medication for disease; to improve their performance (performance-enhancing drugs; PEDs) and, in doing so, to gain an unfair advantage; or for 'recreational' reasons. Some substances are banned only during competition, while others depend on the method of administration (e.g. inhalation versus tablet or injection form). The list of prohibited substances is updated annually to keep up with advances in science and technology, a new list being issued on 1 January. A substance is added to the list if it meets two of the three criteria listed:

- The potential for enhanced performance
- The potential for being detrimental to health
- Violation of the spirit of sport.

The International Olympic Committee permits or prohibits the use of various drugs (Table 33.2). A comprehensive list of banned substances from the World Anti-Doping Agency (WADA) is available at: <http://www.wada-ama.org/en/World-Anti-Doping-Program/> (under 'International Standards/Prohibited List'; accessed 30 September 2013).

Some drugs are banned at all times; others are permissible when not competing but not during competition; and some are banned in some sports but not others. Banned substances can include alcohol and caffeine above a certain level. Some agents are permitted for use for certain complaints (Table 33.3). In some cases, an athlete may have a pre-existing medical condition that requires them to take medication

Table 33.3 Examples of agents permitted for use by athletes for certain complaints^a

Complaints	Drugs permitted
Allergies	Astemizole, cetirizine, chlorphenamine, loratadine, terfenadine
Diarrhoea	Diphenoxylate, loperamide
Bacterial infections	Antibiotics (all)
Fungal infections	Amphotericin, fluconazole, nystatin, miconazole, terbinafine
Viral infections	Aciclovir, idoxuridine
Asthma	Cromoglicate, theophylline, fluticasone (under specific conditions), beclometasone, salbutamol, formoterol, terbutaline, salmeterol
Coughs and colds	Antihistamines, dextromethorphan, guaifenesin, pholcodine
Oral or ear, nose and throat problems	Sprays or drops containing: betamethasone, dexamethasone, docusate, hydrocortisone, beclometasone, fluticasone, tramazoline
Eye problems	Ointments or drops containing: antazoline, betamethasone, hydrocortisone, beclometasone, chloramphenicol
Hay fever	Antihistamines
Pain and inflammation	Aspirin, paracetamol (acetaminophen), non-steroidal anti-inflammatory drugs (NSAIDs), codeine, dextropropoxyphene
Nausea and vomiting	Cimetidine, cinnarizine, domperidone, metoclopramide, prochlorperazine

^aCheck with governing bodies, as regulations may vary, or apply under specific circumstances/conditions.

that is listed. In this case, the athlete can apply to their international federation for a Therapeutic Use Exemption (TUE), which must be verified by their physician. In order for their request to be accepted, the following must be true:

- The athlete would suffer significant health problems if they do not take the medication
- There is no suitable alternative that is not listed
- There are no considerable performance-enhancing benefits.

Anabolic steroids

Anabolic steroids are available legally by prescription only, for conditions in which the body produces abnormally low amounts of testosterone, such as delayed puberty and some types of impotence. They are also used to treat body wasting in, for example, patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS). Athletes (and others) may misuse anabolic (androgenic) steroids (AAS) – synthetic substances related to male sex hormones – to enhance performance (and also to improve physical appearance); these are taken orally or injected, typically in cycles of weeks or months ('cycling'), rather than continuously. There are two types of AAS:

- *Exogenous*: synthetic versions of testosterone. Common examples include nandrolone and danazol.
- *Endogenous*: naturally occurring substances involved in the metabolic pathways of testosterone. For testing of drug use, all endogenous steroids have a normal range. Results outside of this normal range are deemed positive.

Due to the enhancement of testing procedures in the detection of anabolic steroids, 'designer steroids' such as tetrahydrogestrinone (THG) have been developed. THG breaks down during the preparation

method used for normal steroid testing procedures. A test specifically for the detection of THG has since been developed.

Anabolic steroids given to adolescents may accelerate pubertal changes and cause premature skeletal maturation, halting growth. The major toxic effects include kidney and liver tumours (and jaundice), fluid retention and hypertension, increases in low-density lipoprotein (LDL) and decreases in high-density lipoprotein (HDL), severe acne, trembling, hostility and aggression, and other psychiatric effects. Gender-specific adverse effects include: for men – testicular atrophy, low sperm count, infertility, baldness, breast development and prostate cancer; and for women – facial hair growth, baldness, menstrual changes, clitoris enlargement and deepened voice. Injecting anabolic steroids is also associated with the risk of contracting or transmitting HIV or viral hepatitis.

Blood doping

Blood doping is the process of artificially increasing the amount of erythrocytes in an attempt to improve athletic performance. In the past this was accomplished by autologous transfusion, a practice now outlawed. Erythropoietin (EPO) stimulates erythrocyte production and is also illegal. It increases blood viscosity, may lead to thromboses and is one of the causes of the ‘sudden death syndrome’ seen in occasional athletes (see Table 33.1 and www.uksport.gov.uk; accessed 30 September 2013).

There are major side-effects associated with erythropoietin use, which have proven to be fatal in previous cases:

- Increased blood viscosity (which increases the risk of heart attack and stroke)
- Fever
- Seizures
- Nausea
- Headache
- Anxiety.

Human growth hormone

Human growth hormone (hGH), sometimes known as somatotrophic hormone or somatotropin, is credited with having the following effects:

- Increased muscle mass
- Decreased fat stores
- Accelerated muscle recovery

Many small studies, however, have shown no increases in muscle size or strength following injection with hGH. A common practice among body-builders and weightlifters is to combine hGH and anabolic steroids, with recent research demonstrating beneficial effects.

The side-effects of hGH are vast and some are serious:

- Gigantism (pituitary gigantism or giantism) in younger athletes (abnormally excessive growth in height, considerably above average)
- Acromegaly in adult athletes (a condition in which the pituitary gland produces too much hGH, resulting in the growth and swelling of body parts, typically hands, feet, nose but possibly progressing to brow and jaw protrusion and swelling of internal organs)
- Hypothyroidism (low production of thyroid hormone, which disrupts metabolic rate and protein production)
- Cardiomyopathy (disease of the cardiac muscle, increasing the risk of arrhythmia and sudden cardiac death)
- Cardiac failure
- Hypercholesterolaemia (presence of high levels of cholesterol in the blood)

- Ischaemic heart disease (a lack of blood to the heart, often due to coronary artery disease)
- Myopathies (neuromuscular diseases affecting the function of muscle fibres)
- Arthritis
- Diabetes
- Impotence
- Osteoporosis
- Menstrual irregularities in women
- Creutzfeldt–Jakob disease (CJD or mad cow disease; transmission is possible when hGH is obtained from cadavers).

Insulin-like growth factor

Due to its perceived anabolic effects, athletes use insulin-like growth factor (IGF)-1 to increase muscle mass and strength, although clinical studies have not proven that it does so. It is thought that it is actually IGF binding protein-3 that is responsible for growth, rather than the growth factor itself. IGF-1 does, however, inhibit cell death and so may have a role in reducing recovery times.

Side-effects of IGF include:

- acromegaly in adult athletes
- organomegaly (the abnormal enlargement of organs)
- hypoglycaemia (lower than normal levels of glucose in the blood)
- cancer (prostate, lung and colorectal cancers have all been reported).

Human chorionic gonadotrophin

hCG is mainly used by male athletes, as it increases the production of both testosterone and epitestosterone, so keeping the testosterone-to-epitestosterone ratio unchanged from normal values (vital in avoiding detection of the presence of other prohibited substances). It is also used to maintain testicular volume in males who are using anabolic steroids. However, it is now thought that it is follicle-stimulating hormone (FSH) that is responsible for maintaining testicular volume and so hCG use would be entirely ineffective; in females there would be no beneficial effect at all.

Side-effects associated with hCG use are rare and non-serious:

- Gynaecomastia (the development of abnormally large mammary glands in males due to increased levels of the oestrogen).

The combination of hCG and anabolic steroids can cause:

- headaches
- depression
- oedema (swelling caused by fluid within the body's tissues).

Other substances

Gamma hydroxybutyrate (GHB) is also used by some body-builders. Drugs such as modanafil have been used to help alertness. Other banned substances not described above include:

- adrenocorticotrophic hormone (ACTH)
- beta₂ agonists
- hormone antagonists and modulators
- diuretics
- artificial oxygen carriers
- gene doping
- amphetamines
- ephedra

- cocaine
- caffeine
- narcotics
- cannabinoids
- glucocorticosteroids.

Smokeless tobacco

Smokeless tobacco is associated with some sports in the USA, and is potentially dangerous in terms of oral keratoses and malignant change.

EATING DISORDERS IN SPORTS

Some athletes, mainly women, in cross-country, track and field, gymnastics, dancing, figure skating, volleyball and basketball, may be prone to develop eating disorders (Ch. 27). Tooth erosion may then be seen.

In endurance sports, such as long-distance running, triathlons or cycling, athletes may consume a high amount of refined carbohydrates ('carbo-load'), as well as carbohydrate gels or drinks (sports drinks – often containing carbohydrates, electrolytes, B vitamins and an acid such as citric, malic, tartaric or phosphoric).

Further information is available at: <http://www.uk sport.gov.uk/publications/eating-disorders-in-sport> (accessed 30 September 2013).

DENTAL ASPECTS IN SPORTS

Preventive dental care and prevention of caries and erosion are important. Operative care for athletes under local anaesthesia (LA) is permitted. Analgesics such as aspirin, NSAIDs and paracetamol (acetaminophen) are permitted but opioids are banned and opiate-related analgesics are problematical. Codeine is not on the WADA list of banned substances, and combinations such as co-codamol and co-proxamol appear acceptable, but as screening does not always differentiate adequately between the various narcotic or codeine-related compounds, they are best avoided.

Anxiolytics may sometimes be banned. Alcohol and beta-blockers are illegal in certain sports, and therefore alcohol-containing oral health-care products are also best avoided. Some vitamin, herbal and nutritional supplements are banned.

Antimicrobials of all types are generally permitted. Therapeutic preparations used for topical oral use are also generally permitted; for example, topical corticosteroids are permitted but systemic corticosteroids are best avoided, or a TUE is required.

TRAVEL AND LEISURE

International travel is undertaken by ever-growing numbers of people for social, recreational, professional and humanitarian purposes, and can result in a variety of health risks in unfamiliar environments that present variable levels of risk and standards of health care, as well as the transmission of infectious agents and the appearance globally of diseases hitherto confined to certain areas. Most problems can be minimized by common sense, with suitable precautions taken before, during and after travel (see UK Department of Health booklet *Health advice for travellers* [T7.1], Fig. 33.1; available at http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_4123441, accessed 30 September 2013).

The countries to be visited and the duration of the visit are important in determining the likelihood of exposure to many problems, such as violence and infectious agents, and will influence decisions on the

Fig. 33.1 *Health advice for travellers* – a sensible read.

need for protection and certain vaccinations or antimalarial or other medication. The behaviour of the traveller is also important: exposure to the risk of assault or accidents, or to insects, rodents or other animals, infectious agents and contaminated food and water, is often a lifestyle choice. A business trip to a city in the high-income world, for instance, typically involves far fewer risks than a visit to remote rural areas in the tropics. For example, going outdoors in the evenings in a malaria-endemic area without using precautions, such as wearing protective clothing, applying repellents and taking antimalarials, is highly risky. The duration of the visit may also determine whether the traveller may be subjected to wide changes in temperature and humidity, or to other environmental factors.

Travellers are far more likely to be killed or injured in accidents or through violence than to be struck down by an exotic infectious disease. Assaults are common in some areas and lone travellers are particularly vulnerable. Accidents and injuries are common at mass gatherings (where in addition, infections can spread) in mountain sports and other outdoor adventures. Accidents, injuries and infections are also possible in recreational waters in association with swimming, diving, sailing and other activities.

HIGH ALTITUDES

At high altitude, atmospheric pressure is lowered and the fall in oxygen pressure can lead to hypoxia, as discussed below. At 1500–3500m, exercise tolerance is impaired and ventilation is stimulated. At 3500–5500m, there is hypoxia and altitude sickness is possible.

Rapid ascent may lead to acute hypoxia; the affected person becomes faint and may lose consciousness. Acute mountain sickness may develop after 1–6 hours at high altitudes; headache is followed by anorexia, nausea and vomiting, insomnia, fatigue, lassitude and irritability. The outcome is sometimes fatal due to the development of pulmonary and cerebral oedema.

Travellers making a rapid ascent to high altitude (over 3000m) can consider prophylactic medication (acetazolamide). Those planning to climb or trek at high altitude benefit from a period of gradual adaptation.

FLYING

Flight phobia (fear of flying) is common, particularly since 11 September 2001. There also appears to be an increase in the use of alcohol on flights, with air rage – a form of disruptive behaviour – linked to high levels of stress and frequently precipitated by alcohol.

Dehydration is common. Cabin humidity is low, usually less than 20%, and may cause discomfort of the eyes, mouth and nose, especially in Sjögren syndrome. Fluid should be taken to prevent dehydration – non-alcoholic beverages (water and fruit juices) rather than alcohol, which contributes to dehydration.

Deep vein thrombosis (DVT; Ch. 8) can develop from prolonged immobility leading to pooling of blood, which is probably aggravated by dehydration. Most DVTs are in the calves and cause no symptoms; some cause swelling, stiffness and discomfort. They are usually reabsorbed but, occasionally, pulmonary embolism may follow, with serious consequences including chest pain, dyspnoea and even death, sometimes many hours or days later. Exercise and properly fitted, graduated compression stockings specially designed for air travel may be helpful. Aspirin is often advised prophylactically for its antiplatelet activity for long-distance flights, along with ample fluids and exercise in-flight.

Jet lag – the disruption of sleep patterns and other circadian rhythms (the body's internal clock) caused by crossing multiple time zones in a short period of time – is commonplace. The adverse effects of jet lag may lead to indigestion, general malaise, insomnia, and reduced physical and mental performance. Melatonin may help resynchronize the body's internal clock.

Hypoxia may be experienced because cabin air pressure is relatively low; the blood oxygen saturation is therefore slightly reduced, leading to mild hypoxia. Travellers with pre-existing cardiovascular or pulmonary disease or anaemia (especially sickle cell disease) are highly sensitive to hypoxia, which can be dangerous and even life-threatening.

In people with *ear, nose and sinus or dental infections, or after recent surgery* or injury, there may be pain if air or gas trapped in air-filled body cavities expands. This occurs especially after abdominal trauma and gastrointestinal surgery, craniofacial and ocular injuries, brain operations, and eye operations involving penetration of the eyeball.

Dental issues include head and facial barotraumas (barotrauma-related headache, external otitic barotrauma, barosinusitis and barotitis media), dental barotrauma (barometric pressure-related tooth injury) and barodontalgia (barometric pressure-related oro-dental pain). Special considerations may be required when planning restorative, endodontic, prosthodontic and surgical treatment to aircrew. Prevention is crucial, as is periodic examination, good restorative dentistry and flight restriction (grounding) if there are pulpal issues. Dental documentation is important for forensic purposes.

Infections can occasionally be transmitted in aircraft, as in any confined space, and even influenza and tuberculosis have been transmitted between passengers on long-haul flights. Modern aircraft recirculate up to 50% of cabin air by passing it through high-efficiency particulate air (HEPA) filters, which clean recirculated cabin air, but incompletely. Viruses in particular can be recirculated. Passengers may occasionally also be infected by *insects* in the aircraft and there have been outbreaks of malaria in the vicinity of airports, due to the escape of transported mosquitoes ('airport malaria').

Contraindications to air travel are shown in [Box 33.2](#).

Box 33.2 Contraindications for air travel

- Infants under 7 days old
- Women in the last 4 weeks of pregnancy (8 weeks for multiple pregnancies) and until 7 days after delivery
- People with serious medical/surgical conditions:
 - Angina pectoris, recent myocardial infarction or stroke
 - Acute contagious disease
 - Decompression sickness after diving
 - Raised intracranial pressure
 - Recent surgery or injury where trapped air or gas may be present
 - Chronic respiratory disease, breathlessness at rest or unresolved pneumothorax
 - Sickle cell disease
 - Uncontrolled hypertension of more than 200mmHg (27kPa) systolic pressure
 - Recent psychiatric illness.

HOT OR HUMID CLIMATES

Exposure to hot, dry, dusty air may cause irritation and infection of the eyes and respiratory tract, and may lead to heat exhaustion and heat stroke. Dehydration is particularly likely unless care is taken to maintain adequate fluid intake. Consumption of salt-containing food and drink helps to replenish the electrolytes in case of heat exhaustion and after excessive sweating.

Fungal skin infections (e.g. tinea) can be aggravated by heat and humidity, and taking a daily shower, wearing loose cotton clothing and applying talcum powder to sensitive skin areas help control their development or spread. Many other infections are also more prevalent in such climes (Appendix 21.9 and Ch. 21).

SUN EXPOSURE

Ultraviolet (UV) radiation from the sun includes both UVA (wavelength 315–400nm) and UVB (280–315nm) radiation. Radiation may penetrate clear water to a depth of 1m or more. UVB radiation is particularly intense in summer and in the 4-hour period around solar noon. Both forms of UV radiation are damaging to skin and eyes. Adverse acute effects include sunburn, particularly in light-skinned people, acute keratitis ('snow blindness') and actinic cheilitis (solar keratosis). Long-term adverse effects can include accelerated skin ageing, skin cancers (melanoma, basal cell carcinoma and squamous carcinoma), lip cancer (squamous carcinoma), cataracts, photosensitization (to drugs such as oral contraceptives, antimalarials and antimicrobials, and to perfumes containing oil of bergamot or other citrus oils) and immune suppression, increasing the risk of infectious disease and limiting the efficacy of vaccinations.

INFECTIONS PREVALENT IN THE DEVELOPING WORLD

See Appendix 21.9, and also Chapters 21 and 32.

Some infections are acquired mainly in the tropics but can appear elsewhere, particularly in areas bordering the tropics and subtropics, war zones or places where there are other disasters that lead to poor water and food hygiene, and the proliferation of rodents and other pests. Such infections are increasingly found and imported into high-income countries (e.g. airport malaria, severe acute respiratory syndrome [SARS], bird flu and swine flu) with global warming and the spread of vectors, and with increasing global travel and migration.

Box 33.3 Main infective hazards associated with travel to developing countries

- Cholera
- Dengue fever
- Dysentery
- Hepatitis viruses (particularly A)
- HIV and other sexually shared infections
- Infective (travellers') diarrhoea (the most common hazard)
- Malaria (the most important hazard) – a significant health risk in the developing world, especially West Africa; in severe falciparum malaria, mortality is ~30% despite appropriate treatment
- Rabies
- Respiratory viruses
- Tuberculosis
- Yellow fever

The main infective hazards are shown in Box 33.3 but there are many others. Some are potentially lethal, such as dengue fever, which is mosquito-transmitted. Ebola fever, Lassa fever and Marburg disease are highly contagious from human–human contact and are lethal.

BLOOD-BORNE INFECTIONS

Hepatitis B and C, HIV and other agents can be transmitted by direct contact with infected blood or other body fluids, especially by inoculation.

SEXUALLY SHARED INFECTIONS

See Chapter 32.

FOOD-BORNE AND WATER-BORNE HEALTH RISKS

More information on food safety and the prevention of food- and water-borne diseases can be found at: <http://www.cdc.gov/food-safety/diseases/> and <http://www.nathnac.org/pro/factsheets/food.htm> (accessed 30 September 2013).

Food spoilage

Spoilage bacteria cause food to deteriorate and develop unpleasant odours, tastes and textures, but rarely cause food poisoning. There are different spoilage bacteria and each reproduces at specific temperatures: some at low temperatures in refrigerators or freezers, others at room temperature, and most where they have access to nutrients and water. Some of the conditions that accelerate spoilage also encourage growth of pathogenic microorganisms. Food-borne infections are seen worldwide, especially from shellfish, poultry and milk.

Food poisoning

A range of microorganisms can enter the body in food in any country if the food is inadequately cooked, or on the food – for example, if the person preparing the food fails to wash their hands before handling it. *Campylobacter* infection in milk and poultry is the most common cause of food poisoning but other common causes include *Salmonella*, *Listeria*, *Shigella* and *Clostridia*. *Escherichia coli* infections can be serious but are uncommon (Ch. 21). Some infections take a few hours to cause symptoms, others a few days. Contaminated food may also

spread a wide range of other infections or infestations, occasionally even worms, such as cysticercosis and echinococcosis (Ch. 21).

Travellers' diarrhoea

Infections transmitted by ingesting contaminated food and water include 'travellers' diarrhoea' (caused by a wide range of viruses and bacteria); this may affect up to 80% of travellers to high-risk destinations. This is essentially food poisoning, and *E. coli* bacteria are the most common culprit.

Most diarrhoeal attacks are self-limiting, with recovery in a few days. It is important, especially for children, to avoid becoming dehydrated, so fluids (e.g. bottled, boiled or treated water, or weak tea) should be taken. If diarrhoea continues for more than 1 day, oral rehydration salt (ORS) solution should be taken. Antidiarrhoeal medicines (e.g. loperamide) are not generally recommended but may be used exceptionally. If the stools contain blood, medical help should be obtained or a course of antibiotics may be taken (for children and pregnant women, azithromycin; for other adults, ciprofloxacin).

Norovirus

Noroviruses are a group of viruses that cause gastroenteritis and an acute onset of pain, nausea, and severe vomiting and diarrhoea. Norovirus illness is usually brief in people who are otherwise healthy but can be serious, especially in young children, the elderly, and people with other medical illnesses, who are most at risk for more severe or prolonged infection.

Norovirus can be found early on in the faeces and for 2 or more weeks after recovery. Being infected with one type of norovirus may not protect against other types. Norovirus is a highly contagious virus transmitted from an infected person, contaminated food or water, or contact with contaminated surfaces. Norovirus infection is preventable by proper hand-washing and general cleanliness. It can spread quickly in closed places like restaurants, daycare centres, nursing homes, schools and cruise ships.

Foods implicated include

- leafy greens (such as lettuce)
- fresh fruits
- shellfish (such as oysters).

Recreational water illnesses

Chlorine is used to decontaminate recreational water but does not kill all microorganisms instantly; some are very tolerant to chlorine and were not known to cause human disease until recently. Recreational water illnesses (RWIs) are increasing, and include gastrointestinal, skin, ear, respiratory, eye, neurological and wound infections. RWIs are spread by swallowing, breathing in mists or aerosols of, or contact with contaminated water in swimming pools, hot tubs, water parks, water play areas, interactive fountains, lakes, rivers or oceans. RWIs can also be caused by chemicals in the water or chemicals that evaporate from the water and cause indoor air quality problems.

Legionellosis is sometimes an RWI. The most common ones, however, are cryptosporidiosis (diarrhoea caused by *Cryptosporidium*) and *Giardia*, *Shigella*, norovirus and *E. coli* O157:H7. The most common causes of gastroenteritis are certain viruses. In children rotavirus is frequently found to be the culprit, but in adults norovirus is more common. All such organisms are contagious, being transmitted by the faeco-oral route and also by vomiting. Rotavirus is the leading

cause of severe diarrhoea in infants and young children worldwide. Rotavirus causes severe watery diarrhoea, often with vomiting, fever and abdominal pain; in babies and young children, it can lead to dehydration.

Contamination of spas and whirlpools can lead to infection by *Legionella*, *Pseudomonas aeruginosa* and non-tuberculous mycobacteria. Otitis externa and infections of the urinary tract, respiratory tract, wounds and cornea have also been linked to spas.

Swimming or paddling in water in the developing world may lead to schistosomiasis or other infections such as leptospirosis. Other hazards may include cholera, cryptosporidiosis, giardiasis, hepatitis A and E, legionellosis, leptospirosis, listeriosis and typhoid fever. Direct person-to-person contact or physical contact with contaminated surfaces in the vicinity of swimming pools and spas anywhere may spread the viruses that cause molluscum contagiosum and warts (human papillomaviruses), and fungal infections of the hair, fingernails and skin, especially tinea pedis (athlete's foot).

Other issues

See Chapter 21 for other infections.

Illness can also be caused by biological toxins found in seafood, which may be paralytic, neurotoxic or amnesic (e.g. shellfish; ciguatera toxin; scombroid or puffer fish). 'Red tides' are harmful algal blooms in water that result in the production of potentially lethal neurotoxic brevetoxins, mainly domoic acid and saxitoxins. Brevetoxins cause neurotoxic shellfish poisoning (NSP); domoic acid is a neurotoxin that causes amnesic shellfish poisoning (ASP); and saxitoxin causes paralytic shellfish poisoning (PSP).

DISEASES TRANSMITTED FROM SOIL

Soil-transmitted diseases include those caused by spores, such as anthrax, tetanus and deep mycoses. Some intestinal parasites, such as ascariasis and trichuriasis, are transmitted via soil and infections may result from consumption of soil-contaminated vegetables.

ZOONOSES (DISEASES TRANSMITTED FROM ANIMALS)

A zoonosis is an infection seen in wild or domestic animals that can be transmitted to humans. Infections can be caused by bacteria, viruses, fungi, prions or parasites, which include protozoa and helminths. A partial list of animals that can carry infectious organisms that may be zoonotic is shown in Box 33.4. Rats can, for example, transmit rat-bite fever – infection by bacteria (*Streptobacillus moniliformis* [Haverhill fever] or *Spirillum minus* [sodoku]) – and a wide range of other diseases ranging from typhus to leptospirosis.

Zoonoses include a wide range of infections (such as malaria, dengue fever, Chagas disease, rabies, brucellosis, leptospirosis and certain viral haemorrhagic fevers), which can be transmitted to humans through animal bites or from parasites such as fleas or ticks; via contact with contaminated body fluids or faeces from animals; or by consumption of foods of animal origin, particularly meat and milk products. A partial list of important zoonoses is shown in Box 33.5.

Glanders and SARS (possibly, civet cats may spread the disease, or may catch the disease from humans) might also be zoonoses.

The risk of infection can be reduced by avoiding close contact with any insects or animals – including wild, captive and domestic animals – in places where infection is likely to be present. Pets are no exception and, apart from the dangers from bites (Ch. 24), various infections can

Box 33.4 Main animals apart from humans that can transmit zoonoses

- Bats
- Birds
- Cats
- Cattle
- Chickens
- Chimpanzees
- Dogs
- Ducks
- Fish
- Fleas
- Geese
- Goats
- Hamsters
- Horses
- Insects
- Monkeys
- Opossums
- Pigs
- Rabbits and hares
- Raccoons
- Rats
- Rodents
- Sheep
- Sloths
- Snails

be contracted. Particular care should be taken to prevent children from approaching and handling any animals.

INFESTATIONS

See also Chapter 21.

Fleas

General aspects and clinical features

Fleas are parasites of humans and other animals, and are transmitted to those in close proximity. They live mainly on the hairy parts of the body, depositing eggs that can cause an itchy rash. Rodent fleas in particular can act as vectors of life-threatening infections, such as typhus (*Rickettsia prowazekii*; Ch. 21) and plague (*Yersinia pestis*), and have been responsible for recent outbreaks of plague in India and other areas.

General management

Improved hygiene and malathion are indicated.

Lice

General aspects and clinical features

Lice infestations, which are increasing in many areas, especially in vagrants, can be of three main types:

- Head lice (*Pediculus humanus* var. *capitis*) infest hair and are particularly common in schoolchildren.
- *Pediculus corporis* infests the body and clothes.

Box 33.5 Zoonoses

- Anthrax
- Avian influenza (bird flu)
- Bolivian haemorrhagic fever
- Borreliosis (Lyme disease and others)
- Borna virus infection
- Bovine tuberculosis
- Brucellosis
- Campylobacteriosis
- Chagas disease
- Creutzfeldt–Jakob disease (variant CJD)
- Crimean–Congo haemorrhagic fever
- Cryptosporidiosis
- Cutaneous larva migrans
- Dengue fever
- Ebola virus infection
- Echinococcosis
- Hantavirus infection
- Hendra virus infection
- Henipavirus infection
- Korean haemorrhagic fever
- Lábrea fever
- Lassa fever
- Leishmaniasis
- Leptospirosis
- Listeriosis
- Lyme disease
- Lymphocytic choriomeningitis virus
- Malaria
- Marburg virus infection
- Monkey B virus
- Nipah virus
- Ocular larva migrans
- Orf
- Ornithosis (psittacosis)
- Oropouche fever
- Plague
- Psittacosis ('parrot fever')
- Q fever
- Rabies
- Rift Valley fever
- Ringworms (*Tinea canis*, mainly)
- Salmonellosis
- Sodoku
- Swine flu
- Toxoplasmosis
- Trichinosis
- Tuberculosis (badgers, cows, elephants)
- Tularaemia ('rabbit fever')
- Typhus and other rickettsial diseases
- Venezuelan haemorrhagic fever
- Visceral larva migrans
- Yellow fever

- *Phthirus pubis* (crab lice) infests the pubic hair area and is sexually transmitted.

Lice are transmitted by close contact or via discarded clothing and feed off the host's blood; the puncture wounds can become itchy and bleed. Lice can also, under appropriate circumstances,

transmit diseases such as typhus (*Rickettsia prowazekii*), relapsing fever (*Borrelia recurrentis*) and trench fever (*R. quintana*; Ch. 21).

General management

Treatment of lice infestation is with improved hygiene and the use of malathion and carbaryl.

Bedbugs

Bedbugs (*Cimex lectularius*) are small insects that live in cracks and crevices around some beds. Attracted by body heat and carbon dioxide, they bite exposed skin and feed on blood. There has been an explosion in bedbug infestations around the world, particularly in America. Increasing tourism and a growing resistance to insecticides are to blame. Bedbugs feed on blood to mature, but they are resilient and can survive for up to a year without feeding. They can also be found in other furniture, carpets and elsewhere, and spread easily from room to room, not by flying or jumping but by crawling. They can soon invade blocks of flats, hotels, hospitals or other buildings. The bugs can be transported in luggage, clothing, furniture and bedding. Bedbugs do not transmit human diseases. Skin reactions to bedbug bites are typically pruritic red bites, often in straight lines; they appear after 1–9 days, usually on the face, neck, hands or arms.

Treatment is to:

- wash infected materials at 60° or clean in a dryer on a hot setting for 30 minutes to kill the bugs
- dismantle bed and furniture and inspect every seam, crevice and joint
- vacuum to remove any bugs
- use insecticide spray specially designed for bedbugs; ordinary insect repellent for mosquitoes and ticks does not seem to be effective
- throw away a mattress if it appears to be heavily infested.

Ticks**General aspects and clinical features**

Ticks are parasitic on various animals (Table 33.4) and have the following characteristics:

- They are arachnids, relatives of spiders.
- They live in wooded areas mainly.
- They survive by eating host blood.
- They can transmit infections from one host to the next, including humans.

Diseases that can be transmitted to humans include the following:

- 364D rickettsiosis (*Rickettsia phillipi*) is transmitted to humans by the US Pacific Coast tick (*Dermacentor occidentalis*).
- Anaplasmosis is transmitted to humans by the black-legged tick (*Ixodes scapularis*) in the north-eastern and upper mid-western USA, and by the western black-legged tick (*Ixodes pacificus*) along the Pacific coast.
- Babesiosis is caused by parasites that infect erythrocytes. In most cases, *Babesia microti* is transmitted by the black-legged tick (*I. scapularis*) and is found primarily in the north-east and upper mid-western USA.
- Crimean–Congo haemorrhagic fever is found in Eastern Europe, particularly in the former Soviet Union, and in north-western

Table 33.4 Tick-borne diseases of humans

Human disease	Microorganism	Main tick implicated	Main host	Clinical features	Treatment: remove tick and use
Babesiosis	<i>Babesia microti</i>	<i>Ixodes scapularis</i>	Mice	Malaria-like illness. Fatal in elderly or asplenia	Quinine Clindamycin Atovaquone Azithromycin Tetracycline
Colorado tick fever	Coltivirus	<i>Dermacentor andersoni</i> or <i>D. variabilis</i>	Deer Dog	Acute high fever	Doxycycline
Human monocyte ehrlichiosis	<i>Ehrlichia chaffeensis</i>	<i>Amblyomma americanum</i>	Deer	Fever, myalgia, leukopenia, malaise, nausea	Doxycycline
Human granulocyte ehrlichiosis	<i>Anaplasma phagocytophila</i>	<i>I. scapularis</i>	Deer Mice	Fever, myalgia, leukopenia, malaise, nausea	Doxycycline
Lyme disease	<i>Borrelia burgdorferi</i>	<i>I. scapularis</i>	Deer	Rash, arthropathy, neuropathy	Tetracyclines, penicillins, cephalosporins
Powassan virus	Powassan virus	<i>Ixodes</i> spp.	Foxes, skunks, raccoons	Encephalitis	–
Relapsing fever	<i>Borrelia</i> spp.	<i>Ornithodoros</i> spp.	Rodents	Fever	Tetracycline
Spotted fever (many different types worldwide)	<i>Rickettsia rickettsiae</i> in USA (Rocky mountain spotted fever), other species worldwide	<i>D. andersoni</i> or <i>D. variabilis</i> in USA	Deer Dog	Fever, myalgia, rash, malaise, nausea Severe disease in glucose-6-phosphate dehydrogenase (G6PD) deficiency	Tetracycline
Tick paralysis	No organism – tick toxin only	<i>D. andersoni</i>	Dog	Paralysis, including facial, leading to respiratory paralysis	–
Tularaemia, or rabbit fever	<i>Francisella tularensis</i>	<i>A. americanum</i> , <i>D. andersoni</i> or <i>D. variabilis</i>	Rabbit Dog	Ulcer, lymphadenopathy, fever	Streptomycin, gentamicin

China, Central Asia, southern Europe, Africa, the Middle East and the Indian subcontinent.

- Ehrlichiosis is transmitted to humans by the lone star tick (*Amblyomma americanum*), found primarily in the south–central and eastern USA.
- Imported tick-borne spotted fevers (rickettsial infections) have caused infection in returning travellers. In the USA, the culprit is usually *Rickettsia africae* (the agent of African spotted fever).
- Lyme disease can be caused by several different species of *Borrelia burgdorferi*. It is transmitted by the black-legged tick (*I. scapularis*) in the north-eastern and upper mid-western USA, and by the western black-legged tick (*I. pacificus*) along the Pacific coast.
- *Rickettsia parkeri* causes a rickettsiosis that is transmitted to humans by the Gulf Coast tick (*Amblyomma maculatum*).
- Rocky Mountain spotted fever (RMSF) is transmitted by the American dog tick (*Dermacentor variabilis*), Rocky Mountain wood tick (*Dermacentor andersoni*) and the brown dog tick (*Rhipicephalus sanguineus*) in the USA. The brown dog tick and other tick species are associated with RMSF in Central and South America.
- Southern tick-associated rash illness (STARI) transmitted via bites from the lone star tick (*A. americanum*), found in the south-eastern and eastern USA.
- Tick-borne encephalitis (TBE) is caused by three virus subtypes: European or western tick-borne encephalitis virus, Siberian tick-borne encephalitis virus and Far eastern tick-borne encephalitis virus (formerly Russian spring/summer encephalitis virus).
- Tick-borne relapsing fever (TBRF) is transmitted to humans through the bite of infected soft ticks.
- Tularaemia is transmitted to humans by the dog tick (*D. variabilis*), the wood tick (*D. andersoni*), and the lone star tick (*A. americanum*).

General management

Prevention is by wearing long trousers and long-sleeved shirts in rural areas.

SPIDERS

In the UK, spiders are not normally hazardous to health but a dozen or more species are capable of causing a significant bite. There are more hazards in the developing world, and even in some high-income countries. Some produce neurotoxins and other poisons, and so should be avoided.

More information is available at: <http://www.nhm.ac.uk/nature-online/life/insects-spiders/identification-guides-and-keys/spider-bites/>, <http://www.findaspider.org.au/info/hazards.htm> and <http://www.cdc.gov/niosh/topics/spiders/> (accessed 30 September 2013).

SNAKES

Not all snakes are poisonous but some are, and some bites are lethal. Remember that snakes may be swimming in water, as well as hiding under objects. If you see a snake, back away slowly and never touch it.

Signs and symptoms of snakebite may include:

- a pair of puncture marks
- redness and swelling around the bite
- severe pain
- nausea and vomiting
- laboured breathing
- disturbed vision
- increased salivation and sweating
- numbness or tingling around face and/or limbs.

If a person is bitten, try to see and remember the colour and shape of the snake, and:

- keep the bitten person still in order to slow the venom spread
- seek medical attention
- apply first aid:
 - Lay or sit the person down with the bite below the heart level
 - Tell them to stay calm and still
 - Cover the bite with a clean, dry dressing.

Do not interfere in any way with the bite, or let the victim drink alcohol or caffeine.

More information is available at: <http://www.bt.cdc.gov/disasters/pdf/snakebite.pdf> (accessed 30 September 2013).

TRAVEL PRECAUTIONS

Comprehensive travel and medical insurance should be obtained before travelling, checking any exclusions and cover for all intended activities.

Before travelling

Since trauma is the greatest danger, travellers should always avoid areas of conflict, violence or natural disasters. Before travel it is advisable to consult: <https://www.gov.uk/foreign-travel-advice> (accessed 30 September 2013). Infections such as malaria, dengue fever or MERV or H5N7 may need to be considered in the potential traveller's risk-benefit analysis.

Travellers should also consult a travel medicine clinic or medical practitioner at least 4–6 weeks before the journey, particularly if vaccinations or antimalarials may be required, or if they intend to visit a developing country, especially if they intend to be in rural areas for prolonged periods (Box 33.6). Awareness of risk is important and precautionary behaviour indicated. For example, hepatitis, yellow fever, cholera and typhoid immunisation may be prudent or essential before visits to the tropics. Meningitis vaccination may be indicated before hajj or similar gatherings (see Mass Gathering Medicine).

Infants and young children, pregnant women, older people, the disabled and those who have pre-existing health problems may need to take special precautions.

While travelling

Preventing contact with disease-producing organisms is best achieved by: avoiding their habitat (e.g. swamps, jungles); avoiding contact with animals; using barrier precautions (e.g. wearing long sleeves and trousers); avoiding insect bites (e.g. using insect repellents); avoiding exposure to animal excreta; and maintaining high levels of food, water and personal hygiene. Do not consume food that could be contaminated; this is best achieved by drinking and using bottled water, and by eating freshly cooked meat or fish. Use of chlorine and other disinfectants controls most viruses and bacteria in water, though parasites such as *Giardia* and *Cryptosporidium* are highly resistant to routine disinfection; they are, however, inactivated by ozone or eliminated by filtration. Antimicrobial prophylaxis against diarrhoeal disease is not recommended; precautions are shown in Box 33.7.

Avoid direct contact with blood and body fluids by not using potentially contaminated needles and syringes for injection or any other medical or cosmetic procedure that penetrates the skin (including acupuncture, body piercing and tattooing), and by avoiding transfusion of unsafe blood.

Box 33.6 Vaccines for travellers

Routine vaccination

- Diphtheria/tetanus/pertussis (DTP)
- *Haemophilus influenzae* type b (Hib)
- Hepatitis B (HBV)
- Measles (measles/mumps/rubella; MMR)
- Poliomyelitis (oral or inactivated poliomyelitis vaccine [OPV or IPV])

Mandatory vaccination

- Meningococcal meningitis (for Hajj, Umra)
- Yellow fever (certain countries)

Selective use^a

- Cholera
- Hepatitis A (HAV)
- Influenza
- Japanese B encephalitis
- Lyme disease
- Meningococcal meningitis
- Pneumococcal disease
- Rabies
- Tick-borne encephalitis
- Tuberculosis (bacilli Calmette–Guérin; BCG)
- Typhoid fever
- Yellow fever

^aCheck for country to be visited.

Box 33.7 Prophylaxis against diarrhoeal disease

Eat

- Only food that has been cooked thoroughly and is still hot

Boil

- Unpasteurized (raw) milk before consumption
- Drinking water, if its safety is doubtful; a certified, well-maintained filter and/or a disinfectant agent can also be used

Avoid

- Cooked food kept at room temperature for several hours
- Uncooked food, apart from fruit and vegetables that can be peeled or shelled
- Fruits with damaged skins
- Dishes containing raw or undercooked eggs
- Food or ice cream bought from street vendors
- Ice, unless it has been made from safe water
- Brushing teeth with unsafe water; bottled or packaged cold drinks are usually safe, provided that they are sealed
- Contaminated recreational water, particularly sewage-polluted sea water or fresh water in lakes and rivers, as well as water in swimming pools and spas

On return

On return, travellers should have a medical examination if they: suffer from a chronic illness, such as cardiovascular disease, diabetes mellitus or chronic respiratory disease; experience illness, particularly fever, persistent diarrhoea, vomiting, jaundice, urinary disorders, skin disease or genital infection; consider that they have been exposed to a serious infectious disease; or have spent more than 3 months in a developing country.

MASS GATHERING MEDICINE

Mass gatherings are occasions such as sports events, music festivals or religious celebrations that attract a large number of people: for example, the annual Muslim Hajj pilgrimage to Saudi Arabia and Mecca, or the Hindu Magh Mela in India and Allahabad. Mass gatherings may be defined as public events attended by in excess of 1000–25000 people. Such events can give rise to disasters such as stampedes with physical injuries and deaths, and to eventualities ranging from infectious disease outbreaks to terrorist attacks – with implications beyond the scope of typical public health provision. Factors influencing demand for the health care at mass gatherings may include:

- alcohol/drugs
- crowd containment (fenced/contained or not)
- crowd density
- crowd movement
- event duration
- communicable disease spread
- weather.

See Chapter 21.

Dependence or addiction is characterized by impaired control over drug use, compulsive use, continued use despite harm, and/or craving. Substance or chemical dependence or abuse (misuse) covers a range of mind-altering substances and is present when at least three of the conditions listed in [Box 34.1](#) apply. Most addictive substances directly or indirectly stimulate the brain's reward centre by increasing release of dopamine – the neurotransmitter involved in the regulation of emotion, cognition, movement, motivation and pleasure. Brain stimulation with dopamine produces intense euphoria, a pleasurable sensation reinforced by continued drug use.

Drug abuse causes central nervous system (CNS) effects that produce changes in the mind, behaviour, thoughts and mood, levels of awareness or perceptions and sensations. It is defined as self-administration without any medical indication and despite adverse medical and social consequences, in a manner that deviates from the cultural norm and is harmful. Social, mental and physical sequelae are common and discussed below.

Use of some of these drugs is illegal, and being found in possession of them can lead to criminal charges, particularly, if there is any intention of dealing (supplying; [Table 34.1](#)). In the UK, illegal drugs are classified under the Misuse of Drugs Act 1971 as A, B and C, depending on how dangerous they are to health; this classification can only be changed and added to by the Home Secretary. In some countries, use or possession may result in more serious punishments – even execution.

RISK FACTORS FOR DRUG ABUSE

Addiction is a primary, chronic, neurobiological condition, influenced by genetic, psychosocial and environmental factors. Men are twice as

likely as women to experience drug problems. Factors that may contribute to drug use include:

- genetic factors
- environmental factors, such as:
 - home and family, friends and acquaintances who use drugs
 - time of drug use
 - personality (low self-esteem, stress)
 - availability of drugs
 - method of drug administration
 - coexisting mental problems.

PERSONS WHO USE DRUGS (PWUD)

Substance abuse is increasingly common in many parts of the world. The pattern of drug use in the British Crime Survey by 2012 is shown in [Box 34.2](#).

The 2012/13 Crime Survey for England and Wales showed that in the past year:

- Cannabis was the most commonly used drug
- The next most commonly used were powder cocaine and ecstasy.
- Young adults (aged 16 to 24) were more likely to use drugs.
- Around 1 in 12 adults had taken an illicit drug.

In the USA, the highest rates of illicit drug use are: in males – in entertainment, food preparation and service, cleaning services and construction; and in females – in food preparation and service, social work and legal professions, including lawyers and legal assistants. Abuse of alcohol is highest among construction workers, car mechanics, food preparation workers, light truck drivers and labourers. Unmarried workers or those having three or more jobs in the previous 5 years report about twice the rate of illicit drug and heavy alcohol use as married workers or those who had two or fewer jobs.

The lowest rates of illicit drug use are in workers in occupations that require public trust, such as health-care professions (HCPs), police officers, teachers and child-care workers. Between 10 and 15% of HCPs misuse drugs or alcohol at some time during their life – rates similar to those seen in the general population. Alcohol abuse is relatively common among doctors and dentists, and one study of USA medical personnel found that over half had tried marijuana or cocaine recreationally, or opioids or tranquillizers for self-treatment. HCPs have higher rates of abuse with benzodiazepines and opiates, and abuse drugs for performance enhancement and as self-treatment for various reasons, such as pain, anxiety or depression. Those in anaesthesia, emergency medicine and psychiatry have the highest rates of drug abuse.

Drugs and alcohol used by medical and dental students are mostly for 'recreational' purposes. More than a half of UK dental students in 2003 had used cannabis and over one-third admitted other illicit drug use. Some 6–10% of dentists may abuse drugs, but there is limited evidence to suggest that they are at a greater risk for abusing alcohol or other drugs than the public. Alcohol and tobacco are the substances abused most frequently by dentists, followed by opiates (mainly hydrocodone and oxycodone) and nitrous oxide. Other substances abused include marijuana; opiates (e.g. morphine, fentanyl, pethidine (meperidine),

Box 34.1 Features suggesting substance dependence

- Some symptoms of the disturbance must have persisted for at least 1 month or have recurred repeatedly over a longer period
- Substances are often taken in larger amounts or over longer periods than intended
- There is a persistent desire or one or more unsuccessful efforts to reduce or control substance use
- Excessive time is spent in activities that lead to obtaining the substance (e.g. theft), taking the substance (e.g. chain smoking) or recovering from its effects
- Important social, occupational or recreational activities are reduced or abandoned because of substance misuse
- There is continued substance use, despite the knowledge that it produces persistent or recurrent social, psychological or physical problems
- There is growing tolerance – greatly increased amounts of the substance are needed to achieve the desired effect, or greatly diminished effect is produced by continued use of the same amount
- There are characteristic withdrawal symptoms
- Substances are often taken to relieve or avoid withdrawal symptoms

Table 34.1 Main drug classes and penalties for possession and supply

	Class under the UK Misuse of Drugs Act		
	A	B	C
Considered a danger to health	Most dangerous	Dangerous	Least harmful
Drugs	Cocaine (including crack; nicknamed charlie, coke, snow) Diconal Heroin (nicknamed smack, H, gear, skag, brown) LSD (lysergic acid diethylamide; nicknamed acid, trips, blotters, tabs) Magic mushrooms MDMA ((3,4-methylenedioxy-N-methylamphetamine) Mescaline Methadone Methylamphetamine Morphine Opium PCP (phencyclidine; nicknamed angel dust) Pethidine Poppy straw Psilocybin STP (amphetamine; nicknamed serenity, tranquillity and peace)	Amphetamine (an ingredient of ecstasy; nicknamed speed, whizz, dexies) Barbiturates Cannabis, cannabis resin and cannabinal Codeine (in concentrations above 2.5%) DF118 (dihydrocodeine) Cathinones (mephedrone, naphyrone) Methoxetamine Ritalin	Anabolic steroids (nicknamed roids) Benzodiazepines, including valium and Rohypnol (flunitrazepam) (nicknamed roofies and sometimes referred to as date-rape drugs) GHB (gamma-hydroxybutrate; nicknamed liquid ecstasy and sometimes referred to as date-rape drugs) Ketamine (nicknamed special K, vitamin K, green) Methaqualone
Maximum penalties			
Possession	7 years in prison and/or a fine	5 years in prison and/or a fine	2 years in prison and/or a fine
Supply	Life in prison and/or a fine	14 years in prison and/or a fine	5 years in prison and/or a fine

Box 34.2 UK drug use in 2011–2012^a

- 1 in 3 adults (36.5%) had taken an illicit drug in their lifetime
- 15.6% of adults had taken a class A drug in their lifetime
- 8.9% per cent of adults had used an illicit drug in the last year (this remains around the lowest level since measurement began in 1996)
- Among 16- to 59-year-olds, 3.0% had used a class A drug in the last year (similar to levels in the 2010/11 [3.0%] and 2009/10 [3.1%] surveys)
- Cannabis was the most commonly used type of drug in the last year (6.9% of adults), followed by powder cocaine (2.2%)
- The other main drugs used included ecstasy, amyl nitrite, amphetamines and ketamine

^a Does not cover groups like the homeless or those living in institutions such as prisons, who have potentially high rates of drug use, and problematic drug users who are unable to take part in an interview. From <http://www.homeoffice.gov.uk/publications/science-research-statistics/research-statistics/crime-research/drugs-misuse-dec-1112/extent-adults> (accessed 30 September 2013).

hydromorphone and oxycodone); minor opiates (e.g. hydrocodone and codeine); and anxiolytics (e.g. alprazolam and diazepam). Interpersonal and life circumstances that contribute to dentists misusing drugs and alcohol include career choice dissatisfaction, domestic breakdown, low professional or self-esteem, obsessive–compulsive and perfectionist behaviour, interpersonal relationship difficulties, and stress at work.

Dentists who become aware and are sure of a colleague's chemical dependency have professional and ethical responsibilities to intervene in a constructive manner. All dentists have an ethical obligation to urge chemically impaired colleagues to seek treatment. Interventions involve discussing the issue with the addicted dentist, offering help if possible, and reporting the dentist to a wellness committee. Once a person with

an addiction accepts the presence of the issue and expresses a desire to change, treatment can begin, but it should be individually designed by professionals experienced in treating drug and alcohol abuse. Clinicians in the UK who have such issues can receive support from the Practitioner Health Programme, initiated by the National Clinical Assessment Service (NCAS; <http://www.php.nhs.uk/>, accessed 30 September 2013).

RECOGNIZING AND DETECTING SUBSTANCE ABUSE

Behavioural traits that should increase the level of concern include loss of reliability, mood changes, impaired driving, and the self-prescribing of mood-altering medications. Care should be taken with any patient who has subjective symptoms with no objective evidence of the disorder; makes a self-diagnosis and requests a specific drug, especially a psychoactive agent; appears to have a dramatic but unexpected complaint, such as trigeminal neuralgia, requiring potent analgesics; firmly rejects treatments that exclude psychoactive drugs; and has no interest in the diagnosis or investigations, or refuses a second opinion.

To help a friend/colleague address such problems, it is important to document the dates and times when people have expressed concern and when the signs of substance abuse were noted. These may include the smell of alcohol, tremor, slurred speech, ataxic gait and sloppy appearance. It is important to monitor and document incidents so that this information will be available when discussing concerns with a friend or colleague. The user's first response is typically denial – and a person in denial will often try to convince others that their assessments are wrong or misguided. Recognition of abuse in an HCP may include, in addition to the above, patient and staff complaints about deteriorating attitude and behaviour, worsening personal and professional

isolation, excessive amounts of time spent near a drug supply, heavy 'wastage' of drugs, sloppy record-keeping, suspect ledger entries and drug shortages, inappropriate prescriptions, or insistence on the personal administration of injected narcotics to patients.

MEDICAL AND SOCIAL COMPLICATIONS OF DRUG ABUSE

There may be intense drug dependence (or psychological addiction; Table 34.2) and physical effects (physical addiction) in people who use drugs (PWUD) or if a drug of abuse is stopped (withdrawal syndrome) (Fig. 34.1).

Use of illicit drugs is associated with increased rates of infections (e.g. tuberculosis and sexually shared infections [SSIs]), and health and social issues related to alcohol, tobacco and other drugs. Injection drug use is an important route of transmission of blood-borne infections, particularly HIV and viral hepatitis B and C.

Drugs bought on the street are especially hazardous, as they are not necessarily pure and are frequently adulterated or falsely labelled, often with unknown ingredients that may be dangerous in their own right. For example, PWUD who think they are purchasing a drug such as MDMA (ecstasy; 3,4-methylenedioxy-N-methylamphetamine) may be in danger of receiving synthetic cathinones instead; mephedrone has been found as a substitute for MDMA in pills sold as ecstasy in some countries. Intravenous use and the mixing of drugs (polydrug use) are particularly hazardous; those who misuse drugs not uncommonly

misuse several substances, including alcohol and tobacco, and may well neglect their health – general and oral. Heroin and cocaine are especially dangerous. Tobacco and alcohol also cause significant harm, but cannabis appears to be less harmful in general.

Almost every month, new synthetic drugs, opiate painkillers and other substances emerge as popular among partygoers and drug addicts. Recently appearing new drugs include:

- *Molly* – the most-refined, crystalline form of MDMA, blamed for lethal drug overdoses
- *Crocodile* or 'krokodil' – previously used in Russia and former Soviet Bloc nations. Cases have started appearing in the USA and other countries. It is desomorphine, a cheap codeine derivative mixed with gasoline, oil, alcohol or paint thinner. Addicts shoot the mixture directly into their skin with a needle, resulting in dark, scaly patches of necrotic skin. Users are often severely disfigured for life, suffering serious scarring, bone damage, amputated limbs, speech impediments, poor motor skills and varying degrees of brain damage
- *Butane hash oil* (BHO), also known as amber, honey, wax and ear wax – a highly concentrated form of tetrahydrocannabinol (THC). The BHO high is nothing like regular marijuana and users may lose consciousness after inhaling it
- *2C-P* – a long-lasting and very potent psychedelic drug whose effects begin only after a few hours but can last for 10–20 hours
- *Suboxone* (buprenorphine) – an opiate analgesic used to wean addicts off powerful opiates like heroin and hydrocodone; it is also abused.

See also "LEGAL HIGHS" and "EMERGING DRUGS".

Table 34.2 Drug dependence^a

Drug	Psychological dependence	Physical dependence
Heroin	+++++	+++++
Cocaine	+++++	+++
Alcohol	++++	+++
Tobacco	+++++	++++
Barbiturates	++++	++++
Benzodiazepines	++++	++++
Amphetamine	+++	++
LSD	++	+
Cannabis	+++	+
Ecstasy	++	+

Fig. 34.1 Outcomes from substance abuse.

CLINICAL FEATURES

Signs and symptoms that may indicate drug addiction include behavioural and social features, as well as health aspects (Table 34.3). There can be serious medical and behavioural consequences affecting both user (and any fetus) and others in the community, not least because of assaults, theft and prostitution used to fund the drug habit. Maxillofacial injuries and sexually shared and other infectious diseases are thus common consequences. Intravenous injection is common in drug misuse, often with filthy injection technique, sharing of needles or syringes (with the risk of blood-borne infections) and even use of water from a lavatory pan to dissolve the drug. Viral hepatitis (particularly B, C, D and others), chronic liver disease, human immunodeficiency virus (HIV) and other blood-borne agents are common consequences of intravenous drug abuse or drug 'snorting'. Infective endocarditis and consequent cardiac lesions may stem from infected injections. Venous thromboses are common, making intravenous injection difficult.

GENERAL MANAGEMENT

Common management difficulties are behavioural problems, including irregular health care, poor attendance and compliance, effects of trauma and the frequent risk of maxillofacial and other injuries during assaults or fights, and hazards of cross-infection with hepatitis viruses, HIV and, increasingly, tuberculosis. PWUDs who collapse or become hyperthermic, drowsy or panicky may well need emergency care (Table 34.4). Many drugs of abuse can alter behaviour or interact with drugs used for medical or dental purposes (Ch. 29). There can therefore be substantial difficulties in interactions between HCPs and

Table 34.3 Features possibly suggesting drug misuse (recognition of persons who use drugs)

Presentation	Features	Behaviour	Social history
Specific requests for drugs of misuse No fixed abode	Progressive deterioration in personal appearance and hygiene, deterioration of handwriting, alcohol on the breath, nicotine on fingers, smell of marijuana, tremors, avoidance of eye contact, constricted or dilated pupils, a history of liver disease, wearing long sleeves when inappropriate Puncture marks, scars or pigmentation over veins Jaundice	Personality change – mood swings, anxiety, depression, lack of impulse control, suicidal thoughts or gestures, and deteriorating interpersonal relations with rare admittance or acceptance of blame for errors or oversights. Unusually elated, drowsy or restless	Frequent changes of health carers Family disruption Frequent changes in or loss of employment Self-discharge from health care History of offences to obtain money Work absenteeism, frequent disappearances from work, improbable excuses and frequent or long trips to the lavatory or stockroom where drugs are kept Unreliability in keeping appointments, meeting deadlines and work performance

Table 34.4 Emergency care of people who use drugs

Patient problem	Possible causal drugs	Steps		
		1	2	3
Consciousness lost	Alcohol, heroin, tranquillizers, solvent abuse, ecstasy	Place in recovery position. Call ambulance	Cardiopulmonary resuscitation	
Dehydrated and hot	Ecstasy, methedrone, speed	Reassure and calm person. Give non-alcoholic drinks (1 pint/h). Move to cool area. Remove hot clothing	Call ambulance	Cardiopulmonary resuscitation
Drowsy	Heroin, tranquillizers, solvent abuse	Reassure	Place in recovery position Avoid coffee	Call ambulance
Panicky	Ecstasy, LSD, methedrone, magic mushrooms, speed	Reassure and calm the person	Keep in quiet area, accompanied	Call ambulance

drug users. However, it is unethical to withhold treatment from any patient on the basis of a moral judgment that the patient's activities or lifestyle might have contributed to the condition for which treatment was being sought.

MAIN GROUPS OF DRUGS ABUSED

Patterns of drug misuse change rapidly, depending on fashion and cultural factors, availability and cost. New agents are constantly appearing, often in an attempt to circumnavigate the law and frequently under a variety of names, and may have adverse effects. For example, benzylpiperazine (BZP; A2, legal E, legal XTC, legal high, Jax, London Underground, Pep twisted or Pep love) appeared as an alternative to ecstasy but caused serious adverse effects (see <http://www.justice.gov/dea/druginfo/factsheets.shtml> and http://www.talktofrank.com/home_html.aspx; accessed 30 September 2013).

The main groups of drugs abused are stimulants (uppers), depressants (hypnotics/sedatives/downers), hallucinogens (psychedelics) and anabolic steroids (Table 34.5). Alcohol, tobacco, solvents, cannabis and ecstasy have been popular for many years; apart from these, heroin is the main drug of misuse, followed closely by mephedrone, methadone and cocaine (Tables 34.5 and 34.6). Other drugs commonly abused include amphetamines, barbiturates, benzodiazepines, methaqualone and opium alkaloids. Drugs abused may be obtained legally from a doctor or chemist, or may be illicitly obtained. They may be taken orally, inhaled, or injected into the skin, muscle or a vein.

Prescription drugs are commonly abused – notably stimulants, CNS depressants, analgesics and opioids.

Club drugs are those used by teenagers and young adults who are part of a nightclub, bar, trance or rave scene – night-long dances, often

Table 34.5 Common drugs of misuse and the possible consequences

Drug type	Risks from misuse	Examples	Intravenous use and possible consequent blood-borne virus infection transmission, endocarditis or septicaemia
Stimulants	Behavioural disturbances and psychoses	Amphetamines	+
		Cocaine	+
		Crack cocaine	–
		MDMA (ecstasy)	+
Sedatives	Fatal overdose Seizures on withdrawal	Alcohol	–
		Barbiturates	+
		Benzodiazepines	+
Opioids	Respiratory arrest in overdose	Buprenorphine	+
		Dipipanone	+
		Heroin	+
		Methadone	+

held in warehouses (Table 34.7). In high doses, club drugs can cause a sharp rise in body temperature (malignant hyperthermia) leading to muscle breakdown and renal and cardiovascular system failure.

Date-rape drugs, such as gamma-hydroxybutyric acid (GHB), Rohypnol (flunitrazepam) and ketamine, are used because they lack colour, taste and odour, and thus can be added to beverages to be ingested unknowingly by the victim. They are CNS depressants that cause loss of inhibitions and memory. They can also readily cause unconsciousness.

Table 34.6 Main groups of substances abused

Stimulants (uppers)	Depressants (hypnotic/sedatives/downers)	Hallucinogens (psychedelics)	Analgesics	Anabolic steroids
Actions				
Speed brain activity	Slow brain activity	Distort brain activity	Decrease pain	Promote growth and muscle
Examples				
Amphetamine, caffeine, cocaine, crack, dextroamphetamine, diethylpropion, mephedrone, methylphenidate, naphyrone, nicotine, phenmetrazine, tobacco	<i>Anxiolytics:</i> alprazolam, benzodiazepines, clorazepate, meprobamate <i>Barbiturate</i> <i>Ethanol (alcohol)</i> <i>Inhalants:</i> amyl nitrite, butyl nitrite, enflurane, ether, halothane, isoflurane, nitrous oxide, petrol, solvents (various)	Lysergic acid diethylamide (LSD), mephedrone, mescaline (peyote), methyl-dimethoxy amphetamine (STP; DOM), methylene dioxymphetamine (MDA), 3,4-methylenedioxy-methamphetamine (MDMA; ecstasy), phencyclidine (PCP), psilocybin <i>Cannabinoids:</i> marijuana	<i>Opioids:</i> codeine, fentanyl, heroin, hydrocodone, lomitol, pethidine (meperidine), methyl-phenyl-tetra-hydropyridine (MPTP), morphine, oxycodone, propoxyphene	Nandrolone (Deca-Durabolin), Sustanon 250, Dianabol, Anavar, stanozolol
Main CNS and adverse effects				
Exhilaration, energy, reduced appetite, weight loss, alertness; rapid or irregular heart beat; raised heart rate, blood pressure, metabolism	Feeling of well-being; lowered inhibitions; slowed pulse and breathing; lowered blood pressure; poor concentration, confusion, fatigue; impaired coordination, memory, judgment; respiratory depression and arrest	Altered states of perception and feeling; nausea, psychoses, persisting perception disorder (flashbacks)	Pain relief, euphoria, drowsiness, nausea, confusion, constipation, sedation, respiratory depression and arrest, unconsciousness, coma	No intoxication effects

Table 34.7 Currently popular club drugs

Street name	Constituents	Effects	Comments
Cat	Methcathinone	Produces a cocaine-like high with hallucinations similar to mescaline	Analogue of methamphetamine
China white	Beta-hydroxy methylfentanyl	6000 times the potency of natural heroin. Responsible for many narcotic overdose deaths	Analogue of fentanyl
Double stack or PMA	Paramethoxyamphetamine	Does not produce the pleasurable MDMA effects, so users take more drug. Dramatic rise in body temperature in excess of 109°F. Death from hyperthermia	Analogue of methamphetamine
DXM	Dextromethorphan	Hallucinations and a heavy 'stoned' feeling in users but no desirable ecstasy effects	Often passed off as ecstasy. Found in over-the-counter cold remedies
Ecstasy	3,4-Methylenedioxy-methamphetamine (MDMA)	Resembles methamphetamine, but also produces mild hallucinations and a feeling of emotional closeness to other people	The most sought-after club drug
Eve	3,4-Methylenedioxymethamphetamine (MDE)	Does <i>not</i> produce the ecstasy feeling of emotional closeness	Analogue of ecstasy
GBL (gamma-butyrolactone and 1,4-butanediol)	Gamma-butyrolactone and 1,4-butanediol. Together they convert to GHB	Taken alone, or especially when mixed or with alcohol, produces stupor, vomiting and coma	Related to GHB. Sold over the Internet to avoid laws against GHB
GHB, super-G, liquid G, liquid ecstasy	Gamma-hydroxybutyric acid	Taken alone, or especially when mixed with alcohol, produces stupor, vomiting and coma	A clear, odourless liquid with a slightly salty taste. Originally thought to be a human growth hormone, it was abused by body-builders until banned in 1991 by the Food and Drug Administration (FDA)
Ice	Methamphetamine	Produces a 10-h high	A smokable form of recrystallized methamphetamine similar to crack
Meow meow (see also Cat)	Mephedrone	Feelings of euphoria, alertness, talkativeness, empathy, anxiety, paranoia and overstimulation of the heart and circulatory system. Over-excitation of the nervous system, which can cause seizures	Was sold over the Internet as a 'legal high', often described as a plant food, research chemicals or bath salts
Naphyrone		Similar to mephedrone	
Nexus or 2C-B	4-Bromo-2, 5-dimethoxyphenethylamine	Produces strong, ecstasy-like feelings of closeness and sexual enhancement	Phenylethylamine analogue of powerful hallucinatory drug 4-bromo-2, 5-dimethoxyamphetamine (DOB)
Rohypnol	Flunitrazepam	Mixed with alcohol, as a 'date-rape' drug	Analogue of diazepam but ten times as powerful
Special K	Ketamine	Produces hallucinations and stupor and is highly addictive	Analogue of phencyclidine (PCP)
YABA	Methamphetamine	Produces a 10-h high	Ultrapure form of methamphetamine often combined with caffeine

Table 34.8 Common stimulants

Main stimulant groups	Street names ^a	Comments
Adrenaline (epinephrine) derivatives ephedrine and pseudoephedrine	Bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	Raised heart rate, blood pressure, metabolism, feelings of exhilaration, energy, increased mental alertness, rapid or irregular heart beat, reduced appetite, weight loss, heart failure, rapid breathing
Phentermine		Hallucinations/tremor, loss of coordination, irritability, anxiousness, restlessness, delirium, panic, paranoia, impulsive behaviour, aggressiveness, tolerance, addiction
Amphetamine		
Caffeine	Found in tea and coffee, cola and a number of energy drinks	Energy, increased mental alertness, rapid or irregular heart beat
Cocaine	Blow, bump, C, candy, charlie, coke, crack, flake, rock, snow, toot, white	Raised temperature, chest pain, respiratory failure, nausea, abdominal pain, strokes, seizures, headaches, malnutrition
Cocaine hydrochloride		
Methylenedioxy-methamphetamine (MDMA)	DOB, DOM, MDA, adam, clarity, ecstasy, eve, lover's speed, peace, STP, X, XTC, E, pills, XTC, disco biscuits, Mitsubishis, Rolexs, dolphins	Mild hallucinogenic effects, increased tactile sensitivity, empathic feelings, hyperthermia, impaired memory and learning
Methamphetamine	Chalk, crank, crystal, fire, glass, go fast, ice, meth, speed	Aggression, violence, psychotic behaviour, memory loss, cardiac and neurological damage, impaired memory and learning, tolerance, addiction
Mephedrone	White magic, miaow, meph, meow meow, MC, M-CAT, drone, charge, bubble, bounce, 4-MMC	Feelings of euphoria, alertness, talkativeness, empathy, anxiety, paranoia and overstimulation of the heart and circulatory system. Over-excitation of the nervous system, which can cause seizures
Methylphenidate	Ritalin, JIF, MPH, R-ball, skippy, the smart drug, vitamin R	Increase or decrease in blood pressure, psychotic episodes, digestive problems, loss of appetite, weight loss
Naphyrone	NRG, O-2482 or naphthylpyrovalerone	Similar to mephedrone. Was sold over the Internet as a 'legal high', often described as a plant food, research chemicals or bath salts. Feelings of euphoria, alertness, talkativeness, empathy, anxiety, paranoia and overstimulation of the heart and circulatory system. Over-excitation of the nervous system, which can cause seizures
Nicotine	Bidis, chew, cigars, cigarettes, smokeless tobacco, snuff, spit tobacco	Tolerance, addiction, additional effects attributable to tobacco exposure – adverse pregnancy outcomes, chronic lung disease, cardiovascular disease, stroke, cancer

^a See Appendix 34.1.

STIMULANTS

Stimulants are substances that cause excitement and euphoria (a 'high'), which may last several hours. Withdrawal symptoms (restlessness, agitation, sleeplessness and depression) may follow. Heavy use of strong stimulants for weeks may cause paranoia and auditory hallucinations – effects that may be irreversible (Table 34.8).

Stimulants cause moderate to severe psychological addiction. Withdrawal is purely psychological and psychosomatic. They include:

- amphetamine and methamphetamine
- caffeine
- cocaine
- mephedrone
- nicotine.

Stimulants used in various cultures include betel, caffeine, cocaine, kava, khat, kratom, marijuana, salvia and tobacco (Table 34.9). Common herbal sources of psychedelics include *Psilocybe* mushrooms ('magic mushrooms'), seeds of *morning glory* (from the *Convolvulus* family), *peyote* (from a cactus in the south-west USA), various *ayahuasca* preparations (from the *Banisteriopsis* species of vine from Amazonia), *San Pedro cactus* (from a cactus found in Peru, Bolivia, Chile and Ecuador) and *Hawaiian baby woodrose* (a vine from India, the Caribbean, Hawaii and Africa).

Inhalants are stimulants that are volatile chemical vapours that produce psychoactive effects. Many are available over the counter, including solvents (paint thinners, gasoline, glues), gases (butane, propane, aerosol propellants, nitrous oxide), nitrites (isoamyl, isobutyl, cyclohexyl – used to enhance sexual arousal) and sprays (e.g. deodorants; Table 34.10). 'Laughing gas', 'poppers', 'snappers' and 'whippets' are commonly used terms. Sniffing inhalants produces psychotomimetic effects somewhere between those of alcohol and general anaesthesia (GA), in that initially users may feel slightly stimulated; with successive inhalations, they may feel less inhibited and less in control. Users may appear drunk and

giggling with slurred speech and unsteadiness. Adverse effects include headache, nausea or vomiting, wheezing, unconsciousness, cramps, weight loss, muscle weakness, depression, memory impairment, damage to cardiovascular and nervous systems, and unconsciousness. Inhalant misuse is increasingly common in children and young adults, and has led to many deaths. Sniffing highly concentrated chemicals such as fluorocarbons and butane-type gases can damage liver and CNS, or cause delusions, hypoxia, arrhythmias and sometimes sudden death. Deliberately inhaling from an attached paper or plastic bag, or in a closed area, greatly increases the chances of suffocation. Users can also choke on their own vomit. Chronic solvent misuse can impair memory and concentration, and permanent damage to the brain, liver or kidneys has been reported. Respiratory damage, anaemia, lead poisoning and cranial nerve palsies can follow chronic misuse of petrol. A syndrome of learning disability, hypotonia, scaphocephaly and high malar bones has also been reported in children of mothers who inhaled petrol during pregnancy (fetal gasoline syndrome). Specific chemicals may also have additional adverse effects (Table 34.11). Signs of solvent misuse include slurred speech, euphoria, anorexia and a circumoral (glue sniffers') rash. Jaundice may be seen and the pulse may be irregular.

DEPRESSANTS

Depressants (including alcohol) depress the CNS, causing drowsiness; poor concentration, judgment and memory; disorientation; ataxia; and, in severe cases, unconsciousness (Table 34.12). Sedatives and hypnotics may cause mild to severe psychological addiction, and severe physiological addiction; abrupt withdrawal may be fatal. They include:

- alcohol
- barbiturates
- benzodiazepines, particularly alprazolam, Rohypnol (flunitrazepam), triazolam, temazepam and nimetazepam; z-drugs (e.g. zimovane) have a similar effect

Table 34.9 *Stimulants used in various cultures*

Stimulant	Sources	Comments
Betel	See text	
Caffeine	See text	
Cocaine	See text	
Kava	Kava (ava, intoxicating pepper, kawa kawa, kew, sakau, tonga, yangona) from <i>Piper methysticum</i> (intoxicating pepper), a shrub native to the South Pacific Islands, including Hawaii. The term kava also refers to the non-fermented, psychoactive beverage prepared from the rootstock. Kava-containing dietary supplements are marketed for the treatment of anxiety and insomnia	Pacific Island societies have long used kava beverages for social, ceremonial and medical purposes. The pharmacologically active compounds are kavalactones. Effects include euphoria, muscle relaxation, sedation and analgesia. High doses can have transient central nervous system (CNS) depressant effects (e.g. sedation and muscle weakness). Individuals may experience a numbness or tingling of the mouth upon drinking kava due to its local anaesthetic activity. Liver damage (hepatitis and cirrhosis) and failure have been associated with commercial extracts of kava. Kava inhibits cytochrome P450 enzymes and has potential for drug interactions
Khat	Khat (qat, kat, chat, miraa, quaadka), the leaves of <i>Catha edulis</i> , a shrub native to East Africa and the Arabian Peninsula, widely used as a recreational drug by indigenous people from Somalia, Ethiopia, Yemen and the Middle East	Khat has amphetamine-like effects from cathinone and cathine. Cathinone (alpha-aminopropiophenone), the principal active stimulant, is structurally similar to D-amphetamine and almost as potent as a CNS stimulant. Cathine (D-norpseudoephedrine) is about ten times less potent than cathinone as a CNS stimulant. Mephedrone (dimethylmethcathinone) and naphyrone (naphthylpyrovalerone) are cathinones found in khat
Kratom	Kratom (<i>Mitragyna speciosa</i> Korth, thang, kakuum, thom, ketum, biak) – a tree indigenous to Thailand, Malaysia and Myanmar	Used as a herbal drug. Mitragynine (9-methoxy-corynantheidine) is the primary active alkaloid and has opioid-like activity
Marijuana	See text	
Salvia	<i>Salvia divinorum</i> (Maria Pastora, sage of the seers, diviner's sage, salvia, Sally-D, magic mint) – a perennial herb native to the Sierra Mazateca region of Oaxaca, Mexico	Salvinorin A (divinorin A) is believed to be the ingredient responsible for hallucinogenic effects
Tobacco	See text	

Table 34.10 *Inhalants: solvents and gases*

Solvents	Gases
Industrial or household solvents	Butane and propane in household or commercial products
Art or office supply solvents	
Paint thinners or solvents, degreasers (dry-cleaning fluids), petrol and glues	Aerosol propellants Anaesthetics
Correction fluids, felt-tip-marker fluid and electronic contact cleaners	Whipping cream aerosols or dispensers (whippets) and refrigerant gases Spray paints, hair or deodorant sprays, and fabric protector sprays Nitrous oxide, halothane, ether and chloroform

Table 34.11 *Adverse effects from inhalants*

Chemical	Found in	Effects
Benzene	Petrol	Bone marrow damage
Chlorinated hydrocarbons	Correction fluids, dry-cleaning fluids	Liver and kidney damage
Hexane	Glues, petrol	Peripheral neuropathies or limb spasms
Methylene chloride	Varnish removers, paint thinners	Blood oxygen depletion
Nitrites	'Poppers', 'bold' and 'rush'	Blood oxygen depletion
Nitrous oxide	Whipping cream, gas cylinders	Peripheral neuropathies or limb spasms
Toluene	Paint sprays, glues, dewaxers	Liver, kidney and central nervous system damage, hearing loss
Trichloroethylene	Cleaning fluids, correction fluids	Hearing loss

Table 34.12 *Main depressants*

Main groups	Chemical names	Street name(s) ^a	Comments
Alcohol	Ethanol	Booze	Reduced pain and anxiety, feeling of well-being, lowered inhibitions, slowed pulse and breathing, lowered blood pressure, poor concentration, confusion, fatigue, impaired coordination, memory, judgment, respiratory depression and arrest, addiction
Barbiturates	Amobarbital, pentobarbital, secobarbital, phenobarbital	Barbs, reds, red birds, phennies, tooies, yellows, yellow jackets	Sedation, drowsiness, depression, unusual excitement, fever, irritability, poor judgment, slurred speech, dizziness
Benzodiazepines	Various	Ativan, Halcion, Librium, Valium, Xanax; candy, downers, sleeping pills, tranks	Sedation, drowsiness, dizziness
	Flunitrazepam	Rohypnol; forget-me pill, Mexican valium, R2, Roche, roofies, roofinol, rope, rophies	Visual and gastrointestinal disturbances, urinary retention, memory loss while under the drug's effects
GHB	Gamma-hydroxybutyrate	G, Georgia home boy, grievous bodily harm, liquid ecstasy	Drowsiness, nausea/vomiting, headache, loss of consciousness, loss of reflexes, seizures, coma, death
Methaqualone	Methaqualone	Mandrax, quaaludes	Euphoria, depression, poor reflexes, slurred speech, coma

^aSee Appendix 34.1.

Table 34.13 Main hallucinogens

Main hallucinogen groups	Chemical names	Street names ^a	Comments
Ketamine	Ketamine	Ketalar SV; cat, K, special K, vitamin K	Altered states of perception and feeling, nausea, temporary blindness, aggression, chronic mental disorders, persisting perception disorder (flashbacks) plus, at high doses, delirium, depression, respiratory depression and arrest
LSD	Lysergic acid diethylamide	Acid, blotter, boomers, cubes, microdot, yellow sunshines	Increased body temperature, heart rate, blood pressure, loss of appetite, sleeplessness, numbness, weakness, tremors
MDMA	Methylenedioxy-methamphetamine	Ecstasy	Increased body temperature, heart rate, blood pressure, loss of appetite, sleeplessness, numbness, weakness, tremors
Mephedrone	Mephedrone	White magic, miaow, meph, meow meow, MC, M-CAT, drone, charge, bubble, bounce, 4-MMC	Feelings of euphoria, alertness, talkativeness, empathy, anxiety, paranoia and overstimulation of the heart and circulatory system. Over-excitation of the nervous system, which can cause seizures
Naphyrone	Naphyrone	NRG, O-2482 or naphthylpyrovalerone	Similar to mephedrone. Was sold over the Internet as a 'legal high', often described as a plant food, research chemicals or bath salts. Feelings of euphoria, alertness, talkativeness, empathy, anxiety, paranoia and overstimulation of the heart and circulatory system. Over-excitation of the nervous system, which can cause seizures
Mescaline	Trimethoxy-phenethylamine	Buttons, cactus, mesc, peyote	Increased body temperature, heart rate, blood pressure, loss of appetite, sleeplessness, numbness, weakness, tremors
PCP and analogues	Phencyclidine	Phencyclidine; angel dust, boat, hog, love boat, peace pill	Possible decrease in blood pressure and heart rate, panic, aggression, violence, loss of appetite, depression
Psilocybin	Psilocybin	Magic mushroom, purple passion, shrooms	Nervousness, paranoia
THC compounds (tetrahydrocannabinoids; cannabis)	Marijuana	Hashish, boom, chronic, gangster, hash, hash oil, hemp, blunt, dope, ganja, grass, herb, joints, Mary Jane, pot, reefer, sinsemilla, skunk, weed	Euphoria, slowed thinking and reaction time, confusion, impaired balance and coordination, cough, frequent respiratory infections, impaired memory and learning, increased heart rate, anxiety, panic attacks; tolerance, addiction

^aSee Appendix 34.1.

- methaqualone and the related quinazolinone sedative-hypnotics
- opiate and opioid analgesics (mild to severe psychological addiction, mild to severe physiological addiction; abrupt withdrawal is unlikely to be fatal): morphine and codeine (two naturally occurring opiate analgesics) semi-synthetic opiates, e.g. heroin (diacetylmorphine; morphine diacetate), oxycodone, buprenorphine and hydromorphone synthetic opioids, e.g. fentanyl, pethidine (meperidine) and methadone.

HALLUCINOGENS

Hallucinogenic drugs cause sensory distortions, including mood changes, feelings of disassociation, auditory and visual disturbances, and changes to taste or smell. Hallucinations are quite dangerous, as sufferers may present extreme danger either to themselves or to others (Table 34.13).

ANABOLIC STEROIDS

See Chapter 33.

ALPHABET OF DRUGS OF MISUSE

Appendix 34.1 gives the main street names for the most important drugs of abuse but there are many others (see <http://www.drugrehab.co.uk/street-drug-names.htm>).

ALCOHOL

Alcohol (ethanol) is the most common drug of abuse. It accounts for about as much of the burden of world disease as tobacco and

hypertension, is exceeded only by the burdens caused by malnutrition and unsafe sex (Fig. 34.2), and consumption is rising across the globe. Alcohol in drinks is generally measured in units (Table 34.14): 1 alcohol unit (AU) equates to 10–12 mL of pure ethanol, contained in a standard bottle or a can of regular beer, a glass of dinner wine (125 mL), a small glass (30 mL) of spirits and a measure (60 mL) of aperitif. Moderate alcohol use is defined as 1 AU daily for women and 2 for men. A safe maximum daily alcohol consumption is generally regarded as 3 units for a man and 2 for a woman. Alcohol misuse, defined as a daily intake in excess of 5 units, is the most common form of drug misuse. The World Health Organization estimates that there are almost 80 million people worldwide with diagnosable alcohol misuse disorders. Over 25% of the UK population appear to drink to excess (44% of men in Scotland also drink to excess). There seems to be a genetic predilection to alcoholism.

The term 'alcohol', as used in medicine and by the lay public, typically applies to ethanol (CH₃CH₂OH), which is produced by yeast fermentation of carbohydrates, such as in fruit and starch. Fermentation is incomplete in beer but complete in wine, with resulting alcohol contents of 3–8% and 7–18% by volume, respectively. Spirits (e.g. whisky, brandy and vodka) are produced by distillation of fermented products, and are 30% or greater alcohol by volume.

A cocktail is a mixed drink usually containing one or more alcoholic beverages, flavourings and one or more fruit juices, sauces, honey, milk, cream or spices, etc. A subgroup of cocktails are pre-mixed and bottled cocktails, generally known as alcopops, RTDs (ready to drink) or FABs (flavoured alcoholic beverages); they are usually made from vodka, beer, whisky or rum, to reach an alcohol concentration of 4–7% by volume, and are sweet and fruit-flavoured because they are mixed with cola, lemonade, ginger ale, etc.

Ethanol is rapidly absorbed through the gastric and duodenal mucosae, and metabolized by the liver, with a small fraction metabolized by oral and upper digestive tract mucosa. Alcohol dehydrogenase

Fig. 34.2 Alcoholism.

Table 34.14 Alcohol in various alcoholic beverages

Beverage	Strength of alcohol	Amount	Units of alcohol
Beer, cider, lager	3.5%	Half-pint	1
	3.5%	Pint	2
	Export strength 5%	Pint	2.5–3
	8%	Pint	4.5
Alcopop	5%	330 mL	1.7
Wine	10%	One glass	1
	10%	750 mL	7.5
	12%	750 mL	9
	Fortified (e.g. sherry) 15–20%	700 mL	16
Spirits	40%	One measure	1
	40%	700 mL	32

catalyses ethanol oxidation to acetaldehyde, which is oxidized into non-toxic acetate by aldehyde dehydrogenase. In turn, acetate is oxidized into fatty acids, carbon dioxide and water. Ethanol blocks nitrosamine metabolism in the liver, thus allowing nitrosamines to circulate to other organs, such as the kidneys and oesophagus, where they can be activated into carcinogens. Alcoholic beverages also contain polyphenols – plant secondary metabolites, which play an important protective role via their potent antioxidant activity; resveratrol in red wine is one example. In contrast, the diet of alcoholics is often B-vitamin-deficient.

Box 34.3 Mental effects of alcohol

- Acute intoxication
- Amnesic syndrome
- Dependence syndrome
- Psychotic disorder
- Withdrawal state

Table 34.15 Acute effects of alcohol (blood alcohol level in mg/dL)

<100	100–200	200–300	300–400	400–500	>500
Dry and decent	Delighted and devilish	Delinquent and disgusting	Dizzy and delirious	Dazed and dejected	Dead drunk

Clinical features

Alcohol is a CNS depressant and can have a range of mental effects (Box 34.3). Acute effects are mainly on judgment, concentration and coordination, individuals becoming aggressive and failing to comply with instructions. Effects are dose-related; they eventually interfere with cerebellar function, causing ataxia and motor incoordination, and ultimately unconsciousness (Table 34.15). After a large alcoholic binge, suppression of the cough reflex can result in inhalation of vomit and death.

Alcohol misuse (alcoholism) is consumption of alcohol to such a degree as to cause deterioration in social behaviour or physical illness and the development of dependence, from which withdrawal is difficult or causes adverse effects. The mortality rate in alcoholism is significantly raised and over 15 years may be about 300% above the norm. Alcohol interferes with CNS function and is causally related to more than 60 different medical conditions; some, such as suicide, homicide and different forms of accidents (e.g. falls, poisoning, accidents caused by flames or by motor vehicles), are acute consequences of alcohol use. Alcohol is an important, if not the main, causal factor in over 25% of road traffic accidents and also in many other accidents or assaults. Acute alcoholic hepatitis may follow binge-drinking; cirrhosis commonly results from chronic alcoholism. Alcohol contributes to the spread of SSIs (including HIV), and to impaired wound-healing and predisposition to respiratory infections, especially pneumonia and tuberculosis.

The probability of developing alcoholism is greater in several groups, especially those to whom alcohol is freely available (Table 34.16). Late signs or symptoms of chronic excessive alcohol drinking include palpitations and tachycardia, cardiomyopathy, liver disease, chronic pancreatitis, malnutrition, peripheral neuropathy, amnesia and confabulation (in Wernicke and Korsakoff CNS syndromes). Cerebellar degeneration and ataxia, dementia, haemorrhagic stroke and various forms of cancer are consequences of chronic alcohol use (Table 34.17).

A diet poor in fruits and vegetables is typical of heavy drinkers and can cause nutritional defects, leading in turn to immune defects and peripheral polyneuropathies (burning hands and feet), pellagra, amblyopia (visual defects) and organic brain disorders (Wernicke encephalopathy and Korsakoff psychosis).

Alcohol is now the most common teratogen apart from smoking, and drinking during pregnancy has a detrimental effect on fetal development. It can lead to spontaneous abortion or the fetal alcohol syndrome (FAS), the prevalence of which is similar to that of Down syndrome. FAS affects growth, the CNS and orofacial features. Most affected children are of short stature; microcephaly is common and

Table 34.16 *Alcoholism*

Risk factors	Suggestive findings	Outcomes
Armed forces	Absenteeism	Brain damage and epilepsy
Bachelors over 40	Accidents	Cancers
Bored housewives	Assaults	Fetal alcohol syndrome
Commercial travellers	Cirrhosis	Gastrointestinal disease: gastritis and peptic ulcer
Doctors	Family history of alcoholism	Heart disease: cardiomyopathy
Entertainers	Frequent job changes	Inadequate diet leading to immune defects, peripheral polyneuropathies and organic brain disorders
Publicans and other workers in the drinks industry	Gamma-glutamyl transpeptidase raised	Impaired haemostasis
	Macrocytosis	Impaired wound healing
	Marital disharmony	Infections, especially pneumonia and tuberculosis
	Medical history	Injuries (including maxillofacial), from accidents or assaults
	Social history	Liver disease: alcoholic hepatitis and cirrhosis
	Violence	Muscle disease: myopathy
		Nutritional defects
		Pancreatic disease; pancreatitis

Table 34.17 *Effects of chronic alcohol use*

System	Possible effects	Biochemical changes
Cardiac	Cardiomyopathy, hypertension, arrhythmias	–
CNS	Intoxication, dependency, dementia Wernicke–Korsakoff syndrome	Raised blood alcohol Decreased thiamine levels
Gastric	Gastritis, ulceration, carcinoma	–
Haematological	Pancytopenia Folate deficiency Thiamine deficiency Immune defect	Macrocytosis, anaemia Thrombocytopenia, leukopenia Reduced blood-clotting factors: II, VII, IX, X
Hepatic	Hepatitis, fatty liver (steatosis), cirrhosis, liver cancer	Raised gamma-glutamyl transpeptidase, carbohydrate-deficient transferrin (CDT), liver enzymes, bilirubin
Intestinal	Glucose and vitamin malabsorption	Reduced folate, thiamine and vitamins B ₁₂ , A, D, E and K
Musculoskeletal	Myopathy, gout	–
Oesophageal	Gastro-oesophageal reflux disease (GORD), Mallory–Weiss syndrome, carcinoma	–
Pancreatic	Pancreatitis	Raised serum amylase
Reproductive	Impotence, dysmenorrhoea, low-birth-weight babies, fetal alcohol syndrome	–

individuals may have a low IQ, difficulties in eating and speech, and muscular incoordination. The FAS patient is irritable as an infant, hyperactive as a child and highly unsociable as an adult. Facial features include hypoplastic maxillae, a low nasal bridge, an indistinct philtrum with a hypoplastic upper lip, and other features, including small teeth with dysplastic enamel.

Alcohol should only be drunk in moderation, with meals, and when consumption cannot put others at risk. It should not be consumed by: children; women trying to conceive or already pregnant; anyone about to drive a motor vehicle, fly a plane or take on any other skilled activity; HCPs about to treat patients; and anyone taking prescription or over-the-counter medicines that affect CNS or respiratory function.

General management

Recognition of the alcoholic is notoriously difficult and the history unreliable. Findings that suggest alcoholism may arise from the social or medical history (Table 34.18). The CAGE questionnaire may be helpful and a positive response to any of the following questions suggests a diagnosis of alcoholism:

- Have you ever felt the need to cut down on drink?
- Have you ever felt annoyed by criticism of your drinking?

Table 34.18 *Findings suggesting alcoholism*

Social history	Medical history
Absenteeism	Accidents
Assaults	Cirrhosis
Violence	Macrocytosis
Frequent job changes	Folate deficiency or raised carbohydrate-deficient transferrin (CDT) or gamma-glutamyl transpeptidase
Marital disharmony	Family history of alcoholism

- Have you ever felt guilty about drinking?
- Do you drink a morning eye opener?

Two or more affirmative answers indicate probable alcoholism. A five-shot questionnaire suggests alcoholism if it produces scores over 5 (Table 34.19). The NHS has a useful questionnaire (Appendix 34.2).

Signs may include discovery of used bottles at home, at work or elsewhere. Signs or symptoms of chronic excessive alcohol intake include: slurred speech; alcohol on the breath; self-neglect (whether of the mouth or shabbiness of clothes); an evasive, truculent, over-boisterous or facetious manner; indigestion (particularly heartburn); anxiety (often with insomnia); or tremor. Later signs or symptoms

Table 34.19 Five-shot questionnaire for detecting alcoholism

Question	Scores				
	0	0.5	1.0	1.5	2.0
How often do you have a drink containing alcohol?	Never	<Monthly	2–4 times/month	2–3 times/week	≥4 times/week
How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 or 8	10 or more
Have people annoyed you by criticizing your drinking?	No	No	Yes	Yes	Yes
Have you ever felt bad or guilty about drinking?	No	No	Yes	Yes	Yes
Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?	No	No	Yes	Yes	Yes

include palpitations and tachycardia, cardiomyopathy and signs of malnutrition.

Blood investigations that may be diagnostically helpful may detect macrocytosis, raised levels of alcohol, gamma-glutamyl transpeptidase (gamma-GT or GGT) and other hepatic enzymes, levels above 1.3% of carbohydrate-deficient transferrin isoforms (% CDT), and folate deficiency of no obvious cause.

Treatment of alcoholism is by encouraging the patient to drink in a less damaging way and to accept help to deal with the crises and the physical, behavioural and social damage that result, or to learn to abstain from alcohol. Admission to manage rehabilitation and ensure abstinence, nutritional replacement of thiamine and folate, and drugs that reduce dependence (naltrexone, acamprosate or clomethiazole) or that cause unpleasant side-effects if alcohol is taken (disulfiram [Antabuse]) may help.

If the alcohol supply is reduced or cut off, or if blood alcohol levels fall sharply, the abstinence or alcohol withdrawal syndrome (AWS) may appear, with morning 'shakes' – typically trembling of the hands but possibly involving the whole body. Morning nausea and vomiting are sometimes called 'toothbrush heaves'. Other withdrawal symptoms are diarrhoea, sweating, rapid pulse and raised blood pressure, confusion, agitation, fits, illusions, misperceptions, hallucinations or delusions. The full-blown syndrome is called 'delirium tremens' or 'DTs'. The whole withdrawal syndrome lasts about a week and requires medical supervision and use of benzodiazepines or clomethiazole.

Dental aspects

Many alcoholics present no dental management problems, though there may be issues related to informed consent if the person is inebriated. Challenges may also include erratic attendance for dental treatment and aggressive behaviour. Alcoholics are best given an early morning appointment, if that is when they are least likely to be under the influence of alcohol.

The main relevant medical complications stem from the fact that cirrhosis delays the metabolism of many drugs and may cause a bleeding tendency. Chronic alcoholism may also depress the bone marrow to cause anaemia and thrombocytopenia. Other problems may include cardiomyopathy, poly-substance misuse, smoking and drug interactions. Alcohol can interact with other drugs, sometimes inducing the cytochrome P450 enzyme system to accelerate their metabolism, in others depressing their metabolism. Warfarin, paracetamol (acetaminophen) and benzodiazepines may be affected.

GA is best avoided, especially if patients have pre-medicated themselves with alcohol, and increased the risk of vomiting and inhalation of vomit. Alcoholics are especially prone to aspiration lung abscess. Alcoholic heart disease is also a contraindication.

Alcoholics are also notoriously resistant to GA. Once liver disease develops, the position is reversed: drug metabolism is then impaired

(Ch. 9) and drugs have a disproportionately greater effect. Sedatives (including benzodiazepines and antihistamines) or hypnotics generally have an additive effect with alcohol, although these interactions are not entirely predictable. Heavy drinkers, however, become tolerant not only of alcohol but also of other sedatives.

Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided; in the alcoholic patient they are more likely to cause gastric erosions and precipitate bleeding. Opioids may enhance sedation. The hepatotoxic effects of paracetamol (acetaminophen) are enhanced, though it is probably the safest analgesic.

Alcohol-containing preparations, such as some mouthwashes, should be avoided in patients given metronidazole within the last 48 hours. Metronidazole inhibits the liver breakdown of acetaldehyde, which accumulates to cause widespread vasodilatation, nausea, vomiting, sweating, headache and palpitations similar to the disulfiram (Antabuse) reaction. The effects of penicillins and erythromycin may be reduced by alcohol.

Wound healing may also be impaired in the severely chronic alcoholic, and alcoholism may be a common factor in patients with osteomyelitis following jaw fractures. The most common oral effect of alcoholism is neglect, leading to advanced caries and periodontal disease, and there is sometimes tooth surface loss from caries, dental erosion from regurgitation (or from the beverage low pH) and/or attrition from bruxism.

Alcohol may be a cause of leukoplakia and oral cancer. There may be folate deficiency or other anaemia causing glossitis and sometimes angular stomatitis or recurrent aphthae. A rare manifestation is bilateral painless swelling of the parotids or other major salivary glands (sialosis).

Other orofacial features include a smell of alcohol on the breath, telangiectases and possibly rhinophyma ('grog blossom').

AMPHETAMINES

Amphetamines stimulate alpha- and beta-adrenergic receptors in the CNS and peripheral nervous system, essentially producing similar effects to cocaine. They are used for euphoriant effect, for staving off fatigue in order to continue work or for slimming. Amphetamines are usually taken orally but can also be injected, snorted or smoked (ice; crystal).

Amphetamines raise the blood pressure and sometimes temperature, and cause sleeplessness and anorexia. Acute amphetamine toxicity causes dry mouth, dilated pupils, tachycardia, aggression, talkativeness, tachypnoea and hallucinations, leading to seizures, hyperpyrexia, arrhythmias and collapse. High doses can cause mood swings and psychoses – including hallucinations and paranoia – and can cause respiratory failure and death. Chronic amphetamine toxicity causes restlessness, hyperactivity, loss of appetite and weight, tremor, repetitive

movements, picking at the face and extremities, and bruxism, and there can be hyposalivation and increased caries incidence.

Amphetamines have no true withdrawal syndrome and, in this respect, addiction is quite different from opioid or barbiturate dependence. Unfortunately, psychoses can persist after the drug has been stopped. Addicts may be remarkably resistant to GA and, if taking drugs intravenously, may have many of the infective problems of opioid addicts. If GA is required, intravenous barbiturates may induce convulsions, respiratory distress or coma, and should be avoided. Opioids are also contraindicated. Amphetamines enhance the sympathomimetic effects of adrenaline (epinephrine) and thus vasoconstrictors are best avoided, since hypertension and cardiotoxicity can result. Monoamine oxidase inhibitors are contraindicated.

BARBITURATES

Barbiturates are depressant drugs used mainly to treat anxiety, tension and sleep disorders; they cause sedation and depress respiration and heart rate, as well as impairing thought processes and memory, and causing incoordination and ataxia. With chronic use, addicts begin to think slowly and to have increasing emotional lability; concentration and judgment are increasingly impaired, and the barbiturate addict becomes irritable and shows signs of self-neglect.

Although tolerance to barbiturates develops, the lethal dose remains the same, with only a small gap between relatively safe and lethal levels. Accidental overdose is a comparatively common cause of death from respiratory failure and CNS depression, especially if alcohol is also taken. Barbiturates are also often used to adulterate more expensive drugs such as heroin and are responsible for many of the fatal overdoses. There is no antidote to overdose; artificial ventilation is used until respiratory function recovers.

Two main types of barbiturate addict are recognized and either may also misuse other drugs. Middle-aged women, often living alone, taking large quantities of barbiturates orally and living in a dream world, form the largest group; chronic toxicity, such as rashes and ataxia, often develops. Young addicts, who take barbiturates ('sleepers') for immediate effect by injection, are at risk of complications from filthy injection technique, including multiple abscesses, gangrene, hepatitis, HIV infection, infective endocarditis or occasionally tetanus.

Should barbiturates be withdrawn, the addict initially improves and any ataxia disappears but, within 12–16 hours, a dangerous withdrawal syndrome can develop. Nausea, anxiety, tremor, insomnia, tachycardia, weakness and postural hypotension are followed by abdominal pain. After 36–48 hours, in heavy users, there may be loss of consciousness, often fits and sometimes death. The syndrome has a slower onset in those who have been using long-acting barbiturates.

Dental management may be complicated by barbiturates enhancing the sedative effects of some drugs, or inducing liver drug-metabolizing enzymes and causing resistance to anaesthetics. Other problems may include hepatitis B and C, HIV infection and SSI, epilepsy, maxillo-facial injuries and tetanus.

Oral complications of barbiturate misuse are rare. A bullous mucosal reaction has been reported but manifestations such as idiopathic facial pain, related to the underlying condition for which the drug was prescribed, are more common.

BENZODIAZEPINES

Benzodiazepines are prescribed to treat anxiety, acute stress reactions and panic attacks. Memory loss is a major feature. Psychological dependence on benzodiazepines is common but the effects are considerably less

severe than with most other sedatives. Physical dependence can develop fairly quickly – sometimes within 1 month. Withdrawal symptoms are frequently delayed in onset compared with the barbiturates but may last 8–10 days. Typical effects include insomnia, anxiety (which may be incorrectly attributed to the return of the original anxiety state), loss of appetite, tremor, perspiration and perceptual disturbances, and occasionally fits or psychoses. Sudden withdrawal, particularly of short-acting benzodiazepines, is dangerous since it can cause confusion, fits, toxic psychosis or a condition resembling delirium tremens.

BETEL

Betel quid or paan chewing is widely used and is claimed to produce a sense of well-being, euphoria, sweating, salivation, palpitation, heightened alertness and increased capacity to work. Betel quid is a mixture of areca (betel) nut and slaked lime, to which tobacco can be added, all wrapped in betel leaf. Arecoline (methyl-1-methyl-1,2,5,6-tetrahydropyridine-3-carboxylate) is the primary active ingredient of areca nut and is responsible for CNS stimulant effects, comparable to those of nicotine. Arecoline is an agonist of acetylcholine muscarinic M_1 , M_2 and M_3 receptors, causing pupillary constriction, bronchial constriction and so on. Plasma noradrenaline (norepinephrine) and adrenaline (epinephrine) levels also rise during betel quid chewing. The specific quid components vary between communities and individuals where it is used, having a major social and cultural role in communities throughout the Indian subcontinent, South-East Asia and locations in the western Pacific. Betel use is well recognized by tooth and soft-tissue staining (Fig. 34.3) and can have a number of health consequences (Table 34.20), especially oral submucous fibrosis (OSMF). Though not regarded as a connective tissue disease, OSMF has pathological changes very similar to those of scleroderma. It is a chronic disease and is almost entirely confined to Asians, related to the use of areca nut in gutkha or paan masala, or in other chewables (kharra, chewable tobacco). OSMF causes severe and often disabling fibrosis, characterized by fibrous bands beneath the oral mucosa that progressively contract so that mouth-opening is increasingly severely limited. As many as 10% of OSMF patients develop oral carcinoma. Intralesional corticosteroids and regular stretching of the oral soft tissues with an interdental screw may delay fixation in the closed position. Failing this, operative treatment may become necessary.

CAFFEINE

Caffeine is an alkaloid stimulant widely used in many cultures. Found in over 60 plants, it is most commonly derived from coffee or tea plants. Other sources include kola, cocoa, guarana and yerba mate. Chocolate contains a small amount. Caffeine is called guaranine when found in *guarana*, mateine when found in *mate* and theine when found in *tea*. There is far more caffeine in coffees than in teas. Significant amounts of caffeine are also added to some soft and 'energy' drinks (e.g. Red Bull, Relentless, Cocaine; the amount of caffeine has to be stated on the label where it contains more than 150mg caffeine/L). Some of these 'energy drinks' are banned in some countries.

Caffeine is diuretic and psychoactive, leading to a rise in brain dopamine, serotonin and catecholamines. Caffeine metabolites include theobromine (increases the blood flow to the brain and muscles), theophylline (relaxes bronchioles and increases heart rate and efficiency) and paraxanthine (increases lipolysis, releasing glycerol and fatty acids for use as a muscle energy source). Coffee and tea also contain other xanthine alkaloids: for example, cardiac stimulants theophylline and

Fig. 34.3 Betel staining.

Table 34.20 Possible adverse health effects from betel chewing	
Health effect	Examples
Cancer and potentially malignant conditions	Hepatocellular cancer
	Oesophageal cancer
	Oral cancer
	Oral submucous fibrosis
	Pancreatic cancer
Cardiovascular and diabetes	Hypertension
	Metabolic syndrome
Adverse birth outcomes	Lower birth weight
	Lower male-to-female sex ratio
	Reduced birth length
Others	Contact dermatitis
	Chronic kidney disease
	Liver cirrhosis
	Periodontitis
	Urinary calculi (related to use of calcium hydroxide 'chuna' in the betel quid)

theobromine (tea only) and other substances such as polyphenols, which can complex insolubly with caffeine and alter its activity.

Caffeine tolerance develops very quickly, especially among heavy coffee and energy drink consumers; when caffeine use is stopped, the falling serotonin levels can cause anxiety, irritability, inability to concentrate and diminished motivation or depression. Excess caffeine can lead to caffeine intoxication, caffeine-induced anxiety disorder or caffeine-induced sleep disorder.

Studies suggesting caffeine intake is associated with a risk of miscarriage or a reduced risk of developing Parkinsonism or cardiovascular disease are inconclusive. Some Latter-day Saints (Mormons), Christian Scientists and Gaudiya Vaishnava Hindus do not consume caffeine.

COCAINE

Cocaine is widely used worldwide and in all levels of society. Cocaine hydrochloride, from the plant *Erythroxylon coca*, is one of the most widely abused drugs and is powerfully addictive. Having once tried cocaine, individuals may not be able to control the extent to which they will continue to use it. ‘Crack’ is the street name given to cocaine processed with ammonia or sodium bicarbonate (baking soda) and water, and heated to remove the hydrochloride (producing a crackling sound) to a free base for smoking. Cocaine is often snorted – inhaled through the nose, where it is rapidly absorbed into the blood – giving a ‘high’ lasting 15–30 minutes. It may also be injected or smoked.

Cocaine has profound and almost immediate CNS effects, potentiating catecholamines and interfering with dopamine reabsorption. Euphoric effects appear in less than 5 minutes and include hyperstimulation and diminished fatigue and appetite. Extremely high doses reach the brain quickly and bring an intense and immediate high, which can last 5–10 minutes. Physical effects of cocaine mimic those of catecholamines, and include dilated pupils, constricted peripheral blood vessels, and raised temperature, pulse rate and blood pressure. Cocaine causes feelings of well-being and heightened mental activity; the cocaine addict is garrulous, witty and the life and soul of the party – aptly described as a ‘sexed-up extrovert with dilated pupils’. High doses of cocaine and/or prolonged use can, however, trigger paranoia, visual hallucinations (snow lights) and tactile hallucinations. The latter are typically of insects crawling over the skin (formication, ‘cocaine bugs’). Toxic reactions include angina, coronary spasm, ventricular arrhythmias, myocardial infarction, cerebrovascular accidents, convulsions and respiratory depression. Cocaine-related deaths are often a result of cardiac arrest, cerebrovascular accidents or seizures followed by respiratory arrest. Prolonged cocaine snorting can result in ischaemic necrosis with ulceration of the nasal mucous membrane and nasal septum collapse, ulceration of the palate, and sphenoidal sinusitis. It occasionally leads to brain abscess.

As a constituent of Brompton cocktail (cocaine, heroin or morphine, and alcohol), cocaine is also sometimes used to make terminal disease more tolerable. However, when people choose to mix cocaine and alcohol, they are also compounding the dangers, since the liver combines them, manufacturing cocaethylene, which intensifies the euphoric effects and increases the risk of sudden death. Use of cocaine plus heroin intravenously (‘speedballing’) is also highly dangerous.

When cocaine is stopped, symptoms proceed through a crash phase of depression and craving for sleep, a withdrawal phase of lack of energy, and then an extinction phase of recurrence of craving evoked by various external stimuli but of lesser intensity. Depression, fatigue, bradycardia and psychoses may be seen. Behavioural interventions, particularly cognitive behavioural therapy, can be effective in reducing cocaine misuse.

Behavioural problems or drug interactions may interfere with dental treatment. Injected cocaine brings the risk of the same blood-borne infections as in other addicts. It is important to avoid local anaesthesia (LA) containing adrenaline (epinephrine) in persons using cocaine until at least 2 hours have elapsed because of enhanced sympathomimetic action and subsequent arrhythmias, acute hypertension or cardiac failure. Therefore, it is best not to give dental treatment until 6 hours after the last dose of cocaine has been taken. When GA is needed, isoflurane and sevoflurane are preferred to halothane, which may induce arrhythmias. Ketamine and suxamethonium (scoline) are also best avoided.

Oral use of cocaine temporarily numbs the lips and tongue, and can cause gingival or mucosal erosions (Fig. 34.4). The main oral effects of cocaine addiction may be a dry mouth and bruxism or dental erosion. Caries and periodontal disease, especially acute necrotizing gingivitis, are more frequent. Cocaine may precipitate cluster headaches. Children born to cocaine-using mothers are more prone to have ankyloglossia.

DEXTROPROPOXYPHENE

Co-proxamole (because of the dextropropoxyphene, a weak opioid) is also abused.

DIPIPANONE

Dipipanone is sometimes abused in tablet form and in combination with an anti-emetic (Diconal). It is less sedating than morphine.

Fig. 34.4 Cocaine damage in palate.

ECSTASY (3,4-METHYLENEDIOXY-METHAMPHETAMINE; MDMA)

Ecstasy is a synthetic, psychoactive, amphetamine-like drug with sympathomimetic activity, and both stimulant and hallucinogenic properties. Like other amphetamines, it produces euphoria and appetite suppression, but is more potently hallucinogenic.

Ecstasy is usually taken orally, giving effects after 20–60 minutes. Unfortunately, the tablets may contain other amphetamine derivatives, caffeine, ketamine or salicylic acid, or ecstasy may be used along with cannabis, alcohol, amphetamine or cocaine (increasing the hazards of use). Adverse effects from ecstasy include neurological effects (e.g. ataxia and seizures), psychiatric sequelae (e.g. agitation or paranoia) and cardiovascular effects (e.g. tachycardia, arrhythmias or infarction), as well as renal or hepatic failure or other effects – unrelated to the dose. Ecstasy causes brain injury, affecting dopamine-containing neurons that use serotonin to communicate with other neurons. The serotonin system plays a direct role in regulating mood, aggression, sexual activity, sleep and sensitivity to pain. Ecstasy users face risks similar to those caused by cocaine and amphetamine – psychological difficulties, including confusion, depression, sleep problems, drug craving, severe anxiety and paranoia, during and sometimes weeks after taking it, and physical symptoms such as muscle tension, involuntary teeth-clenching, nausea, blurred vision, rapid eye movement, faintness, and chills or sweating.

Ecstasy can cause a sharp, potentially fatal rise in body temperature (malignant hyperthermia), leading to muscle breakdown and kidney and cardiovascular system failure. Ecstasy users need to take water or non-alcoholic drinks frequently and in large amounts to avoid hyperthermia ('chill-out'). Deaths are rare but usually caused by high temperatures, raised heart rate and blood pressure, and myocardial infarcts, hyponatraemia or asthma. At special risk are people with circulatory or heart disease. Individuals who develop a rash resembling acne after using ecstasy may be risking severe liver damage if they continue to use the drug. After long-term use, tolerance develops but there is no physical dependence or withdrawal symptoms.

Teeth-clenching and bruxism appear to be common; temporomandibular joint dysfunction, dry mouth, attrition, erosion, mucosal burns or ulceration, circumoral paraesthesiae and periodontitis have been reported. Ecstasy can interact with adrenaline (epinephrine) and with tricyclic or selective serotonin reuptake inhibitor (SSRI) antidepressants.

GHB (GAMMA-HYDROXYBUTYRATE)

GHB is abused for euphoric, sedative and anabolic (body-building) effects. GHB and two of its precursors, gamma-butyrolactone (GBL) and 1,4-butanediol (BD), have been involved in poisonings, overdoses, date rapes and deaths. Coma and seizures can follow misuse of GHB and, when combined with methamphetamine, there appears to be an increased risk of seizure. Combining use with other drugs such as alcohol can result in nausea, difficulty in breathing and unconsciousness. GHB may also produce withdrawal effects, including insomnia, anxiety, tremors and sweating.

HEROIN

See Opiates and opioids.

KETAMINE

Ketamine is a GA agent related to phencyclidine (PCP), which can cause a dream-like state and hallucinations; it has been used as a date-rape drug. Ketamine effects come on and recede faster than those of LSD but include aggression (as with PCP) and temporary blindness; the drug can also cause delirium, amnesia, impaired motor function, hypertension, depression and potentially fatal respiratory problems.

KHAT (QAT)

Khat is from a shrub that has been chewed for centuries by people from the Horn of Africa and Arabian peninsula, including the UK, particularly from countries such as Somalia, Ethiopia and Yemen. It is a stimulant like amphetamine and the active ingredients, cathinone and cathine, are Class C drugs. Khat chewing causes oral white lesions on the chewing side and a correlation between khat chewing and oral cancer has been suggested. There is weak evidence for khat chewing influencing the incidence of myocardial infarction, cardiomyopathy, hypertension, cerebrovascular disease, diabetes, sexual dysfunction, duodenal ulcer and hepatitis.

LEGAL HIGHS

New psychoactive (NPS) substances include "legal highs" – substances used like illegal drugs but not covered by current misuse of drugs laws – and so it is legal to possess or to use – though temporary laws are being introduced for some. Examples include

- a new range of synthetic cannabinoids, methoxetamine and other related compounds and O-desmethylnaloxone
- desoxypipradrol (2-DPMP), its related compounds and phenazepam
- naphyrone and other synthetic cathinones, tapentadol and amineptine
- NBOMe and benzofuran (Benzofury) compounds
- para-methyl derivative of 4-methylaminorex ('Speckled Red' or 'Brown Cherries').

LSD (LYSERGIC ACID DIETHYLAMIDE)

LSD (acid) is a major hallucinogen; it is manufactured from lysergic acid, found in ergot, a fungus that grows on rye and other grains. Within 30–90 minutes of taking LSD orally, several different emotions appear at once or swinging rapidly from one to another

(a 'trip'). Synaesthesia, the overflow from one sense to another when, for example, colours are heard, is common. These effects can last up to 12 hours and, even months after such a 'trip', many LSD users experience flashbacks – recurrence of certain aspects of a person's experience – without the user having taken the drug again. There is often lability of mood, panic ('bad trip') and delusions of magical powers, such as being able to fly. If taken in a large enough dose, LSD causes delusions, visual hallucinations and paranoia. The sense of time and self becomes distorted. LSD intoxication can cause severe, terrifying thoughts and feelings, as well as despair; fatal accidents have been precipitated. Taking LSD is especially risky because each tablet can contain very different amounts of drug – from as little as 25 micrograms to as much as 250 micrograms – enough to cause serious side-effects. The physical effects from LSD are similar to those of catecholamines – dilated pupils; raised temperature, heart rate and blood pressure; sweating; loss of appetite; sleeplessness; dry mouth; and tremors. The effects of LSD are not only unpredictable but also prolonged, often lasting up to about 12 hours, depending on the amount taken, the user's personality, mood and expectations, and the surroundings in which the drug is used. However, LSD is not considered an addictive drug since it does not produce the compulsive drug-seeking type of behaviour as shown by users of drugs such as cocaine, amphetamine, heroin, alcohol and nicotine. Most users of LSD voluntarily limit or stop its use over time.

MARIJUANA (CANNABIS)

Marijuana is the most commonly abused illicit drug in the developed world, aside from alcohol, and is used religiously in Rastafarianism. A dry, shredded, green/brown mix of flowers, stems, seeds and leaves of the hemp plant *Cannabis sativa* or *Cannabis indica*, it is usually smoked as a cigarette (joint, nail) or in a pipe (bong). It is also smoked in blunts – cigars that have been emptied of tobacco and refilled with marijuana – often in combination with another drug. Use also might include mixing marijuana in food or brewing it as a tea. As a more concentrated, resinous form it is called hashish and, as a sticky black liquid, hash oil.

The main active chemical in marijuana is delta-9-tetrahydrocannabinol (THC), which binds to brain receptors that influence pleasure, memory, thought, concentration, sensory and time perception, and coordinated movement. The marijuana currently used is many times more potent than that taken in the 1950s. The short-term adverse effects of marijuana use can include difficulties with memory and learning, distorted perception, difficulty in thinking and problem-solving, and loss of coordination. Critical skills related to attention, memory and learning are significantly impaired; students who smoke marijuana obtain lower examination grades and are less likely to graduate compared with non-smoking peers. Marijuana use is associated with depression, anxiety and personality disturbances; schizophrenia may be triggered in some.

Marijuana affects blood pressure and heart rate, and lowers the blood oxygen-carrying capacity. Smoking marijuana may more than quadruple the risk of myocardial infarction in the first hour, and frequently leads to respiratory illnesses such as infections, daily cough and sputum production, and obstructed airways. Marijuana smoke contains 50–70% more carcinogenic hydrocarbons than tobacco smoke and THC impairs immune function. Marijuana has been implicated in lung and oral cancer, as well as some other malignant disease, but the evidence is equivocal and could be related to concurrent tobacco use or other factors. Babies born to women who used marijuana during pregnancies display abnormal responses to visual stimuli, tremulousness and a high-pitched cry, features that may indicate neurological

maldevelopment. Later there may be behavioural problems and poor performance on tasks of visual perception, language comprehension, sustained attention and memory. No medications are currently available for treating marijuana misuse.

There are no specific aspects of addiction that influence dental management in most patients, but there is a tendency to a dry mouth and increased cravings for certain foods ('the munchies'), hyposalivation, increased *Candida* carriage and oral white lesions.

MEPHEDRONE (MEOW MEOW)

Mephedrone (dimethylmethcathinone, 4-methylmethcathinone or 4-methylephedrone) and naphyrone (naphthylpyrovalerone) are cathinones, synthetic stimulants closely related to amphetamines and found in the African plant khat. Other cathinones include methadrone, methylone and related compounds. Slang names include drone, meph, MC, 4-MMC, MCAT, miaow, bath salts, white magic, plant feeder, just plant, charge, bounce and Bubbles.

Mephedrone is sold as an inexpensive white powder that is usually snorted in a similar way to cocaine. It is also found in capsules and pills or can be dissolved in a liquid. In very rare cases it can be injected. Mephedrone initially was not controlled under the UK Misuse of Drugs Act and therefore was sometimes called a 'legal high', but in 2010 mephedrone and MDPV (methylenedioxy-pyrovalerone) were reclassified as illegal group B drugs.

The main effects and risks of mephedrone include euphoria, alertness and feelings of affection towards the people around, as well as feelings of anxiety and paranoia. Mephedrone has physical effects: for example, on the cardiovascular system, with tachycardia and arterial constriction leading to cold, blue hands and feet. Excessive CNS stimulation may cause headaches, insomnia, agitation and hallucinations, as well as seizures, which may be fatal. Snorting mephedrone can damage the nose, causing nosebleeds. Other adverse effects include bruxism, nausea and vomiting, appetite suppression, sweating and changes in body temperature. Most of those adverse effects are like those of ecstasy and cocaine. Anecdotal reports suggest that heavy use can lead to paranoia, hallucinations and serious panic attacks.

METHAMPHETAMINE

Methamphetamine is an addictive stimulant with stronger CNS effects than amphetamine, releasing high levels of dopamine, which enhance mood and body movement. Unlike amphetamine, methamphetamine users may become quickly addicted. Methamphetamine is also neurotoxic, damaging brain cells that contain dopamine and serotonin and, over time, lowering levels of dopamine, which can result in Parkinsonism. Methamphetamine also raises heart rate and blood pressure, and can cause cardiovascular collapse, strokes, hyperthermia and convulsions, which can be fatal. 'Meth mouth' is the term given to the neglect and poor oral hygiene seen in methamphetamine users.

METHOXETAMINE

Methoxetamine (also known as roflcoptr, rhino ket, MXE, moxy, MKET, mexy and mexxy) is a newly reported 'legal high', chemically related to 'dissociative anaesthetics' like ketamine and PCP, and having similar effects. It produces feelings of euphoria, warmth, 'enlightenment' and detachment from the world around, as well as hallucinations, restlessness and a feeling of being on edge, insomnia, tremors and sweating. Some people feel as if they have extra energy.

Table 34.21 Main types of tobacco smoking in different cultures

African	Arabic	South Asian	Western
Cigarettes	Cigarettes, hookah (shisha – water pipe)	Cigarettes, bidi (cheerot), chuta (reverse smoking) kreteks, hookah	Cigarettes, cigars, pipe

METHYLPHENIDATE (RITALIN)

Methylphenidate is a CNS stimulant often prescribed for children with attention deficit hyperactivity disorder (ADHD). It may amplify dopamine release, thereby improving attention and focus. It has effects similar to, but more potent than, caffeine but less potent than amphetamine. Some individuals misuse it for stimulant effects, appetite suppression, euphoria, wakefulness and enhanced focus/attentiveness.

NAPHYRONE

Naphyrone is a white crystalline powder that is snorted, or swallowed as ‘bombs’. It may also be known as, or found mixed with other drugs in, NRG-1, Energy1 or O-2482. Naphyrone is much more potent than mephedrone, perhaps even 10 times more so, and this could lead to a greater risk of overdose as the temptation is to use it in amounts similar to mephedrone. There is also a possible risk of naphyrone causing cancer – the naphthyl part of the compound is known to be carcinogenic. Naphyrone has physical effects: for example, on the cardiovascular system – it may cause tachycardia and arterial constriction leading to cold, blue hands and feet. Excessive CNS stimulation may cause headaches, insomnia, agitation and hallucinations, and seizures, which may be fatal.

NICOTINE AND TOBACCO

Tobacco is one of the most common lifestyle habits worldwide. It is frequently smoked in cigarettes but there are several other forms used in different cultures (Table 34.21).

Derived from plants of the genus *Nicotiana*, tobacco releases nicotine, one of the most heavily used and highly addictive stimulant drugs. Nicotine binds to a CNS receptor and, like cocaine, heroin and marijuana, raises the level of dopamine as well as opioids and glucose, and activates the nucleus accumbens. The type of nicotine cholinergic receptor and the enzyme CYP2A6 influence the chances of addiction. Nicotine also causes a discharge of adrenaline (epinephrine) from the adrenals, which stimulates the CNS and other endocrine glands, and a sudden release of glucose. Nicotine is absorbed readily from tobacco smoke in the lungs, acting in seconds on the brain but affecting the body for up to 30 minutes. Stimulation is followed by depression and fatigue, leading the abuser to seek more nicotine. If a person tries to stop smoking, withdrawal symptoms may appear, with excessive anger, hostility and aggression.

Tobacco smoking is a major health hazard, the smoke also containing a dozen gases (mainly carbon monoxide) and tar, which varies from about 15 mg for a regular cigarette to 7 mg in a low-tar cigarette. About 4000 compounds, including 40 known carcinogens such as nitrosamines and aromatic amines, are present, and promote many diseases including cancers (Table 34.22 and Fig. 34.5). There is also now suspicion that nicotine itself may also be carcinogenic. Cigarette smoking is particularly linked to cancers of lung, oesophagus, mouth and bladder, and to increased risk of cardiovascular disease, chronic obstructive pulmonary disease, hypertension and stroke – and thus is a leading cause of death. If women smokers also take oral contraceptives, they

Table 34.22 Diseases associated with cigarette smoking

System	Diseases
Cardiovascular	Ischaemic heart disease Peripheral vascular disease Buerger disease
Respiratory	Sinusitis Chronic obstructive pulmonary disease
Carcinomas	Oropharyngeal and oral Bronchial Bladder Breast Colorectal Laryngeal Pancreatic
Fetus	Higher prevalence of abortion Low birth weight Higher risk of perinatal and sudden infant deaths
Gastrointestinal	Periodontal disease Peptic ulcer
Central nervous system	Alcoholism Cerebrovascular disease Dementia

Fig. 34.5 Health effects of tobacco use.

are more prone to cardiovascular and cerebrovascular diseases than are other smokers; this is especially true for women older than 30. Pregnant women who smoke cigarettes run a greater risk of having stillborn or premature infants or infants with low birth weight, and the children have a raised risk for developing conduct disorders. Women who smoke generally have an earlier menopause. Second-hand smoke

Fig. 34.6 Tar staining on lips and fingers in a tobacco smoker.

Table 34.23 *Smoking history*

Questions	Smoker		
	Current	Former	Never
What smoked?			
How many per day?			
Age starting?			
How many years?			
Quit attempt?			
Quit success?			
Exposed to passive smoke?			

(passive smoking) causes lung cancer in adults and greatly increases the risk of respiratory illnesses in children and of sudden infant death.

Tobacco smoking may be recognized from the odour, or staining of fingers, teeth and even lips (Fig. 34.6), but a smoking history should be taken (Table 34.23).

Smoking cessation

Smoking cessation should be a gradual process, because withdrawal symptoms are less severe in those who quit gradually than in those who quit quickly. Rates of relapse are highest in the first few weeks and months, and diminish considerably after 3 months. There are five crucial steps in advising people to stop smoking, known as the 'five As':

- Ask
- Assess
- Advise
- Assist
- Arrange.

Ask

It is important that every patient who is seen by a health professional has their tobacco use noted on clinic records and that the information is kept as up to date as possible. Such a record should cover the frequency of smoking and how long the person has smoked. If the patient uses other forms of tobacco, this should be noted.

Assess

The HCP should inquire whether the patient is keen to quit, and ideally should elicit more detailed information on whether they have ever tried to give up. Any aids used in smoking cessation in the past should be noted.

Table 34.24 *Nicotine replacement therapies (NRTs)*

Type of NRT	Delivery system	Possible adverse effects
Chewing gum	Chewed gently to release nicotine	Jaw ache Gastric irritation Unsuitability for denture wearers
Inhalor/inhalator	Puffed steadily for about 20 min/h	–
Lozenges	Sucked until dissolution	–
Nasal spray	1–2 doses per hour taken for 2 months	Irritation of nasal mucosa
Sublingual tablets	4mg hourly taken for 3 months	–
Transdermal patches	Worn during waking hours	Local skin irritation

Advise

Every smoker must be told of the value that stopping smoking will have for them and of the dangers in continuing. Particularly if a risk lesion, such as an oral white or red patch was found, it is important to discuss the sequelae of continuing smoking – give plain, precise and personalized advice. Other reasons for quitting (e.g. the benefits for preventing heart disease) should be included in the advice. Pharmacological treatments combined with psychological treatment result in some of the highest long-term abstinence rates, so the advice, where appropriate, should include directions to use nicotine replacement therapy (NRT). There is little difference in effect between the different types of NRT (Table 34.24). Bupropion is as effective as NRT but can cause dry mouth, headache and gastrointestinal symptoms, and is contraindicated in pregnancy, people who have seizures, the under-18s, people with eating disorders, people with a CNS tumour, people on epileptogenic medications and the very old. Varenicline is more effective than NRT, and has a better efficacy and fewer adverse effects than bupropion; it may cause some nausea and depression, however, and interfere with driving. Electronic cigarettes (e-cigarettes) are becoming popular as a smoking cessation aid. The efficacy of e-cigarettes, as evaluated in preliminary studies, suggests success. Studies on nicotine craving when using e-cigarettes have had mixed results. A few studies have examined the effects of e-cigarettes on plasma nicotine levels and heart rate, and found negligible effects. Surveys have shown only minor side-effects, such as mouth and throat irritation, headache, vertigo and/or nausea. However, the Food and Drug Administration (FDA) has expressed concerns about manufacturing practices and the presence of carcinogens in products tested.

Assist

Other clinic staff should be encouraged to help any smoker who wishes to stop. Setting a date for quitting and arranging to remind a smoker through reception staff may be helpful. In the UK, the patient could be provided with the telephone number of the NHS smoking helpline or advised on how to visit an appropriate website. Useful leaflets should be available in the surgery for distribution.

Arrange

Arranging a follow-up is important, preferably within 1 week of quitting. Heavy smokers may also be referred to local smoking cessation services and helplines. This is important since studies show that people are twice as likely to quit successfully with intensive counselling.

Table 34.25 Non-smoking tobacco use in different cultures

African	Arabic	South Asian	Western
Toombak	Shama/ shammaah Nass/ naswar Zarda	Paan (pan; betel quid) ingredients can be used alone (e.g. mishri, zarda and kiwan) Khaini Gutkah Oral cleaning products (e.g. gudakha) Bajar and creamy snuff	Chewing tobacco (plug, loose leaf and twist) Snuff Snuss

Fortunately, smoking is increasingly being banned in public places in many countries.

Smokeless tobacco

Tobacco use in other forms is also deleterious to health (Table 34.25); nicotine is also absorbed readily when tobacco is chewed.

Dental aspects of nicotine and tobacco use

Difficulties in dental management of tobacco users may include associated disorders such as chronic obstructive pulmonary disease, ischaemic heart disease, alcoholism or peptic ulcer. Smokers metabolize some other drugs more rapidly and require, for example, higher doses of benzodiazepines than non-smokers. Smoking may cause mucosal keratinization and pigmentary incompetence, and is linked to oral cancer. Smoker keratosis, in which there is diffuse hyperkeratosis of the palate, is typically caused by pipe smoking; it is benign and rapidly reversible, even after years of pipe smoking. Oral snuff dipping and chewing tobacco predispose to leukoplakia and oral cancer. Up to 46% of regular users develop leukoplakia. Currently there is particular concern over the mucosal reactions and the carcinogenic potential of smokeless tobacco by children and adolescents, which is widespread, especially in the USA. Smoking also predisposes to periodontal disease, particularly necrotizing gingivitis, and to implant failure, dry socket, candidosis and xerostomia. Cigarette smoking is the most common cause of extrinsic staining of teeth.

Stopping smoking reduces the risk of oral cancer so that, by 5 years, it is down to that of a non-smoker. However, smoking cessation not only is difficult but also may bring other problems. Aggravation or the onset of recurrent aphthae is noted by some, while others take to eating sweets as a substitute for smoking and may then have more caries activity or put on weight. Use of nicotine-containing chewing gum may reduce the risk of aphthae but may cause hypersalivation. Bupropion may cause dry mouth.

NITRITES

Aliphatic nitrites, including amyl, butyl and cyclohexyl nitrite (used as ‘poppers’ to enhance sexual activity), may be inhaled. They are dangerous if ingested.

NITROUS OXIDE

Nitrous oxide induces impaired consciousness with a sense of dissociation and often of exhilaration (laughing gas). Addiction to nitrous oxide is an occupational hazard of anaesthetists and others who have access, such as dental staff. Cases of nitrous oxide misuse have been

Table 34.26 Main opiate and opioid analgesics that are abused

Chemical names	Street names	Comments
Codeine	Captain Cody, Cody, schoolboy; (with glutethimide) doors and fours, loads, pancakes and syrup	Less analgesia, sedation and respiratory depression than morphine
Fentanyl	Apache, China girl, China white, dance fever, friend, goodfella, jackpot, murder 8, TNT, tango and cash	100 times more potent analgesic than morphine
Heroin (diacetylmorphine)	Rock, harry, brown sugar, dope, H, horse, junk, skag, skunk, smack, white horse	Staggering gait, constipation, miosis
Methadone	The done	
Opium	Laudanum, paregoric; big O, black stuff, block, gum, hop	

reported in the USA among dental and medical students who stole large hospital cylinders. The reason that it has not become a widely abused drug is simply the practical problem of carrying such heavy cylinders around.

Chronic misuse of nitrous oxide can lead to interference with vitamin B₁₂ metabolism and neuropathy. Vague neurological symptoms have also been reported by dental staff working in environments contaminated by nitrous oxide.

Other GA agents that may be misused include halothane (liver damage can result; Ch. 9), methoxyflurane (fluorosis, hypertension and renal damage) and ketamine. Ether and chloroform were widely abused in the past but now rarely so, as other agents are more readily available.

OPIATES AND OPIOIDS

General aspects

Opiate analgesics (morphine and heroin [diacetylmorphine]) are narcotics derived from the opium poppy. These, and synthetic compounds (opioids) such as methadone, dipipanone, dihydrocodeine and pethidine, are widely used and potent analgesics that act by mimicking the natural brain peptides enkephalins and endorphins. They can produce pain relief and euphoria, but also drowsiness/respiratory depression and arrest, nausea, confusion, constipation, sedation, unconsciousness, coma, tolerance and addiction (Table 34.26). Misuse is widespread, mainly in urban areas, and particularly in new towns and major cities amongst adolescents and young adults. Opiates and opioids can be abused orally and are sometimes smoked, sniffed or injected subcutaneously (skin popping), but the maximum effect is obtained by intravenous injection. Many addicts also misuse alcohol, cocaine or other drugs. Misuse leads to tolerance at an early stage and dependence after some months.

Heroin is highly addictive and differs from morphine mainly in the difficulty in overcoming addiction; indeed, heroin is probably the most addictive drug known. Heroin users will do almost anything to fund their addiction, which is why heroin use is often associated with anti-social and criminal behaviour, such as burglary. Heroin can be sniffed, smoked from a tin-foil (‘chasing the dragon’) or injected.

Clinical features

The short-term effects of heroin misuse appear soon after a single dose, with a surge of euphoria (‘rush’) accompanied by a warm flushing of

the skin, a dry mouth and heavy extremities – probably due to histamine release – that can last up to 4 hours. Mental functioning then becomes clouded due to the depression of the CNS, and the heroin user goes into an alternately wakeful and drowsy state ('on the nod'). The addict is said to be 'a depressed introvert with constricted pupils'. Loss of weight, emaciation, pupil constriction, lack of concentration, poor work performance, irritability, a desire to be left alone, absences from home or self-neglect may be indicators. Constipation, respiratory depression, orthostatic hypotension, infections, neglect of general health and hygiene, and poor diet are common. Early signs of misuse can be difficult or impossible to detect but may be suspected if needle marks are seen, syringes are found or medical complications develop. Needle marks or venous thromboses, particularly in the forearms and legs, are common, but addicts are remarkably adept at finding veins that escape casual inspection, such as lingual or penile veins.

Syringes and needles are often reused or shared by others; therefore, infective complications such as viral hepatitis B, C and D, HIV, septicaemia and pneumonia are common. Acute right-sided staphylococcal endocarditis, from injection of skin bacteria, can be rapidly fatal or leave substantial cardiac damage. Sexually shared infections are also widespread.

Heroin is a respiratory depressant and its use also predisposes to pneumonia, lung abscesses and fibrosis, and other health disorders, including spontaneous abortion. Long-term effects include collapsed veins, infective endocarditis, abscesses and cellulitis. 'Street' heroin may contain only about 10% heroin – most is filler such as lactose, flour, fruit sugars or powdered milk, substances that do not readily dissolve and result in infection or infarction in lungs, liver, kidneys or brain, thromboses, abscesses and gangrene. Drugs such as ecstasy may also have been added.

With regular heroin use, tolerance develops so that, as progressively higher doses are taken over time, physical dependence and addiction ensue. With physical dependence, the body has adapted to the presence of the drug, and withdrawal symptoms result if the drug is reduced or stopped.

The mortality rate among addicts is 2–6% per annum; deaths are usually from overdose, suicide, assaults and HIV/AIDS.

General management

Opiate or opioid withdrawal is unpleasant but not usually dangerous. Early features include lacrimation, rhinorrhoea, sweating and persistent yawning. After about 12 hours, a phase develops of restless tossing sleep (yen) with pupil dilatation, tremor, gooseflesh ('cold turkey'), anorexia, nausea, vomiting, muscle spasms with kicking movements ('kicking the habit'), orgasms, diarrhoea and abdominal pains. Pulse rate and blood pressure also rise. Once the main features have subsided, there may be weakness and insomnia for weeks or months. Sudden withdrawal in heavily dependent users who are in poor health is occasionally fatal.

Medical supervision and opioid agonists such as methadone (a synthetic medication taken orally as a syrup that blocks the effects of heroin for about 24 hours), buprenorphine, naltrexone or LAAM (synthetics that can block heroin effects for up to 72 hours) are used.

Dental aspects

Dental treatment for narcotic addicts can often be given without fear of complications. In the established addict, non-narcotic analgesics may be ineffective in controlling dental pain, so that large doses of opioids may have to be used. However, opioids should not be given or

prescribed without first seeking expert advice and their only indication in dentistry is for severe postoperative pain. Pentazocine, being a narcotic antagonist, should not be used for opiate addicts, as it may precipitate withdrawal. Many addicts tolerate pain poorly and complain that LA is insufficient for operative procedures. Those under treatment for addiction have a period of several weeks during which they are particularly hypersensitive to pain and stress. In such patients, opioids must be avoided. Although the withdrawal syndrome subsides within about a week, the addict is, for a few weeks thereafter, intolerant of stress and pain. Simulation of pain is a common manoeuvre to obtain analgesics. Prescription pads may be stolen or drug cabinets raided. Dental drugs that may attract the opiate addict include pethidine (meperidine), codeine, pentazocine and dextropropoxyphene (in co-proxamol).

Other management aspects include behavioural disturbances and withdrawal symptoms, cardiac lesions, maxillofacial injuries, hepatitis or chronic liver disease, infective endocarditis, SSIs including HIV infection, venous thromboses – making intravenous injection difficult, tetanus and drug interactions. Opioids may enhance the sedation of conscious sedation agents and GA. Methadone can affect the P450 drug metabolism system. GA requires admission to hospital. Nausea and vomiting are common if the narcotics are stopped preoperatively.

There are no specific oral effects of opiate dependence but there is often oral neglect, advanced periodontal disease and caries. Diet and sometimes the medications predispose to caries because they contain sugar and/or they cause hyposalivation. Opiate addicts also tend to adopt a cariogenic diet. Caries is often left untreated by the patient who, because of the opioid, may be undisturbed by the pain.

Adverse effects relevant to dentistry include impaired ability to metabolize drugs, hypertension, arrhythmias, hypercoagulability and disturbed behaviour, such as aggression, irritability, paranoia, headache and psychoses. In relation to the use of GA, gastrointestinal inflammation may predispose to vomiting, and there may be suxamethonium (scoline) sensitivity. Low plasma cortisol levels might be an indication for corticosteroid cover before operation. Bleeding tendency or drug intolerance may influence dental care.

Lofexidine and methadone can cause hyposalivation. Preventive oral health care is indicated. Sugar-free preparations should be used but they are acidic and may predispose to tooth erosion.

PARAMETHOXYAMPHETAMINE

Paramethoxyamphetamine (PMA) is an MDMA (ecstasy)-like substance that has been involved in the deaths of some people who mistakenly thought they were using MDMA. Deaths were mainly due to complications from hyperthermia.

PCP (PHENCYCLIDINE; ANGEL DUST)

PCP was developed as an intravenous anaesthetic but discontinued because patients often became agitated, delusional and irrational. PCP has a reputation for causing unpleasant psychological effects, users often becoming violent or suicidal, and a danger to themselves and to others. Many people, therefore, after using the drug once, will not knowingly use it again.

PCP is addictive and snorted, smoked or eaten. Low to moderate doses of PCP cause a slight rise in breathing rate, a pronounced rise in blood pressure and pulse rate, flushing and profuse sweating. Generalized numbness of the extremities and muscular incoordination may also occur.

High doses of PCP cause a fall in blood pressure, pulse rate and respiration, which may be accompanied by nausea, vomiting, blurred

vision, flicking up and down of the eyes, drooling, loss of balance, and dizziness, and sometimes a syndrome closely resembling schizophrenia and manic depressive psychosis. Speech is often sparse and garbled. PCP can also cause seizures, illusions and hallucinations, coma and death. Long-term PCP use can lead to memory loss, difficulties with speech and thinking, depression and weight loss. PCP may cause facial grimacing and flushing, hypersalivation and jaw clenching.

PENTAZOCIN

Pentazocine, despite its dysphoric effects, is also used as a drug of dependence, particularly amongst medical and paramedical personnel in the USA. Pentazocine tablets together with an antihistamine (Ts and blues) have been used intravenously as an alternative to the more expensive heroin.

ROHYPNOL (FLUNITRAZEPAM)

Rohypnol is a benzodiazepine that has been used by perpetrators to commit rapes, especially when mixed with alcohol, as it can incapacitate victims and prevent them from resisting sexual assault; since it causes 'anterograde amnesia', individuals may not remember such events. Rohypnol may be lethal when mixed with alcohol and/or other depressants.

EMERGING DRUGS

Designer drugs, created to avoid drug laws, appear at a remarkable pace. 'Spice' refers to designer cannabinoids such as JWH-018, JWH-073, JWH-200 and (C8)-CP 47,497, initially found in 'herbal smoking blends'; these are sold under many names, including K2, fake weed, Yucatan fire, skunk, moon rocks and others. Synthetic cannabinoid agonists, including RCS-4, RCS-8 and AB-001, are also available. Spice abusers report tachycardia, vomiting, agitation, confusion and hallucinations. Spice can raise blood pressure and cause myocardial ischaemia, and has occasionally been associated with heart attacks. Regular users may experience withdrawal and addiction symptoms. One concern is that there may be harmful heavy metal residues in spice mixtures.

'Bath salts' contain synthetic substituted cathinones related to amphetamines such as mephedrone, methylenedioxypyrovalerone (MDPV) and methylone – all highly addictive. Sometimes marketed as 'plant food', 'jewellery cleaner' or 'phone screen cleaner', they are sold online under a variety of names, such as K4 rage, cloud nine, ocean snow, ivory wave, sextacy ultra, white rush, white lightning, bloom, lunar wave, vanilla sky and scarface. Bath salts are typically taken orally, smoked, inhaled or injected – the worst outcomes being after snorting or injection. Users experience euphoria followed by paranoia, depression, agitation and intense craving for more, and some display psychotic and violent behaviour. Bath salts produce an intense high, extreme energy, tachycardia, excessive sweating and insomnia reported to last up to 8 hours, but with redosing the symptoms are prolonged, even for several days. Patients with the 'excited delirium' syndrome from taking bath salts may become dehydrated, with skeletal muscle breakdown, renal failure and even death. K2 can induce a limitless high the more a user smokes, and effects can be up to 10 times more intense than those of marijuana.

Salvia (*Salvia divinorum*) is an herb from Mexico and Central and South America that contains salvinorin A, a potent activator of brain kappa opioid receptors. Salvia users may chew leaves, drink extracted juices or use dried leaves smoked as a joint, consumed in water pipes,

or vaporized and inhaled. People who abuse salvia generally have hallucinations or 'psychotomimetic' episodes (a transient psychosis).

Designer stimulants include geranamine, mephedrone, MDPV and desoxyipradrol. Designer sedatives include methylenmethaqualone and premarazepam.

Another novel development is the use of agents for cosmetic rather than recreational purposes, such as the non-approved alpha-melanocyte-stimulating hormone tanning drugs known as melanotan peptides. Designer analogues of sildenafil (Viagra) have been used as active compounds in 'herbal' aphrodisiac products.

DENTAL ASPECTS OF DRUG ABUSE

Drug abuse may be associated with:

- rampant caries
- periodontal disease
- tooth grinding and tooth surface loss (and masseteric hypertrophy)
- oral mucosal lesions.

Rampant caries is seen in opioid abuse including methadone treatment, stimulant abuse including methamphetamines ('meth mouth'), cocaine and ecstasy, and barbiturate abuse. Rapidly progressing caries affects all tooth surfaces and may involve surfaces that are usually caries-free. The following may predispose to rapidly progressing caries:

- drug-induced hyposalivation; stimulants (e.g. methamphetamine) may lead to dehydration hyposalivation
- poor oral hygiene
- consumption of large amounts of carbonated sugary drinks; opiates and amphetamines often lead to sugar craving
- use of methadone in a sugar syrup form.

Addicts tend to have poor oral hygiene, and many also smoke tobacco – another risk factor in periodontal disease.

Tooth surface loss may be caused by:

- bruxism and clenching – reported mainly with opioid and stimulant use
- hyposalivation
- erosive (acidic) drinks taken in an effort to relieve xerostomia
- regurgitation, bulimia and vomiting, as in alcoholism – may induce erosion, particularly of palatal surfaces of maxillary anterior teeth.

Candida infection is common in drug abusers due to:

- dry mouth
- compromised immune responses
- poor denture hygiene.

Premalignant and malignant mucosal lesions are particularly associated with alcohol, tobacco and betel, and marijuana use.

Management issues include:

- behavioural problems
- compliance with treatment
- viral hepatitis (C and/or B), HIV or other SSIs
- liver damage causing a bleeding tendency and impaired drug metabolism
- malnourishment
- immune defects
- acute anxiety, dysphoria and paranoid thoughts.

LA with adrenaline (epinephrine) may prolong the acute tachycardia already induced by cannabis.

Pain management may be challenging for several reasons:

- Resistance to LA
- Anxiety
- Dental pain from carious teeth – may become evident when a patient stops heroin and starts a methadone maintenance programme
- Potentially addictive analgesics – NSAIDs are best for pain control
- GA or sedation – can trigger a relapse to drug abuse
- Methadone – if prescribed by the physician, this should be maintained during treatment.

Dental management should include:

- attention to oral hygiene
- attention to diet, reducing frequency of sugar intake
- sugar-free chewing gum to stimulate salivary flow
- treatment that is kept as simple as possible
- use of simple excavation of gross caries and glass ionomer cement (ART)
- application of fluoride varnish to saveable carious lesions
- extraction of grossly carious and painful teeth
- treatment of candidal infections with sugar-free topical antifungals.

APPENDIX 34.1 SOME STREET NAMES AND OTHER TERMS FOR DRUGS OF MISUSE

Street names	Drugs
Acapulco gold	Cannabis
Acid	LSD
Angel dust/mist	Phencyclidine
Animal tranquilizer	Phencyclidine
Base	Cocaine
Bath salts	Mephedrone
Beans	Amphetamine
Bennies	Amphetamine
Bhang ^a	Cannabis
Billy	Amphetamine
Biscuits	Ecstasy
Black tar	Heroin
Blanco	Heroin
Blow	Cannabis
Blue angel/devil/heaven	Amylobarbitol
Bolivian	Cocaine

Street names	Drugs
Booze	Alcohol
Bounce	Mephedrone
Bubble	Mephedrone
C	Cocaine
Cadillac	Cocaine
Candy	Barbiturates
Charas	Cannabis
Charlies	Cocaine
Chip	Heroin
Christmas trees	Barbiturates
Coke	Cocaine
Co-pilot	Methamphetamine
Crack	Cocaine free base
Crystal	Methamphetamine
Crystal joints	Phencyclidine
Cubes	LSD
Dagga ^a	Cannabis
Dennis the Menace	Ecstasy

(Continued)

Street names	Drugs
Dexies	Dexamphetamine
Disco (disco biscuit)	Ecstasy
Doe	Methamphetamine
Dope	Heroin
Dot	LSD
Downers	Barbiturates
Drinamyl	Amphetamine
Drone	Mephedrone
E	Ecstasy
Ecstasy	Methylenedexy-methamphetamine
Edwards	Ecstasy
Elephant	Phencyclidine
Freebase	Cocaine
Ganga ^a	Cannabis
GHB	Gamma-hydroxybutyrate
Girl	Cocaine
Gold dust	Cocaine
Goofballs	Barbiturates
Goon	Phencyclidine
Grass	Cannabis
Gunk	Morphine
H	Heroin
Hash (hashish ^a)	Cannabis
Hocus	Morphine
Hog	Phencyclidine
Horse	Heroin
Horse tranquillizer	Phencyclidine
Ice	Methamphetamine
Jack up	Amylobarbitol
Jellies	Tranquillizers
Junk	Cocaine
K (special K)	Ketamine
KJ	Phencyclidine
Lady	Cocaine
Lilly	Secobarbitol
Love drug/dove	Methamphetamine or ecstasy
Ludes	Methaqualone
(Marihuana) ^a marijuana	Cannabis
Meow meow	Mephedrone
Meph	Mephedrone
Mesc	Mescaline
Microdot	LSD
Mist	Phencyclidine
Monkey	Morphine
Mushroom	Psilocybin

Street names	Drugs
Nebbies	Pentobarbitol
Panama gold	Cannabis
Paris	Methaqualone
PCP	Phencyclidine
Peace pills	Phencyclidine
Peaches	Amphetamine
Pink	Morphine
Plant feeder	Mephedrone
Poppers	Amyl nitrite
Pot	Cannabis
Purple haze	LSD
Purple hearts	Dexamphetamine and amylobarbitol
Quads	Methaqualone
Red devils	Secobarbitol
Reefer	Cannabis
Rhubarb and custard	Ecstasy
Rock	Cocaine
Rocket fuel	Phencyclidine
Scuffle	Phencyclidine
Sensi	Cannabis
Shit	Heroin
Silly putty	Psilocybin
Skunk	Cannabis
Smack	Heroin
Snow	Cocaine
Soapers	Methaqualone
Soma	Phencyclidine
Speed	Amphetamine (intravenously)
Speedball	Opioids and amphetamine (or cocaine and heroin)
Spliff	Cannabis
Strawberry	LSD
Sulfate	Amphetamine
T	Phencyclidine
Tea	Cannabis
Tic tac	Phencyclidine
Ts and blues	Pentazocine and tripeleminamine
Vitamins	Ecstasy
Wash	Cocaine
Weed	Cannabis
White lightning	LSD
White magic	Mephedrone
Yellow jackets	Pentobarbitol

^aCorrect name in country of origin.

APPENDIX 34.2 NHS ALCOHOL SELF-ASSESSMENT

From: <http://www.nhs.uk/Tools/Documents/Alcohol%20self%20assessment.htm> (accessed 30 September 2013).

ARE YOU DRINKING TOO MUCH?

If you're not really sure about the amount you are drinking, take this short test.

It'll help you to assess the effects of your drinking and if it suggests you're drinking too much you'll get advice on how to cut down or seek further help.

QUESTIONS**1. How often do you have a drink containing alcohol?**

- a) Never (0 points)
- b) Once a month or less (1 point)
- c) 2 to 4 times a month (2 points)
- d) 2 to 3 times a week (3 points)
- e) 4 or more times a week (4 points)

2. How many units of alcohol do you have on a typical day when you are drinking?

- 1–2 (0 points)
- 3–4 (1 point)
- 5–6 (2 points)
- 7–9 (3 points)
- 10 + (4 points)

What is a unit?

You can't just count each drink as a unit of alcohol. The number of units depends on the different strength and size of each drink, so it can vary a lot.

Here's some examples:

- Pint of beer, 4%, is 2.3 units
- 500ml can of strong lager, 6%, 3 units
- 250ml glass of wine, 11%, 2.8 units
- 330ml can of cider, 5%, 1.7 units
- Single (25ml) measure of spirits (e.g. vodka or gin), 1 unit

3. How often do you have six or more units on one occasion?

- a) Never (0 points)
- b) Less than monthly (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily or almost daily (4 points)

What's binge drinking?

Binge drinking usually refers to drinking lots of alcohol in a short space of time or drinking to get drunk.

There is no consistently agreed measure of binge drinking but drinking more than eight units on any day for men, and more than six units for women, is the measure normally used.

The vital thing is to avoid drinking heavily in one session or drinking to intoxication.

Binge drinking is a major factor in accidents, violence and anti-social behaviour.

4. How often during the last year have you failed to do what was normally expected from you because of your drinking?

- a) Never (0 points)
- b) Less than monthly (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily or almost daily (4 points)

5. How often during the last year have you found that you were not able to stop drinking once you had started?

- a) Never (0 points)
- b) Less than monthly (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily or almost daily (4 points)

6. How often during the last year have you needed an alcoholic drink in the morning to get yourself going after a heavy drinking session?

- a) Never (0 points)
- b) Less than monthly (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily or almost daily (4 points)

7. How often during the last year have you had a feeling of guilt or remorse after drinking?

- a) Never (0 points)
- b) Less than monthly (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily or almost daily (4 points)

8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?

- a) Never (0 points)
- b) Occasionally (1 point)
- c) Monthly (2 points)
- d) Weekly (3 points)
- e) Daily (4 points)

9. Have you or somebody else been injured as a result of your drinking?

- a) No, this has never happened (0 points)
- b) Yes, but not in the past year (2 points)
- c) Yes, during the past year (4 points)

10. Has a relative, friend, doctor or health worker been concerned about your drinking or suggested you cut down?

- a) No, never (0 points)
- b) Yes, but not in the past year (2 points)
- c) Yes, during the past year (4 points)

RESULTS**0–8 points**

Based on your answers today you're drinking in a way that is sociable and is unlikely to harm your health.

As long as your drinking does remain within recommended levels, there is only a low risk that the way you drink will contribute to future health problems.

The NHS recommends that women should not regularly drink more than 2–3 units a day and men should not regularly drink more than 3–4 units a day.

Remember, there can be risks from one-off episodes of heavy drinking too.

8–20 points

Based on your answers today your drinking does appear to be putting you at increased risk of developing health problems, so you might want to think about cutting down.

The following can help you cut down:

- Work out a daily limit and stick to it.
- Do more activities that don't involve drinking.

- Eat before and while you're drinking.
- Don't let anyone top up your drinks.
- Tell your friends you're cutting down.
- Count your units.

The NHS recommends that women should not regularly drink more than 2–3 units a day and men should not regularly drink more than 3–4 units a day.

20–100 points

Based on your answers today your drinking is already causing you problems.

The NHS recommends that women should not regularly drink more than 2–3 units a day and men should not regularly drink more than 3–4 units a day.

You may want help to reduce your drinking. You can find local alcohol services through the 'Find services' section of NHS Choices or your GP will be able to help you find them. You can also contact the National Drinkline 0800 917 8282 open 24 hours, seven days a week.

TRANSPLANTS

Transplantation of organs and tissues has developed rapidly alongside enormous advances in immunology, immunosuppressive therapy (Ch. 19) and medical and surgical technology. Organs and tissues currently transplanted are shown in Table 35.1.

INDICATIONS

Transplantation is frequently a life-saving procedure. Solid organ transplants (SOTs) of kidney, liver, heart, lung, pancreas and small bowel are now the treatments of choice for end-stage organ failure with substantial limitation of daily activities and limited life expectancy.

Autografts (autologous transplants) refer to cells that are collected from an individual and given back to that same person (e.g. veins used for coronary artery bypass grafting, skin used for grafts or blood). Autografts are the most common type of transplant used to treat patients with haemopoietic stem-cell transplantation (HSCT; or bone marrow transplantation [BMT]).

Allografts (allogeneic transplants) refers to cells that come from another individual, who may be a relative or not, but the donor's blood must be closely matched to the recipient's (more likely when the donor is a sibling).

Isografts are allografts in which organs or tissues are transplanted from a donor to a genetically identical recipient (e.g. an identical twin). Most human tissue and organ transplants are allografts that are not so closely matched, which means that the recipient needs to be immunosuppressed to prevent transplant rejection. Organ donation is crucial to provide adequate material.

HSCT is the transfer of haemopoietic stem cells from one individual to another (allogeneic HSCT), or the return of previously harvested cells to the same individual (autologous HSCT) after manipulation of the cells and/or the recipient. It developed from the infusion of bone marrow cells into patients after prior radio- or chemotherapy and is also widely employed in many neoplastic and autoimmune conditions (Fig. 35.1). *Allogeneic* HSCT can cure or improve outcomes in a variety of conditions, including leukaemias, lymphomas, myeloproliferative disorders, myelodysplastic syndromes, bone marrow failure syndromes, congenital immunodeficiencies, enzyme deficiencies and haemoglobinopathies.

Best transplant results are in ambulatory patients with rehabilitation potential, who have no other significant co-morbidity, a satisfactory psychosocial profile, an emotional support system and nutritional status. Transplantation may be refused by some Jehovah's Witnesses and Orthodox Jews.

Peripheral blood stem-cell transplantation (PBSCT) and umbilical cord blood transplantation are also used as sources of haemopoietic stem cells for transplants.

SOLID ORGAN SOURCES

Transplants can be from live or dead ('cadaveric') donors, or from donors who are living but 'brain-dead' – a state defined by an

Table 35.1 Transplantation

Organs/tissues	Source	Type
Thoracic organs	Heart	Deceased donor only
	Lung	Deceased donor and living donor
	Heart/lung	Deceased donor and domino transplant
Abdominal organs	Kidney	Deceased donor and living donor
	Liver	Deceased donor and living donor
	Pancreas	Deceased donor only
Tissues, cells, fluids	Small intestine	Deceased donor and living donor
	Blood transfusion/ blood parts transfusion	Living donor and autograft
	Blood vessels	Autograft and deceased donor
	Bone	Deceased donor, living donor and autograft
	Bone marrow/adult stem cell	Living donor and autograft
	Cornea	Deceased donor only
	Face replant	Autograft
	Face transplant (rare)	Deceased donor only
	Hand	Deceased donor only
	Heart valve	Deceased donor, living donor and xenograft (porcine/bovine)
	Pancreas islet cells	Deceased donor and living donor
	Penis	Deceased donor only
	Skin	Deceased donor, living donor and autograft
	Trachea	Autograft

irreversible cessation of all brain and brainstem functions; this is determined on clinical criteria during two separate examinations performed 24 hours apart, or by ancillary studies to assess brain activities. An absence of drugs, hypothermia or metabolic derangements must be confirmed. Brain death criteria are shown in Box 35.1. One of the main obstacles to transplantation is the lack of donors (Fig. 35.2).

TRANSPLANTATION OUTCOMES

Success for different types of organ transplanted can, in some instances, approach 90% at 1 year, the major barrier to success being immunological rejection. Except for transplants between identical twins, all transplant donors and recipients are immunologically incompatible and host cells attempt to destroy or reject the transplanted organ, which, with time, can lead to graft failure or patient death. The other main cause of graft rejection is patients' failure to continue taking their immunosuppressive drugs.

To try to avoid transplant rejection, transplant recipients and donors are tissue-typed to determine the human leukocyte antigen (HLA) class I and class II loci; the degree of incompatibility is defined by the number of antigens mismatched at each HLA locus. The degree of humoral sensitization to HLA antigens is also determined; sensitization happens when the recipient has received multiple blood

Fig. 35.1 Stem cell (SC) transplantation for lymphoproliferative disease.

Box 35.1 Criteria for brain death

- Known cause of condition
- Temperature higher than 95°F
- No drug intoxication or neuromuscular blocking agent
- No significant metabolic derangement
- No gag, cough or corneal reflexes
- Absence of dull-eye reflex
- Pupils fixed and dilated
- No spontaneous respirations or movements
- Negative results on apnoea test
- Isoelectric electroencephalogram (EEG)
- Computed tomographic evidence of brain herniation
- Negative results on cerebral blood flow studies (i.e. brain scan or intracranial angiography)

transfusions from a previous organ transplant or during pregnancy. Cross-matching is an *in vitro* assay to determine whether a potential transplant recipient has preformed anti-HLA class I antibodies against those of the organ donor. A negative cross-match must be obtained before accepting an organ for transplantation. Transplantation of an organ into a recipient sensitized against donor class I HLA antigens puts the recipient at high risk of hyperacute antibody-mediated rejection. ABO blood group determination is used to establish whether the

Fig. 35.2 Organ donation is crucial to transplantation programmes.

patient is a potential target of recipient circulating preformed cytotoxic anti-ABO antibody. Transplantation across incompatible blood groups may result in a humorally mediated hyperacute rejection.

PREVENTION OF REJECTION

Following transplantation, all patients need treatment with immunosuppressive drugs for life, to prevent T-cell alloimmune rejection. These are discussed in Chapter 19.

Treatment goals are to achieve the highest rates of patient and graft survival, and to minimize toxicity, infections and malignancy. The current high graft survival rate is due to increasingly effective immunosuppression. There is no consensus as to the single best protocol, and each transplant programme uses slightly different regimens.

Induction immunosuppression immediately after transplantation is a short course of intensive treatment to almost abolish the circulating lymphoid cells critical to rejection. Induction agents are given less often if the graft functions immediately, as in recipients of living kidney donors, especially HLA-ID grafts. *Maintenance immunosuppression* usually uses corticosteroid-sparing agents, such as calcineurin inhibitors (e.g. ciclosporin or tacrolimus) and/or corticosteroids, sometimes along with antiproliferative agents (e.g. azathioprine, mycophenolate mofetil or rapamycin; Table 35.2), inhibitors of mechanistic target of rapamycin (mTOR; e.g. temsirolimus, everolimus, sirolimus or deforolimus), anti-T cytotoxic (anti-Tc; abatacept, belatacept) or anti-interleukin-2 (basiliximab, daclizumab) agents, or other biological therapies. Many new agents are being trialled, such as eculizumab and bortezomib for treatment of antibody-mediated rejection; these and the more commonly used immunosuppressive drugs and agents, along with their adverse effects, are discussed more fully in Chapter 19. Transplantation regimens used in children may affect the developing dentition.

Table 35.2 Immunosuppressive agents commonly used in transplantation

Drug	Mode of action	Main adverse effects	Main drug interactions with
Azathioprine	Metabolized by thiopurine methyl transferase (TPMT) to the active mercaptopurine, which reduces DNA synthesis and inhibits lymphocyte division	Myelosuppression Leucopenia Thrombocytopenia Increases risk of myelosuppression with low TPMT Hepatotoxicity Hypersensitivity reactions	Allopurinol, cytostatic drugs, muscle relaxants, warfarin
Basiliximab	Antibody against cluster of differentiation 25 (CD25) T cells		–
Ciclosporin	Highly lipid-soluble and metabolized in the liver by cytochrome P450 (CYP3A4). Ciclosporin binds to cyclophilins (cytosolic receptors) and inhibits calcineurin. Ciclosporin prevents dephosphorylation of NFAT (nuclear translocation of nuclear factor of activated T cells), and thus blocks interleukin-2 (IL-2)	Neurotoxicity, hypertension, tremulousness, hypertrichosis, gingival swelling, hepatotoxicity, nephrotoxicity with hyperkalemia and/or renal tubular acidosis No bone marrow effect	Carbamazepine, phenytoin, isoniazid, rifampicin, phenobarbital and other drugs that induce CYP3A4 may lower ciclosporin levels. Drugs that inhibit CYP3A4 may raise ciclosporin levels (see Table 35.4) Acute renal failure, rhabdomyolysis, myositis and myalgias when taken concurrently with statin
Corticosteroids	May reduce inflammation by reversing increased capillary permeability and suppressing polymorphonuclear neutrophilic leukocytes (PMNs)	Hypertension, diabetes, osteoporosis and fractures, hip necrosis, cataracts, acne and obesity	–
Daclizumab	Antibody against IL-2 receptors	Hypersensitivity reactions	–
Mycophenolate mofetil	Inhibits inosine monophosphate dehydrogenase to impair cytotoxic T cells	Bone marrow suppression	Aciclovir, antacids, ganciclovir, colestyramine
Rapamycin	Cytotoxic	Cytopenias and hyperlipidaemia	–
Sirolimus	A non-calcineurin inhibitor. Inhibits lymphocyte proliferation and impairs cytotoxic T cells	Hyperlipidaemia	See Table 35.4
Tacrolimus	A calcineurin inhibitor macrolide antibiotic similar to ciclosporin. Inhibits IL-2, interferon-gamma and IL-3 production; transferrin and IL-2 receptor expression; mixed lymphocyte reactions; and cytotoxic T-cell generation through an immunophilin protein – the FK-binding protein (FKBP) that inhibits NFAT. Tacrolimus is metabolized by the same P450 system as ciclosporin	Hyperglycaemia, neurotoxicity and nephrotoxicity Cardiomyopathy if given with ciclosporin to children	Aciclovir, antacids, azathioprine, colestyramine, probenecid See Table 35.4

Adverse effects may include the following:

- *Ciclosporin*: liver/kidney dysfunction, hypertension, bleeding tendency and poor wound healing. Gingival overgrowth incidence varies and is dependent on each patient and their drug regimen. Calcium-channel blockers may exacerbate the problem. Children tend to be more susceptible to gingival overgrowth than adults.
- *Tacrolimus*: less gingival overgrowth but associated with oral ulceration and numbness or tingling, especially around the mouth.
- *Azathioprine*: bone marrow suppression and related complications, such as stomatitis and opportunistic infections.
- *Mycophenolate mofetil*: decreased white cell counts, opportunistic infections, and gastrointestinal problems.
- *Corticosteroids*: hypertension and high blood glucose (steroid-induced diabetes), increased risk for infection, poor wound healing, peptic ulceration, depression and adrenal suppression. Corticosteroids may also mask the early signs of oral infection.
- *Sirolimus*: hypertension, joint pain, low white-cell count, hypercholesterolaemia and oral ulceration.

A number of drugs can interfere with immunosuppressive agents (see [Tables 35.4](#), 29.1 and 29.2).

TRANSPLANTATION COMPLICATIONS

Patients who survive transplant surgery are liable to infection, multi-organ failure and acute allograft rejection; in the long term, malignant neoplasms may possibly supervene.

INFECTIONS

Immunosuppressive therapy is designed to suppress T-lymphocyte-mediated transplant rejection but leads to liability to infections especially with mycobacteria, fungi and viruses ([Table 35.3](#)). Infections may spread rapidly, may be opportunistic and may be clinically silent or atypical. Even mild infections can be a serious threat and, as an adjunct to anti-infective therapy, immunosuppression may need to be reduced or even stopped temporarily. Antimicrobial prophylaxis may be appropriate. Bacterial sepsis is better tolerated with ciclosporin than with azathioprine but still must be treated aggressively, as it is the most common cause of death during the first postoperative months. *Legionella* infections are increased in immunosuppressed patients, and often cause dyspnoea and hypoxaemia before the chest radiograph shows any significant infiltrate; a patient who develops such symptoms or a pulmonary infiltrate of unknown aetiology should be treated early with erythromycin.

Table 35.3 Main possible post-transplantation infections

Infection	Month post-transplantation		
	1	2	>2
Fungal	Candidosis	Candidosis	Candidosis
		Deep mycoses	Deep mycoses
Viral	Hepatitis	Hepatitis	Hepatitis
	Herpesviruses	Herpesviruses	Herpesviruses
Bacterial	Wound	Wound	Tuberculosis
	Urinary tract	Urinary tract	Pneumonia
	Pneumonia	Tuberculosis	
		Pneumonia	

Viral infections also account for substantial morbidity and mortality. Herpes simplex virus (HSV) infections are common and usually treated with a 10–14-day course of aciclovir or famciclovir. Varicella zoster virus (VZV) infections may appear, especially herpes zoster, and should be treated with similar antivirals. Cytomegalovirus (CMV) infection is one of the other most common viral infections; it usually appears 3 weeks or more after transplantation, presenting with fever, leukopenia and malaise. The CMV status of the donor must therefore be recorded and the CMV titre assessed as part of the pre-transplant evaluation, so that the results are available immediately after transplantation. A tissue diagnosis of CMV should be sought, either by the histological findings or by biopsy cultures. Patients with systemic CMV infections are treated with ganciclovir.

Fungi commonly cause severe local or even systemically invasive infections in transplant patients, and infections in sputum, blood, urine, bile or drains are an indication for systemic antifungal therapy. *Candida* species are behind the most common fungal infections; as a general rule, if *Candida* grows from two or more sites (e.g. urine, wound), even if not from blood, the patient should be treated and managed as having systemic candidosis. Intravenous amphotericin, or fluconazole intravenously or orally, is usually used. *Aspergillus niger*, *A. flavus* or *A. fumigatus* infections may infect the lungs, upper respiratory tract, skin, soft tissues or central nervous system (CNS), most frequently causing diffuse pneumonia with patchy infiltrates. Amphotericin should be initiated; a long course of systemic therapy is indicated. Development of a brain abscess is insidious and cure rare. *Cryptococcus neoformans* infections may cause pulmonary, CNS and disseminated disease, diagnosed by examination of the cerebrospinal fluid (CSF; lumbar puncture), staining with traditional India ink stains and testing for CSF cryptococcal antigen. Systemic amphotericin treatment is indicated. *Mucor* and *Rhizopus* infections (phycomycoses) are rare but can cause destructive CNS or soft-tissue infections. Treatment includes local excision and a long course of systemic amphotericin. *Pneumocystis* infections are frequently found, and a patient who develops a pulmonary infiltrate of unknown aetiology should be treated early with co-trimoxazole for *Pneumocystis* infections; these commonly cause dyspnoea and hypoxaemia before chest radiography shows any significant infiltrate.

MALIGNANCIES

Transplant recipients are at increased risk from some malignant neoplasms – including melanoma, basal cell carcinoma, Kaposi sarcoma, lymphoma, squamous cell carcinoma of skin and lip, and carcinoma of cervix, external genitalia and perineum. There may be a recurrence of pre-existing cancers in recipients, or donor-transmitted neoplasms or *de novo* malignancies.

Skin cancers affect more than half of organ-transplant recipients and those who develop cutaneous squamous cell carcinomas are at high risk (up to 80%) for multiple subsequent skin cancers. Skin cancers are up to 20 times more frequent in transplant recipients than in the general population and tend to be aggressive. Transplant recipients should therefore avoid sun exposure and undergo routine skin evaluations, with aggressive management of any suspect lesions.

Malignancies are often virally induced. Carcinoma of the skin, lip and cervix may be associated with human papillomaviruses (HPV). Kaposi sarcoma is associated with human herpesvirus-8 (HHV-8; KSHV); it may affect the skin, oropharynx, lungs or other viscera, and treatment involves lowering immunosuppression and then often chemotherapy or radiotherapy. Lymphomas and post-transplant lymphoproliferative disease may be associated with Epstein–Barr virus (EBV).

Some malignancies are seen more frequently in certain subpopulations, according to pre-existing risk factors or behaviours, such as oropharyngeal and lung cancer in those who smoke, or colon cancer in patients with pre-existing inflammatory bowel disease. Directed screening in these patients is desirable, by regular oropharyngeal examinations, chest radiographs and colonoscopies.

Post-transplant lymphoproliferative disorders

General aspects

Post-transplant lymphoproliferative disorders (PTLDs) are a heterogeneous group of potentially, and frequently, fatal B-cell proliferations, associated with EBV infection (from either virus reactivation or primary post-transplant infection); they range from B-cell hyperplasia to malignant immunoblastic lymphoma. The more intense the immunosuppression, the higher the incidence of PTLD, and the earlier it appears. In cardiac transplantation, the incidence ranges from 5% to 13%, reflecting the greater immunosuppression used. PTLDs are relatively uncommon after solid organ and allogeneic bone marrow transplantation (about 2%), but about ten times higher if the patient receives mismatched T cell-depleted bone marrow or anti-T-cell monoclonal antibodies for graft-versus-host disease (GVHD).

Clinical features

PTLDs typically develop within 1 year of transplantation (range 1 month to 14 years). Clinical presentation varies from aggressive diffuse disease appearing early in the post-transplantation period and with polyclonal lesions developing over days or weeks, to localized indolent lesions growing slowly over months. Whether localized or disseminated, PTLD tumours are progressive, with mortality rates as high as 60–100%.

Features include fever, weight loss, an infectious mononucleosis-like syndrome (anorexia, lethargy, sore throat, lymphadenopathy), gastrointestinal symptoms (diarrhoea, abdominal pain), pulmonary symptoms (dyspnoea) and CNS or neurological symptoms. Sites most commonly involved are lymph nodes (59%), liver (31%), lung (29%), kidney (25%), bone marrow (25%), small intestine (22%), spleen (21%), CNS (19%), large bowel (14%), tonsils (10%) and salivary glands (4%).

General management

PTLDs are diagnosed by having a high index of suspicion. A patient who has recently undergone transplantation and presents with unexplained fever, weight loss, lymphadenopathy, hepatosplenomegaly and positive histopathology, and with EBV-DNA, RNA or viral protein on biopsy, is likely to have PTLD.

Treatment is ganciclovir for EBV and reduction or withdrawal of immunosuppression but, since this carries the risk of allograft dysfunction or loss, additional treatment modalities are indicated. These may include rituximab, interferon-alpha (IFN α), intravenous immunoglobulin, cytotoxic T lymphocytes, surgical excision, localized radiation or combination chemotherapy.

T-cell PTLD not associated with EBV infection tends to affect extranodal sites.

MULTIORGAN FAILURE

Transplant patients may also develop recurrent organ and multiorgan disease; for example, they have a 10–20 times increased risk of coronary heart disease. HSCT in particular may be complicated by GVHD.

IMMUNE RECONSTITUTION SYNDROME (IRIS OR IRS)

Restoration of immunity during treatment of infections, particularly if restoration is abrupt and rapid, has the potential to promote excessive inflammatory pathology and tissue damage and an immune reconstitution syndrome (IRIS or IRS). IRIS is more commonly seen in HIV/AIDS therapy but can occur after transplantation. It probably is mediated by anti-inflammatory (Tregs and Th2 cells) and proinflammatory (Th17 and Th1 cells) responses. Pathogens activate naive CD41 cells (Th0) to differentiate into Th1 and Th2 cells. IRIS is mainly an antigen-driven Th1-cell response; Th1 cells produce IFN- γ , activate macrophages, promote natural killer (NK) cell-induced cytotoxicity, and elicit proinflammatory responses. Th2 cells secrete interleukin (IL)-4 and IL-10, leading to anti-inflammatory responses. Th17 cells, which produce IL-17 and IL-22, promote potent proinflammatory responses and induce chemokines and metalloproteinases, which recruit neutrophils. Tregs limit the inflammation and subsequent tissue damage.

Antimicrobial agents (e.g. antimycotics) may contribute to the pathogenesis and post-transplant IRIS has been observed with infection with various fungi, *Mycobacterium tuberculosis*, cytomegalovirus and polyoma virus.

Treatments include corticosteroids, intravenous immunoglobulins, non-steroidal anti-inflammatory drugs (NSAIDs) and infliximab.

DENTAL ASPECTS

BEFORE ORGAN TRANSPLANTATION

There should be a full oral and dental evaluation, and careful attention to oral and dental disease, bearing in mind that after transplantation the patient will be chronically immunosuppressed and at high risk from infection. A full oral health care programme should be instituted, and oral hygiene and preventive care must be maintained at a high standard throughout and following transplantation.

Where possible, active dental disease should be treated before transplantation:

- Eliminate oral infections.
- Extract unrestorable teeth.
- Consider removing orthodontic bands or adjusting prostheses for patients expected to receive ciclosporin to obviate gingival overgrowth.
- Carry out treatment on days that the patient with end-stage renal disease does not undergo haemodialysis.
- Educate patients about effective oral health care.
- Consider anxiety and pain tolerance in organ transplant patients.

The timing of treatment, need for antibiotic prophylaxis, precautions to prevent excessive bleeding, and appropriate medication and dose should be taken into account. Some patients are only suitable for treatment in a hospital setting and factors that should be considered include:

- antibiotic prophylaxis
- infection: active infections should be treated
- excessive bleeding: take precautions to limit bleeding
- medication: transplantation patients are usually on multiple medications such as anticoagulants, beta-blockers, calcium-channel blockers, diuretics and others. Their adverse effects and drug interactions must be borne in mind
- other medical problems: patients with end-stage organ failure may have co-morbidities.

AFTER ORGAN TRANSPLANTATION

Immunosuppressive therapy can lead to liability to infections and to a bleeding tendency. After transplantation, elective dental care is best deferred for at least 3 months, to avoid unnecessary complications. Infection is most likely at this time – the period of intense immunosuppression. During the immediate post-transplant and chronic rejection phases, only emergency dental care is recommended and should be undertaken in a hospital. Any invasive dental treatment should only be carried out after consultation with the responsible physician and with due consideration to the liability to infection, bleeding tendency related to anticoagulation, risk of adrenal crisis in relation to steroid therapy and impaired drug metabolism; this applies probably for at least 2 years post-transplantation. Dental treatment guidelines include attention to prevent infection – use of antiseptic mouthwashes (e.g. chlorhexidine gluconate) – before treatment. Antibiotic prophylaxis is indicated for invasive dental procedures, particularly if provided within 6 months post-transplantation. In addition, steroid cover may be indicated. Macrolide antibiotics and azole antifungal drugs should be avoided because they may alter serum levels of some immunosuppressive drugs, thus increasing their toxicity. Pre-existing illnesses of transplant candidates often need to be considered, as they can influence oral health care.

GA should be avoided, but, if essential, must only be given in hospital with appropriate expertise and facilities.

Drugs that should be used with caution include aspirin and NSAIDs; these should be avoided since they potentiate the nephrotoxicity of ciclosporin and tacrolimus, may cause a bleeding tendency, and exacerbate peptic ulcer if the patient is on corticosteroids. Sedatives and paracetamol (acetaminophen) are also best avoided. Erythromycin and azole antifungals may affect ciclosporin levels (Table 35.4). There may also be a greater risk from nephrotoxicity with co-trimoxazole, aminoglycosides and quinolones. Drugs used in transplant patients, such as ciclosporin, nifedipine and basiliximab, may induce gingival overgrowth, impaired healing and infections, and may interact with prescribed drugs.

Patients may need steroid supplementation and cover during dental treatment (Ch. 6), probably for at least 2 years post-transplantation. Viral hepatitis B and C infections may be present, especially in older patients who have received blood transfusions before blood was routinely screened. Oral infections, such as HSV, VZV, CMV or EBV, to which the immunosuppressed patient is prone, are discussed in Chapter 20. Several other complications associated with marked immunosuppression manifest in the mouth, including herpes zoster, hairy leukoplakia and aphthous ulcers. Progressive periodontal disease, delayed wound healing and excessive bleeding may also become problems.

Table 35.4 Drug use in transplanted patients that may change blood levels of immunosuppressants and affect treatment or health

Drugs that may change blood levels of immunosuppressants			Drugs that increase nephrotoxicity	Drugs that increase hepatotoxicity
Ciclosporin	Tacrolimus	Sirolimus		
Raise levels				
Amphotericin	Clarithromycin	Ciclosporin	Amphotericin	Aminoglycosides
Clarithromycin	Diltiazem	Diltiazem	Clarithromycin	Co-trimoxazole
Erythromycin	Erythromycin	Grapefruit juice	Diclofenac	Erythromycin
Grapefruit juice	Fluconazole	Itraconazole	Erythromycin	Halothane
Ketoconazole	Grapefruit juice	Ketoconazole	Indometacin	Quinolones
Norfloxacin	Itraconazole	Miconazole	NSAIDs	Tetracyclines
	Ketoconazole	Telithromycin	Sulfamethoxazole	
	Miconazole	Voriconazole	Vancomycin	
	Nelfinavir			
	Nifedipine			
	NSAIDs			
	Omeprazole			
	Quinupristin			
	Ritonavir			
	Telithromycin			
Lower levels				
Carbamazepine	Rifampicin (rifampin)	Rifampicin (rifampin)		
Phenytoin				
Sulfamethoxazole				

Oral HSV and VZV infections can be prevented, deferred or ameliorated by prophylactic low-dose oral aciclovir.

Spontaneous bacterial peritonitis and endarteritis are possible peri- and post-transplantation, particularly after liver transplantation, and may necessitate antimicrobial prophylaxis; however, there is no evidence that, after the first 3 months following transplantation, there is any routine need for antimicrobial cover for dental interventions. Some patients carry enterococci in plaque. Rarely, oral or dental infections may spread, with serious complications such as cavernous sinus thrombosis or metastatic infections, and oral bacteria are an important source of bacteraemias.

Oral candidosis may be persistent or mixed bacterial plaques may develop on the oral mucosa. Oral candidosis can usually be managed with topical nystatin, amphotericin or miconazole (Fig. 35.3).

Routine cancer surveillance is mandatory to assure rapid diagnosis and treatment of any malignancy, since patients on immunosuppressive treatment after organ transplantation have a greatly raised incidence of malignant disease, as discussed above (Fig. 35.4). This may be the case especially in those with a history of tobacco or alcohol use and is often so in adults needing liver transplants. Kaposi sarcoma, lymphoma and squamous cell carcinoma are among the oral malignancies that sometimes occur in organ transplant patients.

ORGAN REJECTION

If there is organ rejection, only emergency dental care should be provided.

HAEMOPOIETIC STEM-CELL TRANSPLANTATION (BONE MARROW TRANSPLANTATION)

General aspects

HSCT is increasingly used in the treatment of haematological conditions, neoplasms and some genetic defects (Table 35.5). It involves

Fig. 35.3 Thrush.

Fig. 35.4 Kaposi sarcoma in a renal transplant patient with diabetic nephrosclerosis.

stem cells of myeloid, erythroid, megakaryocyte, lymphoid and macrophage origins. The cells are either autologous or allogeneic and obtained from bone marrow (BMT), peripheral blood, or banked cryopreserved umbilical cord or fetal liver blood. Most transplants are

Table 35.5 Main indications for haemopoietic stem-cell transplantation (HSCT)

Indications	Examples
Lymphoproliferative disease	Leukaemias Lymphomas Myelomatosis
Solid tumours	Breast cancers Colon cancers Ewing sarcoma Germinal cell tumours Gliomas Lung cancers Melanomas Ovarian carcinomas Renal carcinomas Sarcomas
Non-malignant diseases	Aplastic anaemia Autoimmune diseases Fanconi syndrome Immunodeficiencies Inborn errors of metabolism Thalassaemia

Table 35.6 Donor cells used in haemopoietic stem-cell transplantation (HSCT)

Donor	Comments
Autologous	Best for HSCT in non-malignant disease – no graft-versus-host disease (GVHD). In malignant disease, there is a risk of re-introducing malignant cells
Sibling: syngeneic (identical twin)	Best: no GVHD
Sibling: human leukocyte antigen (HLA)-matched	Minimal GVHD
Unrelated donor: HLA-matched	Some GVHD

made between HLA-identical siblings, though other family members, or matched volunteers, may be used (Table 35.6).

General management

Patients destined for HSCT must first be profoundly immunosuppressed to reduce the chances of graft rejection by ‘conditioning’, often with cyclophosphamide, plus total body irradiation (TBI) or busulfan (‘reduced intensity conditioning’). All conditioning regimens are toxic but those using reduced intensity conditioning have lower morbidity and mortality.

The donor cells are then mixed with heparin and infused intravenously in order to colonize the recipient’s marrow; over the next 2–4 weeks, they start to produce blood cells. Throughout this period and for the following 3 months, the patient is usually provided with an indwelling catheter to facilitate therapy and intravenous feeding. Recipients must also be treated with methotrexate, corticosteroids, ciclosporin, intravenous immunoglobulins, tacrolimus, sirolimus or alemtuzumab (anti-CD52 lymphocytes) for 6 months or more to prevent or ameliorate GVHD. Since patients are severely immunoincompetent until the donor marrow is fully functioning, they must also be isolated and protected from infections, and may require transfusions

of granulocytes, platelets or red cells, granulocyte colony-stimulating factors and antimicrobials.

Dental aspects

Oral mucositis is the most distressing complication of HSCT, seen in 30–50% of patients and particularly problematic after TBI. Mucositis may also be a predictor of gastrointestinal toxicity and the onset of hepatic veno-occlusive disease. Mucositis is also an important driver of health-care costs; patients use more antibiotics and analgesics, have more days of fever, and stay in the hospital longer. Less common oro-facial complications include infections (which usually develop within the first month of the transplant), sinusitis, parotitis, oral pain or bleeding. GVHD presents with lichenoid reactions or xerostomia. Ulceration may be drug-induced (e.g. by everolimus). Ciclosporin may cause gingival swelling, and this and other immunosuppressants have resulted in lip and occasionally oral carcinomas, Kaposi sarcoma or lymphomas.

A meticulous pre-transplant oral assessment is required and dental treatment should be undertaken with particular attention to establishing optimal oral hygiene and eradicating sources of potential infection. Dental treatment should be completed before transplant and elective dental care is best deferred for 6 months after transplant not least because there is temporarily a bleeding tendency and immune defect since patients become thrombocytopenic and leukopenic. If surgical treatment is needed during that period, antibiotic prophylaxis is probably warranted. Local anaesthetic (LA) is satisfactory. Conscious sedation can be given if needed. General anaesthesia (GA) must always be given in hospital.

Consideration must also be given to the implications of immunosuppressive therapy, bleeding tendencies, infection and veno-occlusive liver disease.

GRAFT-VERSUS-HOST DISEASE

General aspects

Graft-versus-host disease (GVHD) is a serious complication of transplantation; it is seen mainly after HSCT but can occasionally follow solid organ transplants, especially liver and small bowel transplantation. Allogeneic T lymphocytes recognize host major histocompatibility complex (MHC) antigens (HLA mainly) and, even in HLA-identical individuals, may recognize minor non-MHC histocompatibility antigens (mHag). Such activated T cells secrete cytokines (IL-2, IFN γ) and tumour necrosis factor alpha [TNF α], causing a ‘cytokine storm’, exaggerated by the release of bacterial lipopolysaccharides from the gastrointestinal tract that has been damaged by TBI.

The overall HSCT survival rate is 42% but patients with progressive chronic GVHD have only a 10% survival rate. GVHD affects a number of tissues, including mucosae, and may be acute or chronic.

Acute GVHD involves the skin, liver and gut with a distinctive syndrome of fever, dermatitis, hepatitis and enteritis within 100 days of HSCT. The overall grade of acute GVHD predicts outcome, with the highest rates of mortality in those with severe (grade IV) GVHD. Response to treatment also predicts outcome in grades II–IV GVHD. Patients with no response or with progression have a mortality rate as high as 75%, compared with 20–25% in those with a complete response.

Chronic GVHD also affects skin, liver and gut but is a more diverse syndrome and develops after day 100. Chronic GVHD may arise as an extension of acute GVHD but may also start *de novo* or may emerge

after a quiescent interval. The immunopathogenesis of chronic GVHD is, in part, Th2 lymphocyte-mediated, resulting in a syndrome of immunodeficiency and autoimmunity. Chronic GVHD mortality rates are higher in patients with extensive disease, progressive-type onset, thrombocytopenia and HLA-non-identical marrow donors.

Clinical features

Acute GVHD may initially cause a pruritic or painful red to violaceous rash, typically first on the palms and soles, cheeks, neck, ears and upper trunk, but sometimes progressing to cover the whole body. Liver involvement causes asymptomatic rises in serum bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and alkaline phosphatase (similar to cholestatic jaundice). Gastrointestinal involvement affects the distal small bowel and colon, causing diarrhoea, bleeding, cramping pain and ileus. Other findings include a greater risk of infectious and non-infectious pneumonia, sterile effusions, haemorrhagic cystitis, thrombocytopenia, anaemia and haemolytic-uraemic syndrome (HUS; thrombotic microangiopathy).

Chronic GVHD resembles systemic progressive sclerosis, systemic lupus erythematosus, lichen planus, Sjögren syndrome, eosinophilic fasciitis, rheumatoid arthritis and primary biliary cirrhosis. It can lead to skin and mucosal lichenoid lesions or sclerodermatous thickening, sometimes causing contractures and limitation of joint mobility. Oral effects mimic Sjögren syndrome (Ch. 18) with hyposalivation and decreases in salivary immunoglobulin A and antioxidants. Oral and gastrointestinal manifestations include dysphagia and increasing pain. Ocular manifestations include symptoms of burning, irritation, photophobia and pain from lack of tears. Pulmonary manifestations include obstructive lung disease with wheezing, dyspnoea and chronic cough unresponsive to bronchodilators. Neuromuscular manifestations include weakness, neuropathic pain and muscle cramps, and sometimes myasthenia gravis or polymyositis.

General management

Most patients undergoing HSCT are given systemic prophylaxis for GVHD with ciclosporin or tacrolimus in combination with methotrexate and/or prednisolone (prednisone). There are no reliable strategies known specifically to prevent GVHD but several systemic agents, such as corticosteroids, cyclophosphamide, azathioprine, methotrexate, ciclosporin, tacrolimus and mycophenolate mofetil, may be beneficial; strategies under investigation include sirolimus, thalidomide, clofazimine, pentostatin, hydroxychloroquine, photopheresis therapy, anti-TNF and rituximab.

Acute GVHD is treated with intravenous methotrexate for up to 14 days. Subsequent dose-tapering or switching to an oral agent is continued over several weeks to months. *Chronic GVHD* is treated with oral prednisolone alone or in combination with ciclosporin. If the response is positive, it is continued, tapering off over 6–9 months.

Dental aspects

Oral aspects may be encountered in addition to those discussed above in relation to HSCT. Oral GVHD may be associated with mucositis, hyposalivation, higher caries risk, altered taste, candidosis, herpes infections, lichenoid lesions, progressive systemic sclerosis-like changes, oral pain and oral cancer.

Other transplant complications may include a bleeding tendency, various adverse drug effects, such as adrenal suppression, and drug-induced gingival overgrowth, which is dose-related and thus more

common in those on higher doses of ciclosporin (i.e. heart, liver and lung transplant patients), in arterial hypertension (an adverse effect of immunosuppressives) and in diabetes mellitus (caused by some immunosuppressive medications such as corticosteroids).

TRANSPLANTATION AND TISSUE ENGINEERING OF CRANIOFACIAL STRUCTURES

Craniofacial tissue replantation or transplantation to treat congenital anomalies, trauma and diseases is in its infancy. Tissue engineering also promises the regeneration or *de novo* formation of dental, oral and craniofacial structures. Most craniofacial structures are derivatives of mesenchymal cells, and mesenchymal stem cells have been isolated from the dental pulp, deciduous teeth and periodontium. Several craniofacial structures, such as calvarial bone, the mandibular condyle and subcutaneous adipose tissue, have been engineered from mesenchymal stem cells, growth factor and/or gene therapy approaches.

TOOTH TRANSPLANTATION

Autotransplantation of teeth is useful, has many indications in dentistry and has been used for decades. Transplanted teeth can survive for an average of 6 years but some survive for 4 decades. Immature teeth survive best as donor teeth, and the shorter time out of the mouth, the better the success. Transplanted teeth may, however, develop replacement resorption or ankylosis. Cryopreservation of teeth creates new possibilities (e.g. when autotransplantation is needed, but the recipient site is too small and orthodontic treatment is needed to gain space for the transplant). Biological tooth replacement using stem cells is experimental at present.

The molecular control of key processes in tooth development, such as initiation, morphogenesis and cytodifferentiation, is being increasingly better understood and already bioengineered tooth tissues can be regenerated at the site of previously lost teeth.

SALIVARY GLANDS TRANSPLANTATION

Transplantation of the major salivary glands has been used successfully to provide substitute lubrication in severely dry eyes, significantly improving Schirmer's test, tear break-up time, rose Bengal staining and symptoms. Long-term graft survival is around 70%. However, the surgery is fairly complex and, in over one-third of eyes with a viable graft, salivary epiphora results, which is independent of gustatory stimuli. Since the salivary tear film is substantially hypo-osmolar, microcystic epithelial oedema can result and subsequent corneal transplantation can be unsuccessful.

Transplantation of minor salivary glands is a promising new treatment option – as the procedure is simple with minimal surgical risks, the grafts remain viable in over 90% and they seem to be capable of sustaining a basal secretion for up to at least 36 months. Prospective controlled studies are needed to establish the long-term gland survival and to characterize the salivary tear film and its impact on the eye.

Salivary gland regeneration and gene transfer to salivary glands are currently experimental only.

JAW TRANSPLANTATION

There is potential for regeneration within the bony tissues of the craniofacial region, and guided tissue regeneration and distraction osteogenesis (Ch. 16) are already in widespread use.

In Germany, in 2004, a patient who lost his mandible in radical cancer surgery had a functional jawbone created using bone stem cells. Three-dimensional computed tomography (CT) and computer-aided design techniques were used to create a titanium mesh cage to replace the jaw defect; this was filled with bone mineral blocks and infiltrated with recombinant human bone morphogenetic protein (BMP) and liquid bone marrow containing the patient's stem cells. This transplant was implanted into the latissimus dorsi muscle and, 7 weeks later, transplanted as a bone-muscle free flap to repair the mandibular defect. *In vivo* skeletal scintigraphy showed bone remodelling and mineralization inside the transplant both before and after transplantation. CT provided evidence of new bone formation. Postoperatively, the patient's mastication and aesthetics improved.

FACE TRANSPLANTATION

By 2013, almost a score of composite tissue allotransplants of the face had been reported.

Self as donor ('face replantation')

The first account of a procedure to replace all or part of a person's face was in the second century BC, when an Indian surgeon, Sushruta, used autografted skin in rhinoplasty. The world's first full-face *replant* operation was in 1994, also in India, on 9-year-old Sandeep Kaur, whose face was ripped off when her hair was caught in a thresher. In 1997, a similar operation was reported from Australia, when a person's face and scalp were torn off in an accident, and successfully reattached.

Partial face transplantation

The world's first partial face *transplant* operation was in France in 2005. A triangle of central facial tissue from a brain-dead woman was grafted on to a 38-year-old woman whose nose, lips, chin and adjacent cheeks had been amputated. Bone-marrow graft and immunosuppression with thymoglobulin, tacrolimus, mycophenolate mofetil and prednisolone (prednisone) were used; they were well tolerated and there were no surgical complications. Mild rejection at day 20 responded to prednisolone. Rejection episodes on days 18 and 214 were similarly reversed. Anatomical and psychological integration and recovery of sensation were good. Sensitivity to light touch, heat and cold were normal by 6 months. Motor recovery and labial contact allowing complete mouth closure was achieved by 10 months. At 18 months, the patient was satisfied with the functional and aesthetic results.

In April 2006, in China, a similar transplant of the cheek, upper lip and nose was reported. In 2008, a patient in France received the world's first successful almost full-face transplant as treatment for neurofibromatosis. In 2009, there were reports of two similar transplants in the USA and two in France (one of the French patients died from cardiac arrest).

Full-face transplant

In 2010, the first full-face transplant was performed in Spain on a man injured in a shooting accident, and the French media reported another full-face transplant, including lacrimal ducts and eyelids. In 2011, a full-face transplant was performed in Boston and a successful face transplant was reported from Forth Worth, Texas. In 2012, one of the longest and most extensive facial transplants ever was carried out in

Baltimore. In the same year, three successful full-face transplants were reported from Turkey.

Causes of disease are genetic (inherited) or acquired – which can be environmental (from trauma, infection, chemicals or irradiation) or related to lifestyle (e.g. lack of exercise, poor diet, habits – tobacco, alcohol, drugs, betel and others). Many diseases result from an interaction of several of these factors.

GENERAL HEALTH PROMOTION

Since disease arises from the interactions of negative genetic, environmental and lifestyle factors, it follows that it may be prevented by avoiding or minimizing these factors – as summarized in [Table 36.1](#) and [Figure 36.1](#). Already the effects of genetic diseases like haemophilia can be minimized by providing the missing protein (blood clotting factor VIII) and, in the future, genetic manipulation may be more widely possible ('gene therapy'). The term 'lifestyle' refers to how individuals live their life and how they handle problems and interpersonal relations – 'the unique way in which individuals try to realise their fictional final goal and meet or avoid the three main tasks of life: work, community, love' (Adler). Lifestyle choices are crucial. Apart from improving or maintaining good health by avoiding contracting infections, including sexually shared infections (SSIs; Ch. 32), the three most important measures are to take regular exercise, eat a healthy diet, and avoid substance dependence and other deleterious habits.

EXERCISE

When exercise is combined with a proper diet, weight can be controlled and obesity – a major risk factor for many diseases – prevented. In contrast, physical inactivity often occurs together with an unhealthy diet, contributing to obesity, diabetes, heart disease and cancer.

There are real health benefits from exercise, ranging from protecting against cardiac disease (hypertension, atheroma and coronary artery disease) to reducing the chances of cancer and Alzheimer disease. In addition, exercise can: increase stamina; improve brain function; reduce stress (by releasing endorphins), depression and anxiety; control weight; build and maintain healthy bones, muscles and joints; and reduce the risk of developing diabetes.

To achieve health benefits, enough regular, moderately intense physical activity to burn an extra 200 calories daily is needed at the very least. At a minimum, this means about 30 minutes of activity daily – such as a brisk walk.

There are at least ten scientifically proven reasons for taking regular exercise, as follows:

1. *Exercise helps minimize obesity.* Exercise, by burning calories, helps minimize obesity (Ch. 27). Men who are obese are more likely than non-obese men to die from cancer of the colon, rectum or prostate; obese women are more likely to die from cancer of the gallbladder, breast, uterus, cervix or ovaries. Other health problems that stem from obesity include diabetes, ischaemic heart disease (IHD), hypertension, metabolic syndrome, stroke, gallbladder disease, liver disease, osteoarthritis,

gout, sleep apnoea, menstrual irregularities and infertility in women, and psychosocial effects.

2. *Exercise helps increase levels of HDL or 'good' cholesterol.* Levels of high-density lipoproteins (HDL), when low, and low-density lipoproteins (LDL), when high, predict a risk for IHD. Exercise helps increase HDL and lower LDL levels and, by strengthening the heart and lowering blood pressure, protects against atheroma, myocardial infarcts and strokes (Ch. 5).
3. *Exercise helps lower high blood pressure.* Hypertension can be reduced by exercise. Blood pressure levels predict the risk for coronary heart disease and stroke. Physical activity also reduces obesity, which is associated with hypertension (Ch. 5).
4. *Exercise helps promote healthy blood sugar levels.* High blood sugar levels in diabetes, a risk factor for coronary heart disease, can be lowered by exercise (Ch. 6).
5. *Exercise helps improve the metabolic syndrome.* The metabolic syndrome (syndrome X or insulin resistance syndrome) is a cluster of abdominal obesity (excess body fat around the waist), insulin resistance (causing high blood sugar) and increased blood pressure, which increases the risk for diabetes, heart disease and stroke (Ch. 23). Having just one of these factors contributes to the risk of serious disease and, in combination, the risk is even greater. Exercise improves these factors.
6. *Exercise helps build muscle strength.* By building or preserving muscle mass and strength, and improving the ability to use calories, exercise helps reduce body fat. By increasing muscle strength and endurance, and improving flexibility and posture, regular exercise also helps prevent back pain. Exercise helps build muscle but this benefit fades if exercise stops for any reason, so regular exercise is needed.

Table 36.1 Prevention of disease

	Environmental		Lifestyle
Trauma	Avoid alcohol use, accidents, aggression and dangerous environments, activities and sports	Exercise	Take regular daily exercise for a minimum of 30 min
Infections	Avoid needlestick injuries and use latex protection (condoms, gloves, rubber dam). Be vaccinated	Diet	Eat a balanced diet with five portions of fruit/vegetables daily, minimize sugar and avoid food fads
Chemical	Label and take care with toxic agents and avoid communicable diseases	Substance dependence	Abstain if possible from use of tobacco, alcohol, recreational drugs and betel
Irradiation	Minimize exposure (to sun, X-rays, lasers, damaging lights, etc.) and use safety measures such as protective eyewear and screens		

Environment

Health and safety at work

Vehicle and road safety

Body protection in sports

Lifestyle

Exercise regularly

Eat more vegetables and fruit; fewer calories

Tobacco abstinence

Alcohol and other drugs of abuse abstinence

Prevent infections (immunization: hygiene: avoid contact)

Sleep hygiene

Sun avoidance

convenience foods and takeaways are often high in added salt, sugar or fat, and should only be eaten in moderation. See the US Department of Agriculture's food guidance system (<http://www.choosemyplate.gov>; accessed 30 September 2013).

CALORIES

A calorie is the amount of energy required to heat 1 g of water to 1°C; however, because this is a small energy quantity, it more common to use the kilocalorie or Calorie – equivalent to 1000 calories. Energy is usually expressed either in kilojoules or in kilocalories. These two units – joules and calories – are directly related. To convert one to the other, the number of calories multiplied by 4.186 gives the number of joules; or the number of kilocalories multiplied by 4.186 gives the number of kilojoules.

ELEMENTS (MINERALS) AND TRACE ELEMENTS

Iron (Fe) is an important component of haemoglobin. Sodium (Na), potassium (K), calcium (Ca) and phosphorus (P) are needed in large quantities to take part in physiological reactions such as nerve impulse transmission or to form bones and teeth. Trace elements vital to good health include iodine (I), which is necessary for thyroxine, and fluoride (F), which helps to protect against caries.

VITAMINS

See Chapter 27.

Fig. 36.1 Health promotion.

7. *Exercise helps promote bone density.* Regular exercise from a young age can increase bone density and help avoid or minimize osteoporosis (Ch. 16).
8. *Exercise helps improve mobility.* People who exercise regularly have been shown to be more mobile and independent compared with those having a sedentary lifestyle (Ch. 25).
9. *Exercise helps the immune system.* Exercise helps the immune system combat infections. The mechanism is unclear. In contrast, when exercise is performed without food intake, and is too continuous, prolonged or of high intensity (as in athletes), immune function can be depressed.
10. *Exercise helps improve mood.* People who exercise regularly have been shown to be generally happier and less liable to depression compared with those having a sedentary lifestyle (Ch. 10).

DIET

The keys to a healthy diet are eating the right amount of food for the activity undertaken *and* eating a range of foods to ensure a balanced diet. This includes: fruit and vegetables; wholegrain bread, pasta and rice; some protein-rich foods such as meat, fish, eggs and lentils; and some dairy foods. The diet must also be low in fat (especially saturated fat), salt and sugar. Generous amounts of vegetables and fruit daily appear to protect against cancers of stomach, colon and lung, and possibly against cancers of the mouth, larynx, cervix, bladder and breast. Carbohydrates as wholegrain unrefined products may help protect against colon cancer, diverticulitis and caries. A high-fibre diet may also offer some protection against hypertension and IHD. Minimizing the intake of saturated fats (especially those from dairy sources) and partially halogenated vegetable fats may lower the risk of IHD and some cancers. Ready meals,

SUBSTANCE DEPENDENCE

Substance dependence is defined as self-administration without any medical indication and despite adverse medical and social consequences, and in a manner that deviates from the cultural norm and is harmful. This applies to tobacco, alcohol and a range of drugs of abuse (Ch. 34).

TOBACCO

Nicotine is absorbed readily from tobacco smoke in the lungs; it is one of the most heavily used addictive drugs, and is highly addictive (Ch. 34). Cigarette smoking is a major hazard to health and promotes many diseases (Box 36.1). Smoking cessation should be gradual because withdrawal is less severe in those who quit gradually. Aids include nicotine chewing gum or patches, or drugs.

ALCOHOL

Alcohol is damaging to health and high in calories, so cutting down can help control weight. Women can drink up to 2–3 units of alcohol a day and men up to 3–4 units a day without significant risk to their health (Ch. 34). A unit is half a pint of standard strength beer, lager or cider, or a pub measure of spirit. A glass of wine is about 2 units and alcopops are about 1.5 units.

DRUG ABUSE

Use of illegal drugs can cause dry mouth, bruxism, dilated pupils, tachycardia, aggression, talkativeness, tachypnoea and hallucinations, leading to hyperpyrexia, seizures, arrhythmias and collapse (Ch. 34).

Box 36.1 *Health problems from tobacco*

- Cigarette smoking is particularly linked to atherosclerotic heart disease, cancers of the lung, oesophagus, mouth and bladder, and chronic obstructive pulmonary disease
- Carbon monoxide in the smoke increases the risk of cardiovascular disease
- Tobacco use is a major cause of stroke and leading cause of death
- Smokers metabolize some other drugs more rapidly and require, for example, higher doses of benzodiazepines than non-smokers
- Women who smoke generally have an earlier menopause. If women smokers also take oral contraceptives, they are more prone to cardiovascular and cerebrovascular diseases than are other smokers; this is especially true for women older than 30
- Pregnant women who smoke cigarettes run a greater risk of having stillborn or premature infants, or infants with a low birth weight
- Children of women who smoked while pregnant have a raised risk for developing conduct disorders
- Second-hand smoke (passive smoking) causes lung cancer in adults and greatly increases the risk of respiratory illnesses in children and sudden infant death
- Tobacco use can also damage oral health and cause:
 - oral cancer
 - keratosis
 - periodontal disease, particularly necrotizing gingivitis
 - Implant failure
 - dry socket
 - candidosis
 - dry mouth (xerostomia)
 - halitosis
 - staining of teeth

High doses can cause mood swings and psychoses, including hallucinations and paranoia, and can give rise to respiratory failure and death. Intravenous use of illegal drugs can also easily lead to infections, including SSIs, viral hepatitis and HIV/AIDS.

This chapter includes synopses of many relevant conditions; if a specific condition is not located here, please see index, as it may be elsewhere in the book. For eponymous medical signs, see also http://en.wikipedia.org/wiki/List_of_eponymous_medical_signs (accessed 30 September 2013).

Abrikossof tumour. Granular cell tumour.

Adamantiades syndrome. Behçet syndrome.

Addison disease. Autoimmune hypoadrenocorticism (Ch. 6).

Adie's (Holmes–Adie) pupil. A benign condition in which one pupil is dilated and reacts only very slowly to light or convergence.

Albers–Schonberg disease. Osteopetrosis.

Albright syndrome (McCune–Albright syndrome). Polyostotic fibrous dysplasia with skin pigmentation and an endocrine abnormality (usually precocious puberty in girls; Ch. 16).

Allgrove syndrome. Autosomal recessive condition due to chromosome 12 mutation. Achalasia of cardia, adrenal insufficiency, alacrima (triple A syndrome) plus hyposalivation.

Alstrom syndrome. Congenital nerve deafness and retinitis pigmentosa.

Apert syndrome. Craniofacial synostosis with craniosynostosis, facial dysmorphism, hands and feet defects, and learning disability.

Argyll Robinson pupils. Small, irregular, unequal pupils that fail to react to light but do react to accommodation. Caused by neurosyphilis and other diseases.

Arnold–Chiari syndrome. A congenital malformation in which the brainstem and the cerebellum are longer than normal and protrude into the spinal cord.

Ascher syndrome. Congenital double lip with blepharochalasis (redundant eyelids) and thyroid goitre.

Asperger syndrome. A form of autism.

Avellis syndrome. Unilateral paralysis of the larynx and palate.

Battle's sign. Bruising over the mastoid bone, a sign of basilar skull fracture.

Becker syndrome. Severe muscular dystrophy resulting in progressive weakness of limb and breathing muscles, almost exclusively in boys.

Beckwith–Wiedemann syndrome. Congenital gigantism, omphalocele or umbilical hernia.

Beeson's signs. Myalgia, facial oedema and fever in trichinosis.

Behçet syndrome. The triad of oral aphthous ulcers, genital ulceration and uveitis.

Bell palsy. A common lower motor neuron facial palsy, caused by inflammation in the stylomastoid canal (Ch. 13).

Bence Jones protein. Overproduction of gamma-globulins in myelomatosis, particularly of immunoglobulin light chains that spill over into the urine (Bence Jones proteinuria; Ch. 8).

Berardinelli–Seip syndrome. An autosomal recessive form of generalized lipodystrophy.

Biemond syndrome. Congenital obesity and hypogonadism.

Binder syndrome. Congenital maxillonasal dysplasia, and absent or hypoplastic frontal sinuses.

Blackfan–Diamond syndrome. Congenital red cell aplasia.

Block–Sulzberger disease (incontinentia pigmenti). Congenital hyperpigmented skin lesions, skeletal defects, learning disability and hypodontia.

Bloom syndrome. Congenital telangiectasia, depigmentation, short stature and susceptibility to oral carcinoma.

Boeck syndrome. Sarcoidosis (Ch. 15).

Book syndrome. Autosomal dominant disorder of palm and sole hyperhidrosis, hypodontia and premature whitening of hair.

Bourneville disease (epiloia, tuberous sclerosis). Autosomal dominant phakomatosis including fibromas at the nail bases (subungual fibromas), hamartomas in the brain, kidneys and heart, and nodules in the nasolabial folds (adenoma sebaceum) (Ch. 13).

Briquet syndrome. Somatisation (Ch. 10).

Brugada syndrome. A genetic disease characterized by abnormal ECG and a risk of sudden cardiac death (Ch. 5).

Bruton syndrome. Sex-linked agammaglobulinaemia, cervical lymph node enlargement, oral ulceration, recurrent sinusitis and absent tonsils.

Burkitt lymphoma. (Ch. 8).

Byar–Jurkiewicz syndrome. Gingival fibromatosis, hypertrichosis, giant fibroadenomas of the breast and kyphosis.

Cannon disease. Congenital white sponge naevus.

Carabelli cusp. Congenital additional palatal cusp on upper molars.

Carney syndrome. Autosomal dominant multisystem disorder of myxomas and lentigos.

Carpenter syndrome. Autosomal recessive acrocephalopolysyndactyly type II.

Castleman disease (angiolymphoid hyperplasia). Nodal lymphoproliferation that may progress to a malignant vascular tumour or lymphoma. Sometimes associated with paraneoplastic pemphigus.

CATCH22. Cardiac abnormality, abnormal facies, T-cell deficit (due to thymic hypoplasia), cleft palate and hypocalcaemia (due to hypoparathyroidism). A chromosome 22 defect (DiGeorge syndrome).

Charles Bonnet syndrome. Visual hallucinations arising in people who have eye conditions such as age-related macular degeneration, cataract, glaucoma or diabetic eye disease.

Chediak–Higashi syndrome. Congenital immune defect in which neutrophils have large inclusions.

Christmas disease. Deficiency of blood clotting factor IX (Ch. 8).

Chvostek sign. Tapping the skin over the facial nerve elicits involuntary twitching of the upper lip or ipsilateral side of face – seen in hypoparathyroidism (Ch. 6).

Clutton joints. Syphilitic neuropathic joints.

Cockayne syndrome. Premature ageing, dwarfism, deafness and neuropathy.

Coffin–Lowry syndrome. Congenital osteocartilaginous anomalies and learning disability.

Coffin–Siris syndrome. Congenital defective neutrophil function, susceptibility to infection and skin pigmentation.

Costen syndrome. Outmoded term relating to patients with facial pain, otalgia and possible occlusal abnormalities.

Cowden syndrome. Congenital multiple hamartoma syndrome, with oral papillomatosis and risk of breast and thyroid cancer.

Coxsackie virus. Named after Coxsackie in New York State. Coxsackie viruses can cause herpangina, hand, foot and mouth disease, and other illnesses.

CREST syndrome. Calcinosis, Raynaud disease, Oesophageal involvement, sclerodactyly and telangiectasia (see Scleroderma; Ch. 18).

Crohn disease. Chronic inflammatory idiopathic granulomatous disorder of the ileum or any part of the gastrointestinal tract, including the mouth (Ch. 7).

Cronkhite–Canada syndrome. Hypogeusia is the dominant initial symptom, followed by diarrhoea and ectodermal changes (alopecia, nail dystrophy, and skin and buccal melanotic hyperpigmentation).

Cross syndrome. Athetosis, learning disability, gingival fibromatosis and hypopigmentation.

Crouzon syndrome. Autosomal dominant premature fusion of cranial sutures, mid-face hypoplasia and proptosis.

Curry–Jones syndrome. Unilateral coronal synostosis and microphthalmia, plagiocephaly, craniofacial asymmetry, iris coloboma, broad thumbs, hand syndactyly, foot polydactyly, erosive skin lesions, gastrointestinal abnormalities and developmental delay.

Cushing syndrome. Moon face with buffalo hump, hirsutism and hypertension due to an pituitary adenoma producing adrenocorticotrophic hormone (ACTH; Ch. 6).

Danon disease. Rare genetic condition causing muscular dystrophy, cardiomyopathy and learning problems.

Darier disease (Darier–White disease). Autosomal dominant skin disorder with follicular hyperkeratosis and sometimes white oral papules.

Destombes–Rosai–Dorfman syndrome. Rosai–Dorfman syndrome (see below).

DiGeorge syndrome. Congenital immunodeficiency with hypoplasia of thymus and parathyroids, characteristic facies with down-slanting palpebral fissures and ocular and nasal anomalies, and cardiac, thyroid and parathyroid defects due to a third and fourth branchial arch defect related to a chromosome 22 anomaly (CATCH 22 syndrome – see above) (Ch. 20).

Down syndrome (trisomy 21). Chromosomal anomaly causing learning disability, short stature, brachycephaly, mid-face retrusion and upward-sloping palpebral fissures (mongoloid slant; Ch. 28).

Duhring disease. Dermatitis herpetiformis.

Duncan disease. Rare sex-linked lymphoproliferative syndrome, characterized by severe Epstein–Barr virus mononucleosis, immunoblastic sarcoma or lymphoma.

Eagle syndrome. Elongated styloid process associated with dysphagia and pain on chewing, and on turning the head towards the affected side.

ECHO viruses. Enteric cytopathogenic human orphan viruses.

Ehlers–Danlos syndrome. Congenital disorders of collagen characterized by joint hyperflexibility, hyperextensible skin, bleeding and bruising, and mitral incompetence (Ch. 16).

Ellis–van Creveld syndrome (chondroectodermal dysplasia). Congenital polydactyly, dwarfism, ectodermal dysplasia; hypodontia and hypoplastic teeth; multiple fraena.

Epstein–Barr virus. Herpesvirus implicated in infectious mononucleosis, hairy leukoplakia, nasopharyngeal carcinoma and some lymphomas.

Epstein pearls. Small cysts due to persistence of epithelial rests in the alveolar ridge.

Fabry disease (angiokeratoma corporis diffusum universale). X-linked recessive error of glycosphingolipid metabolism with skin angiokeratomas, hypertension, fever, renal disease and risk of myocardial infarction.

Fallot tetralogy. Combination of ventricular septal defect (VSD) and pulmonary stenosis, with aorta ‘overriding’ (sitting ‘astride’) the VSD and with right ventricular hypertrophy.

Fanconi anaemia. Rare autosomal recessive syndrome of congenital anaemia, congenital skeletal defects (e.g. abnormal radii), hyperpigmentation and pancytopenia; associated with abnormal susceptibility to oral or other head and neck carcinomas and leukaemia at an early age (Ch. 8).

Felty syndrome. Rheumatoid arthritis and neutropenia.

Fitzgerald–Gardner syndrome. Gardner syndrome (see below).

Fordyce disease (Fordyce spots). Congenital ectopic sebaceous glands seen mainly in the buccal mucosa or lips.

Freeman–Sheldon syndrome. Rare form of multiple congenital contracture syndrome (arthrogryposis).

Frey syndrome. Skin gustatory sweating and flushing after trauma to skin over a salivary gland, due to crossover of sympathetic and parasympathetic innervation to the gland and skin.

Friedreich ataxia. Inherited progressive central nervous system damage causing features ranging from muscle weakness and speech problems to heart disease. Usually an autosomal recessive trait, leading to degeneration of many spinal cord tracts extending to the brainstem, and thus severe ataxia, loss of reflexes and secondary deformities. Degenerative heart disease with arrhythmias may be associated.

Froehlich syndrome. Congenital obesity, hypogonadism, and risk of learning disability and open bite.

Gardner syndrome. Autosomal dominant syndrome of intestinal polyposis, bony abnormalities, soft-tissue tumours, multiple osteomas, fibromas and pigmented lesions of fundus of eye.

Garré osteomyelitis. Proliferative periostitis.

Gasserian ganglion. Trigeminal ganglion.

Gaucher disease. Inherited defect of lysosomal glucocerebrosidase – most common in Ashkenazi Jews, and causing skeletal defects, hepatosplenomegaly, anaemia and thrombocytopenia.

Gilles de la Tourette syndrome. A familial early-onset syndrome, seen mainly in males, of chronic motor tics involving the head and neck especially and associated with compulsive vocal tics and sometimes swearing (coprolalia). Tongue-thrusting and lip-smacking are common and sometimes regarded as lewd (copropraxia). Many of those affected have obsessive–compulsive tendencies or attention-deficit hyperactivity, but intelligence is usually normal. Temporomandibular or other oral pain may result and self-mutilation, such as tongue- and lip-biting, may be associated. The dopamine receptor blocker haloperidol is usually effective; pimozide and/or clonidine may also be used. Drugs used to treat the syndrome may cause xerostomia or tardive dyskinesia. Interactions of these drugs with general anaesthetic agents, other central nervous system depressants and atropine means that dental treatment is best carried out under local analgesia.

Glossopharyngeal neuralgia. Severe pain in the posterior tongue, fauces, pharynx and sometimes beneath the angle of the mandible.

Goldenhar syndrome. Variant of congenital hemifacial microsomia, with microtia (small ears), macrostomia, agenesis of mandibular ramus and condyle, vertebral abnormalities and epibulbar dermoids.

Goltz syndrome (focal dermal hypoplasia). X-linked disorder with multiple mesenchymal defects, skin lesions, oral warts and dental defects.

Gorham disease. Rare osteolysis without sex, race or age predilection, affecting bones. Jaw is the main location; histology mostly shows haemangioma-like proliferation.

Gorlin–Goltz syndrome (Gorlin syndrome; multiple basal cell naevi syndrome). Autosomal dominant trait, with multiple basal cell carcinomas, odontogenic keratocysts, and vertebral and rib anomalies.

Graves disease. Hyperthyroidism with ophthalmopathy and exophthalmos (Ch. 6).

Grinspan syndrome. Lichen planus, diabetes and hypertension (probably due to lichenoid reactions to antihypertensive and antidiabetic drugs).

Guillain–Barré syndrome. Acute infective polyneuritis; facial palsy may be seen.

Hailey–Hailey disease. Autosomal dominant benign familial pemphigus presenting in second or third decade with skin and oral blisters and vegetations.

Hajdu–Cheney syndrome. Ulcerating lesions on the palms of the hands and soles of the feet, with softening and destruction of bones (acro-osteolysis).

Hallermann–Streiff syndrome. Congenital cranial anomalies, micro-ophthalmia, cataracts, mandibular hypoplasia and abnormal temporomandibular joint.

Hand–Schuller–Christian disease. Langerhans histiocytosis causing skull lesions, exophthalmos and diabetes insipidus (Ch. 8).

Hansen disease. Leprosy.

Heck disease. Focal epithelial hyperplasia. Caused by human papillomavirus 13 or 32, and seen especially in various ethnic groups such as American Native Indians and Inuits.

Heerfordt syndrome (uveoparotid fever). Sarcoidosis associated with lacrimal and salivary swelling, uveitis, fever and sometimes facial palsy (Ch. 15).

Henoch–Schönlein purpura. Allergic purpura, typically following streptococcal infection.

Hermansky–Pudlak syndrome. Congenital albinism and bleeding tendency.

Hirschsprung disease. Congenital aganglionic megacolon.

Hodgkin disease. Nearly one-half of all lymphomas are Hodgkin disease, which can affect any age group, particularly males in middle age (Ch. 8).

Horner syndrome. Usually unilateral miosis (pupil constriction); ptosis (drooping of the upper eyelid); loss of sweating of the ipsilateral face; enophthalmos (retruded eyeball). Caused by interruption of sympathetic nerve fibres peripherally (e.g. as a result of trauma to the neck, or lung cancer infiltrating the superior cervical sympathetic ganglion; Ch. 13).

Horton cephalgia. Migrainous neuralgia.

Hunter syndrome. A mucopolysaccharidosis.

Hunterian chancre. Syphilitic primary chancre.

Hurler syndrome (Hurler–Scheie syndrome). Congenital mucopolysaccharidosis causing growth failure, learning disability, large head, frontal bossing, hypertelorism, coarse facial features (gargoylism) and mandibular radiolucencies (Ch. 23).

Hutchinson–Gilford syndrome (progeria). See Werner syndrome.

Hutchinson teeth. Screwdriver-shaped incisor teeth in congenital syphilis.

Hutchinson triad. Hutchinson teeth, interstitial keratitis and deafness.

Immerslund–Grasbeck syndrome. Congenital vitamin B₁₂ deficiency.

Jackson–Lawler syndrome. A type of pachyonychia in congenital syphilis with no oral leukoplakia, but neonatal teeth and early loss of secondary teeth.

Jadassohn–Lewandowsky syndrome. Pachyonychia congenita.

Jones syndrome. See Curry–Jones syndrome.

Kallmann syndrome. Hypogonadotropin eunuchoidism (Ch. 6).

Kaposi sarcoma. Malignant neoplasm of endothelial cells caused by human herpesvirus 8 (KSHV or KS herpesvirus), seen mainly in AIDS, immunosuppressed patients, elderly Jews and those of Mediterranean or Middle Eastern origin (Ch. 20).

Kartagener syndrome. Congenital dextrocardia, immunodeficiency and sinusitis.

Kawasaki disease (mucocutaneous lymph node syndrome). Idiopathic disorder with fever, lymphadenopathy, desquamation of hand and feet, cheilitis and cardiac lesions.

Kearns–Sayre syndrome. A mitochondrial cardiomyopathy.

Kikuchi–Fujimoto disease. A self-limiting lymphadenopathy that can be confused histologically and clinically with lymphoma or systemic lupus erythematosus.

Kimura disease. A chronic inflammatory disorder, mostly in males, causing a painless, slowly enlarging, soft-tissue mass, lymphadenopathy and peripheral eosinophilia.

Kindler syndrome. Autosomal recessive skin disorder with blistering, photosensitivity, progressive poikiloderma and diffuse cutaneous atrophy.

Klinefelter syndrome. A chromosomal abnormality affecting men and causing hypogonadism.

Klippel–Feil anomalad. Congenital association of cervical vertebrae fusion with short neck, low-lying posterior hairline, syringomyelia and other neurological anomalies, and sometimes unilateral renal agenesis and cardiac anomalies.

Koplik spots. Small white spots on the buccal mucosa in measles prodrome.

Kostmann syndrome. Autosomal recessive defect in neutrophil numbers. In contrast to normals, CD64+ (FC γ RI receptor) is expressed on neutrophils but CD16+ (FC γ RIII receptor) is expression decreased.

Kuttner tumour. Immunoglobulin G4 syndrome.

Kveim test. Outdated skin test for sarcoidosis using antigen from the lymph nodes or spleen of human sarcoidosis patients, injected intracutaneously.

Laband syndrome (Zimmermann–Laband syndrome). Hereditary gingival fibromatosis with skeletal anomalies and large digits.

Langerhans cell histiocytoses (histiocytosis X). Rare tumours arising from dendritic intraepithelial antigen-presenting cells (Langerhans cells; Ch. 8).

Larsen syndrome. Autosomal recessive condition, consisting of cleft palate, flattened facies, multiple congenital dislocations and deformities of feet.

Laugier–Hunziker–Baran syndrome. A rare, acquired, benign hyperpigmentation of the lips, oral mucosa and nails.

Laurence–Moon–Biedl syndrome. Congenital retinitis pigmentosa, obesity, polydactyly, learning disability and blindness.

Leigh disease. A progressive neurodegenerative disorder related to respiratory chain deficiency and a mitochondrial defect.

Lesch–Nyhan syndrome. Congenital defect of purine metabolism causing learning disability, choreoathetoid cerebral palsy and self-mutilation.

Letterer–Siwe disease. Rapidly progressive disseminated form of Langerhans histiocytosis, often fatal because of pancytopenia and multisystem disease (Ch. 8).

Lewar disease. Pulse granuloma.

Löfgren syndrome. Acute benign form of sarcoidosis, with erythema nodosum and bilateral hilar lymphadenopathy (Ch. 15).

Lowe syndrome (cerebrohepatorenal syndrome). Congenital hypotonia and flexion contractures.

Ludwig angina. Infection of sublingual and submandibular fascial spaces.

Lyme disease. *Borrelia burgdorferi* infection from deer ticks, causing rashes, fever, arthropathy and facial palsy. First recognized in Lyme, Connecticut, USA.

Madelung disease. Benign symmetrical lipomatosis.

Maffucci syndrome. Multiple enchondromas, haemangiomas (often in the tongue) and risk of malignant chondrosarcomas.

MAGIC syndrome. Mouth and genital ulcers and interstitial chondritis – a variant of Behçet syndrome.

Mallory–Weiss syndrome. Mucosal gastric tear near the oesophageal/stomach junction causing bleeding.

Mantoux test. Skin test for delayed-type hypersensitivity reaction to bacillus Calmette–Guérin (BCG; for tuberculosis).

Marcus Gunn syndrome. Jaw-winking syndrome (eyelid winks during chewing), with ptosis.

Marfan syndrome. Autosomal dominant condition in which patient is tall and thin, and has arachnodactyly (long, thin, spider-like hands) (Ch. 16).

Marie–Sainton syndrome. Cleidocranial dysplasia.

Maroteaux–Lamy syndrome. A mucopolysaccharidosis.

Meig syndrome. Ascites, pleural effusion and benign ovarian tumour.

Melkersson–Rosenthal syndrome. Facial swelling similar to that in Crohn disease or orofacial granulomatosis, with facial palsy and fissured tongue.

Mendelson syndrome. Inhalation of gastric contents causing pulmonary oedema.

Ménière disease. Labyrinthine dysfunction with vertigo, tinnitus and sensorineural hearing loss, nausea and sometimes nystagmus. Betahistine and cinnarizine are helpful but phenothiazines, prochlorperazine or thiethylperazine may be required.

Miescher cheilitis. Oligosymptomatic orofacial granulomatosis or Crohn disease affecting the lip alone.

Migrainous neuralgia (cluster headaches; histamine cephalgia; Sluder headaches). Pain in the head and face, defined by the International Headache Society as unilateral, excruciatingly severe attacks of pain in the ocular, frontal and temporal areas, recurring in separate bouts with daily or almost daily attacks for weeks or months, usually with ipsilateral lacrimation, conjunctival injection, photophobia and nasal stuffiness and/or rhinorrhoea.

Mikulicz disease. Salivary gland and lacrimal gland swelling often related to Sjögren syndrome or immunoglobulin G4 syndrome.

Mikulicz syndrome. Salivary gland and lacrimal gland swelling related to malignant disease.

Mikulicz ulcer. Minor aphthous ulceration.

Miller syndrome. Autosomal recessive post-axial acrofacial dysostosis.

Moebius syndrome. Congenital anomaly involving multiple cranial nerves, mainly the abducens (VI) and facial (VII), often associated with limb anomalies.

Moon molars. Hypoplastic molars from congenital syphilis.

Morquio syndrome. A mucopolysaccharidosis (Ch. 23).

Munchausen syndrome. The fabrication of stories by the patient, with the aim of receiving operative intervention (Ch. 10).

Murray–Puretic–Drescher syndrome (juvenile hyaline fibromatosis). Autosomal recessive disease characterized by large cutaneous nodules, especially around the head and neck, joint contractures, gingival swelling and osteolytic lesions.

Nager syndrome. Acrofacial dysostosis.

Nelson syndrome. Hyperpigmentation caused by overproduction of adrenocorticotrophic hormone in response to adrenalectomy – used for breast cancer (Ch. 6).

Neumann bipolar aphthosis. The association of recurrent aphthae with genital ulceration; this is probably emerging Behçet syndrome.

Nikolsky sign. Blistering, or the extension of a blister, on gentle pressure (seen in pemphigus and pemphigoid; Ch. 11).

Noonan syndrome. Congenital short stature and webbed neck, sometimes with cardiac anomalies, pulmonary stenosis and cherubism.

Ollier syndrome. Multiple enchondromas.

Osler–Rendu–Weber disease (hereditary haemorrhagic telangiectasia; HHT). Autosomal dominant disorder where telangiectases are present orally and periorally, in the nose and gastrointestinal tract, and occasionally on the palms (Ch. 8).

Paget disease. Disease of bone (Ch. 16).

Pallister Hall syndrome. Autosomal dominant disease due to mutations in the *GLI3* gene and neonatally lethal.

Papillon–Lefèvre syndrome. Congenital defect in cathepsin C, causing palmoplantar hyperkeratosis, juvenile periodontitis that affects both dentitions, and immunodeficiency.

Parrot nodes. Frontal bossing in congenital syphilis.

Parry–Romberg syndrome. Hemifacial atrophy.

Patterson–Brown–Kelly syndrome (Plummer–Vinson syndrome). Dysphagia (due to post-cricoid candida web), microcytic hypochromic anaemia, koilonychia and angular cheilitis (Ch. 8).

Paul–Bunnell test (Paul–Bunnell–Davidsohn). Serological test for heterophile antibodies in infectious mononucleosis (glandular fever).

Peutz–Jegher syndrome. Autosomal dominant condition of circumoral melanosis and intestinal polyposis.

Pfeiffer syndrome. Craniosynostosis.

Pierre Robin sequence. Congenital micrognathia, cleft palate and glossoptosis.

Pindborg tumour. Calcifying epithelial odontogenic tumour.

Plummer–Vinson syndrome. See Patterson–Brown–Kelly syndrome.

Pospischill–Feyrter aphthae. Palatal ulceration in neonates.

Prader–Willi syndrome. Congenital obesity, hypogonadism, learning disability, diabetes and dental defects.

Quinke oedema. Angioedema.

Ramon syndrome. Cherubism, arthritis, epilepsy, gingival fibromatosis and learning disability.

Ramsay Hunt syndrome. Lower motor neuron facial palsy with vesicles in ipsilateral pharynx, external auditory canal, and face – due to herpes zoster of geniculate ganglion of seventh nerve.

Rapp–Hodgkin syndrome. Ectodermal dysplasia, kinky hair, cleft lip/palate, popliteal pterygium and ectrodactyly.

Raynaud syndrome. Vascular spasm in response to cooling, seen in the digits in connective tissue disorders (Ch. 18).

Reiter disease. Association of arthritis, urethritis, balanitis and conjunctivitis, found mainly in men with sexually shared infection and human leukocyte antigen (HLA)-B27.

Rett syndrome. Congenital bruxism and hand-wringing, often with learning disability.

Reye syndrome. Rare serious illness affecting brain and liver, occurring in children after viral infection and treated with aspirin.

Reynolds syndrome. A rare autoimmune disease, consisting of the combination of primary biliary cirrhosis and progressive systemic sclerosis.

Rieger syndrome. Congenital ocular anomalies, iridal hypoplasia, glaucoma, maxillary hypoplasia and dental hypoplasia with oligodontia and microdontia.

Riley–Day syndrome. Inherited familial dysautonomia, seen particularly in Ashkenazi Jews. Sympathetic dysfunction, enlarged salivary glands, sialorrhoea and self-mutilation.

Robinow syndrome. Fetal facies syndrome: a rare autosomal syndrome of short stature, characteristic facial dysmorphism, genital hypoplasia and mesomelic brachymelia.

Romberg syndrome (Parry–Romberg syndrome; hemifacial atrophy). Progressive atrophy of half the face, associated with contralateral Jacksonian epilepsy and trigeminal neuralgia.

Rosai–Dorfman syndrome (sinus histiocytosis with massive lymphadenopathy or Destombes–Rosai–Dorfman syndrome). A benign histiocytic proliferative disorder that primarily affects lymph nodes.

Rothmund–Thomson syndrome. Congenital poikiloderma, hypogonadism, dwarfism, cataracts and microdontia.

Rubinstein–Taybi syndrome (broad thumb–great toe syndrome). Short stature, small head, prominent beaked nose, down-slanting eyes, developmental delay, and broad, sometimes angulated thumbs and

first toes. Undescended testes occur in males. Other variable features include congenital heart disease, kidney abnormalities, and eye and hearing problems.

Rud syndrome. Recessive disorder marked by ichthyosis, hypogonadism, learning disability, epilepsy and dwarfism.

Rutherford syndrome. Corneal dystrophy, gingival fibromatosis and delayed tooth eruption.

Ruvalcaba–Myhre–Smith syndrome. Congenital macrocephaly, learning disability, intestinal polyps, pigmented macules on penis, tongue polyps.

Sabin–Feldman test. Serological test for toxoplasmosis.

Saethre–Chotzen syndrome. Autosomal dominant craniosynostosis with mutations in TWIST gene (7p21), cleft palate and disturbances of the facial skeleton and extremities.

Sanfilippo syndrome. A mucopolysaccharidosis.

SAPHO syndrome. Synovitis, acne, pustulosis, hyperostosis and osteitis.

Scheie syndrome. A mucopolysaccharidosis (Ch. 23).

Schmidt syndrome. Congenital hypoadrenocorticism, hypoparathyroidism, diabetes and malabsorption, with candidosis.

Seckel syndrome. Congenital microcephaly, learning disability, zygomatic and mandibular hypoplasia.

Shprintzen syndrome. Velocardiofacial syndrome.

Shwachman–Diamond syndrome. Rare disorder affecting the pancreas, bone marrow – with neutropenia and thrombocytopenia – and skeletal defects.

Sipple syndrome. Multiple endocrine neoplasia type 3 (MEN 3; sometimes called 2b) affecting several endocrine glands with multiple mucosal neuromas, pheochromocytoma and medullary thyroid carcinoma (Ch. 6).

Sjögren syndrome. Hyposalivation and keratoconjunctivitis sicca (i.e. dry mouth and dry eyes; Ch. 18).

Sjögren–Larsson syndrome. Congenital ichthyosis, learning disability, cerebral palsy and indifference to pain.

Sluder syndrome. Migrainous neuralgia.

Sly syndrome. A mucopolysaccharidosis.

Smith–Lemli–Opitz syndrome. Congenital short stature, learning disability, syndactyly, urogenital and maxillary anomalies.

SSS syndrome (silent sinus syndrome). A rare entity of unilateral enophthalmos and hypoglobus secondary to thinning of the maxillary sinus roof in the absence of sinonasal inflammatory disease.

Stevens–Johnson syndrome. Severe erythema multiforme (Ch. 11).

Stickler syndrome. Collagenopathy affecting collagens II and IX, causing a distinctive facial appearance, eye abnormalities, hearing loss and joint problems.

Still disease. Juvenile rheumatoid arthritis.

Sturge–Weber syndrome (encephalotrigeminal angiomatosis). Congenital hamartomatous angioma of face (naevus flammeus), oral mucosa and underlying bone (with hemihypertrophy of bone and accelerated eruption of associated teeth), extending intracranially to cause convulsions, and contralateral hemiplegia and intracerebral calcifications, and sometimes learning disability.

Sutton's ulcers. Major aphthae.

Sweet syndrome. Acute neutrophilic dermatosis; red mucosal lesions and aphthae.

Takayasu disease. Pulseless aorta and large arteries.

Thibierge–Weissenbach syndrome. CREST syndrome – scleroderma with calcinosis and ischaemia.

Treacher Collins syndrome (mandibulofacial dysostosis). Autosomal dominant defect in first branchial arch with downward-sloping (antimongoloid slant) palpebral fissures, hypoplastic malar,

mandibular retrognathia, deformed pinnae, hypoplastic sinuses, colobomas in outer third of the eye, middle and inner ear hypoplasia (deafness).

Trotter syndrome. Acquired unilateral deafness, pain in mandibular (third) division of trigeminal nerve, ipsilateral palatal immobility, and trismus due to invasion of nasopharynx and trigeminal nerve, by a malignant tumour. Pterygopalatine fossa syndrome is a similar condition where first and second divisions of trigeminal nerve are affected.

Turner teeth. Hypoplastic tooth due to damage to the developing tooth germ.

Tzanck cells. Abnormal squamous cells in pemphigus or herpetic infections

Urbach–Wiethe disease. Lipoid proteinosis.

Van der Woude syndrome. Cleft lip or palate with lip pits and hypodontia.

Vincent disease (acute ulcerative gingivitis). Non-contagious anaerobic infection with overwhelming proliferation of *Borrelia vincentii* and fusiform bacteria. Predisposing factors include smoking, viral respiratory infections and immune defects such as in HIV/AIDS.

von Hippel–Lindau disease. Autosomal dominant condition with café-au-lait spots, retinal angiomas, central nervous system haemangioblastomas, pheochromocytomas, pancreatic neuroendocrine tumours and renal cancer.

von Recklinghausen disease. Multiple neurofibromas with skin pigmentation, skeletal abnormalities and central nervous system involvement (Ch. 13).

von Willebrand disease. Common bleeding disorder caused by defective blood clotting factor VIII and platelet dysfunction (Ch. 8).

Waardenburg syndrome. Congenital heterochromia iridis (differently coloured eyes), deafness and white forelock, with prognathism. Specific associated genes are members of the homeobox family that regulate the transcription of other genes: Waardenburg type 1 with PAX3; Waardenburg type 2 with MITF, 3q14.1; and Waardenburg type 3 with PAX3, 2q35.

Waldeyer ring. Lymphoid tissue surrounding the entrance to the oropharynx (tonsils and adenoids).

Warthin tumour. A benign salivary gland neoplasm – adenolymphoma or papillary cystadenoma lymphomatosum.

Wegener granulomatosis. Idiopathic disseminated malignant granulomatous disorder that may affect lungs, kidneys and mouth, sometimes related to *Staphylococcus aureus* (Ch. 8).

Weil disease. Leptospirosis.

Werner syndrome. Congenital alopecia, dwarfism, senility, early atherosclerosis, delayed tooth eruption and mandibular hypoplasia.

Whipple disease. A bacterial infection with *Tropheryma whippelii*, which affects primarily middle-aged white men.

Williams syndrome. Genetic disorder of cognitive impairment (usually mild learning disability), unique personality characteristics, distinctive ('elfin') facial features and cardiovascular disease (elastin arteriopathy).

Wilson disease. Hepatolenticular degeneration.

Wiskott–Aldrich syndrome. X-linked recessive immunodeficiency with thrombocytopenia, eczema, infections and lymphoreticular malignancies (Ch. 20).

Witkop disease. Hereditary benign intraepithelial dyskeratosis – seen mainly in parts of the USA.

Yersiniosis. Infection with *Yersinia pseudotuberculosis*.

Zimmermann–Laband syndrome. See Laband syndrome.

Zinsser–Engman–Coles syndrome. Rare syndrome of skin pigmentation, oral leukoplakia, nail dystrophy, pancytopenia and predisposition to malignancy.

Zollinger–Ellison syndrome. Intractable peptic ulcers, high gastric acidity and gastrin-secreting, non-beta islet cell tumours (nesidioblastomas), usually of the pancreas, but sometimes duodenum (Ch. 7).

Anal diseases, 208–209
Analgesia
general anaesthesia, 69–77
Analgesic ladder, pain management, 55*t*
Analgesics, 51–53, 62*t*, 693–695
breastfeeding, contraindicated in, 647*t*
chronic kidney disease, 341*t*
contraindications and cautions for, 52*t*
drug use in patients on warfarin, 232*t*
liver disease, contraindications in, 280*t*
for pain control, 589*t*
that may impair platelets, 222*t*
see also specific analgesics
Anaphylaxis, 8*t*, 10–11, 458
drug treatment for, 4*t*
epinephrine (adrenaline) for, 11
main precipitants of, 458*t*
management of, 11, 19
treatment algorithm, 10*f*
Anaplasma phagocytophila, 746*t*
Anaplasmosis, 745
Ancylostoma duodenale infection, 555*t*
Androgenic alopecia, 97
Aneurine, 668
Angel dust (phencyclidine/PCP), 767–768
Angelman syndrome, 686*t*
Angina, 8*t*
Angina bullosa haemorrhagica, 218, 325*t*
Angina pectoris, 99*t*, 138–139
clinical features of, 138, 138*b*
definition of, 138
dental aspects of, 139
general management of, 138–139
medical treatments for, 139*b*
pain relief and prophylaxis of, 137
stable, 139
unstable, 139
variants of, 138
Angioedema, 459–460, 459*f*
drug-related, 705
hereditary, 605*t*–606*t*
various forms of, 459*t*
Angiokeratoma corporis diffusum universale, 791
Angiolymphoid hyperplasia, 790
Angioplasty, 159
Angiostrongyliasis, 574*t*–575*t*
Angiotensin 1, 183
Angiotensin 2, 183
Angiotensin II receptor blockers (ARBs)
as antihypertensive drugs, 133*t*
as cardiovascular drugs, 131*t*
chronic kidney disease, 339–340
in heart failure, 156
Angiotensin-converting enzyme (ACE), 46*t*
inhibitors. *see* ACE inhibitors
Angular cheilitis. *see* Angular stomatitis
Angular stomatitis, 38*f*, 549–550
iron-deficiency anaemia, 249
Ankylosing spondylitis, 444, 444*f*
Anorexia, 80*t*–83*t*, 97
Anorexia nervosa, 662*t*, 663, 663*b*, 663*f*, 664*t*
Anosmia, 97
Antacids, effects on drug absorption, 671, 671*b*
Anthracosis, 426*t*
Anthracyclines, 587*t*
Anthrax, 562*t*–567*t*
Antiarrhythmic agents, 62*t*, 143*t*
Vaughan-Williams classification of, 163
Anti-asthmatic drugs, management complications, 409*t*
Antibacterial agents, 559*t*–560*t*
drug use in patients on warfarin, 232*t*
used in dentistry, 560*t*–562*t*
Antibiotic(s), 87*t*–93*t*, 201, 694
contraceptive pill, effects of antimicrobials on, 694*f*
drug, 694
drug-induced hepatitis, 287
liver disease, contraindications in, 280*t*
oral mucositis, 587*t*
osteomyelitis, 433
porphyrias, 598*t*
stomatitis, 549
that may impair platelets, 222*t*
Antibiotic-associated (pseudomembranous) colitis, 208
Antibiotic prophylaxis, osteoarthritis (osteoarthrosis), 439, 440*b*
Antibiotic-resistant infections, 534–537
Antibody deficiency syndromes, 519–520
Antibody-dependent cellular cytotoxicity (ADCC), 483
Anticholinergic drugs, in Parkinson disease, 369
Anticholinesterase eye drops, 62*t*
Anticoagulants, 62*t*, 231
dental management of patients on, 160*t*
Anticonvulsants, 62*t*, 384, 385*t*, 694
adverse effects of, 391, 391*t*
in chronic kidney disease, 341*t*
drugs used in dentistry, 385*t*
liver disease, contraindications in, 280*t*
Antidepressants, 83*t*–87*t*, 297, 313–315, 629*t*
actions of, 315*t*
classification of, 313*t*
liver disease, contraindications in, 280*t*
warfarin interactions, 232*t*
Antidiabetics, 62*t*
that may impair platelets, 222*t*
Antidiuretic hormone (ADH), 172, 172*t*
Antiemetics, general anaesthesia, 75*t*
Antifungal drugs, 573*t*
drug use in patients on warfarin, 232*t*
porphyrias, 598*t*
Antigen-processing cells (APCs), 483
Antihæmophilic factor, 213*t*
Antihistamines, 56*t*, 75*t*
allergy management, 458, 458*t*
chronic kidney disease, 342
Antihypertensive drugs, 133, 133*t*
and cardioactive drugs, adverse effects from, 134*t*
as cardiovascular drugs, 131*t*
hypotension resulting from interaction with, 16–17
Anti-inflammatory agents, 481
Anti-inflammatory cytokines, 482*t*
Anti-interferon immunodeficiency, 514
Antileukotrienes, 458, 458*t*
Antimetabolites, 586*t*
oral mucositis, 587*t*
Antimicrobial prophylaxis, 79, 95–96, 532, 532*b*
in HIV/AIDS, 508
Antimicrobial therapy, indications for, 530*t*
Antimicrobial(s), 62*t*
breastfeeding, contraindicated in, 647*t*
chronic kidney disease, 341*t*
for infections in HIV disease, 509*t*
for odontogenic and antral infections, 529*t*

- Antimuscarinic bronchodilators, for asthma management, 408*t*
- Antineutrophil cytoplasmic antibody (ANCA) - associated vasculitides, 478
- Antinuclear antibodies (ANAs), 467, 467*t*
